This optimal control problem (OCP), for the linear systems, has an analytical solution given by the state feedback law, that is, a function $\boldsymbol{u}(x(t))$ that minimizes the cost functional of Equation (3.4), given by

$$\boldsymbol{u}(t) = -R^{-1}B^T S(t)x(t), \tag{3.6}$$

where S is the solution of the matrix Riccati equation. To simplify the notation, the Kalman gain matrix is defined as

$$K(t) = R^{-1}B^T S(t). \tag{3.7}$$

Since the matrix $K(t)$ saturates to a constant matrix K as $t \to \infty$ [6], it is then possible to use what is known as the suboptimal control law, given by

$$\boldsymbol{u}(t) = -K(\infty)x(t). \tag{3.8}$$

To calculate the Kalman gain matrix $K(\infty)$, one solves the algebraic Riccati equation, given by

$$0 = A^T S + SA - SBR^{-1}B^T S + Q, \tag{3.9}$$

yielding the steady-state solution $S(\infty)$, which can be used to calculate the steady-state Kalman gain matrix $K(\infty)$ using Equation (3.7).

3.3. *Controller Summary*

By defining state and an input penalizing matrices Q and R, it is possible to calculate the optimal state feedback gain matrix $K(\infty)$ by simply solving the algebraic Riccati Equation (3.9). This can be done using standard numerical methods optimized for this task and available in scientific computing libraries in Python [9], turning the lower level problem of finding the controller gains into a computationally efficient task.

The advantages of using the LQR method in this context are that solving the OCP is computationally efficient and that the resulting controller has good robustness properties [6], which is important since the same decision matrices Q and R are used for all the different EMA design attempts made by the optimizer.

It is important to note that the controller itself is based on a linearized model of the EMA, thus, it is not necessarily optimal for the nonlinear system. However, it is a good starting point and it is also representative of the controllers used in practice.

4. Optimization Problem Formulation

With the model and controller defined, the optimization problem can be formulated. The goal of the optimization problem is to find the design variables that minimize the cost function, while satisfying the constraints. The design variables are the physical dimensions of the EMA, which in turn define the parameters of the model. In the next subsections, the cost function of the upper problem is motivated and defined, the constraints are defined and the design variables are presented.

4.1. *Cost Function*

To examine the usefulness of considering the whole drive cycle in the optimization problem, the optimization of an EMA for a crane application is considered. This kind of application is nowadays dominated by hydraulic actuators, which have a high power density and are able to deliver high forces. To compete with hydraulic actuators, the designed EMA needs to have similar characteristics. There are, however, some differences between the two technologies that can be more easily accommodated in a crane application. One of those differences is related to

the power density, it is probably much easier to accommodate a higher length than a larger diameter, thus, the power density might not be as critical as the diameter power density. This is one of the considerations made in the cost function, instead of trying to minimize the volume of the EMA, we try to minimize its diameter. Moreover, whatever the designed EMA is, it should be able to closely follow the desired load trajectory while respecting the constraints, the major ones being the maximum voltage and current that can be supplied to the EMA's motor.

One of the major motivators of substituting hydraulic actuators with EMAs is the potential increase in system efficiency. Thus, the cost function should also consider the efficiency of the EMA over the drive cycle. This is done by considering the total dissipated energy, which should be minimized. An important technical aspect to consider is that the optimizer might suggest designs that are not able to follow the desired trajectory and or are unstable. Those designs should be penalized in the cost function to prevent the optimizer from suggesting EMAs that are close to those designs, and thus, wasting computational resources evaluating those designs. This is done by penalizing the cost function with the squared residuals $\boldsymbol{r}(t)$ of the solver used to simulate the EMA dynamics over the drive cycle.

The above considerations motivate the following cost function for the dynamic optimization problem

$$J_{\text{dyn}}(\boldsymbol{x}(t)) = w_1 \int_0^T \frac{e_\theta(t)^2}{\max(|\theta_{\text{ref}}(t)|)} dt + w_2 l_2 + w_3 \frac{1}{E_{\text{ref}}} \int_0^T P_{\text{loss}}(t) dt + w_4 \int_0^T \|\boldsymbol{r}(t)\|^2 dt, \tag{4.1}$$

where the first term penalizes the position tracking error, the second term penalizes the diameter of the EMA, the third term penalizes the total energy loss over the drive cycle, and the fourth term penalizes the residuals of the EMA dynamics. The weights w_1, w_2, w_3 and w_4 are used to balance the different terms in the cost function, and E_{ref} is given by

$$E_{\text{ref}} = \int_0^T |F_{\text{ref}}(t) v_{\text{ref}}(t)| dt. \tag{4.2}$$

The other normalization terms in Equation (4.1) are used to make the different terms in the cost function have similar magnitudes.

For the static optimization approach, the cost function is similar to Equation (4.1), but instead of integrating over the entire drive cycle, only a few significant design points are considered in the drive cycle. Thus, the cost function for the static approach is given by

$$J_{\text{stat}}(\boldsymbol{x}) = w_2 l_2 + w_3 \frac{1}{E_{\text{ref}}} \sum_{k=1}^{N_{dp}} P_{\text{loss},k} \Delta t_k \tag{4.3}$$

where N_{dp} is the number of design points considered, Δt_k is the time spent at design point k, $P_{\text{loss},k}$ is the power loss at design point k.

4.2. *Constraints*

One of the main constraints in designing an EMA is the maximum voltage and current that can be supplied to its motor. In real applications, another important constraint is the thermal limits of the motor, which are usually the limiting factor in the motor's power density. However, the main focus of this work is to show the potential of considering the entire drive cycle in the optimization problem, and thus, it suffices to consider only the electrical constraints, given by

$$\begin{aligned} u_{\text{mag}}(t) &= \sqrt{u_d(t)^2 + u_q(t)^2} \leq u_{\max}, \\ i_{\text{mag}}(t) &= \sqrt{i_d(t)^2 + i_q(t)^2} \leq i_{\max}, \end{aligned} \tag{4.4}$$

where $u_{\max}$ and $i_{\max}$ are the maximum voltage and current magnitude that can be supplied to the motor, respectively.

The constraints of Equation (4.4) need to be satisfied at each time instant. To enforce those constraints in the dynamic optimization approach, the penalty method is used, adding the following penalty terms to the cost function

$$G_{\text{dyn}}(\boldsymbol{x}(t)) = w_5 \max\left(0, \max(u_{\text{mag}}(t)) - u_{\max}\right)^2 + w_5 \max\left(0, \max(i_{\text{mag}}(t)) - i_{\max}\right)^2, \quad (4.5)$$

where w_5 is the penalty weight.

The static approach needs to consider the constraints of Equation (4.4) at each design point k, but to account for the steady-state dynamics, there is an additional constraint that needs to be satisfied, the residual of the steady-state dynamics $\boldsymbol{r}_k$, that is, the right hand side of Equation (3.1) with the derivatives zeroed out and evaluated at design point k. Since the steady-state, optimization-driven design needs to satisfy a set of constraints at every operating point, the problem is much more sensitive, and it was therefore also necessary to penalize non-integer values of the number of pole pairs n_p and the number of turns per phase N_S. The constraints are enforced, in a similar way as in the dynamic case, that is, by adding the following penalty terms to the cost function

$$G_{\text{stat}}(\boldsymbol{x}) = w_6 \sum_{k=1}^{N_{dp}} \sin(\pi n_p)^2 + \sin(\pi N_S)^2 + w_7 \sum_{k=1}^{N_{dp}} \boldsymbol{r}_k^T \boldsymbol{r}_k + G_{\text{dyn}}(\boldsymbol{x}_k), \quad (4.6)$$

4.3. *Design Variables*

The design variables are the physical dimensions of the EMA, which in turn define the parameters of the model. The design variables are given, together with their respective bounds, in Table 4.1.

Table 4.1 Design variables and their respective lower and upper bounds, $\boldsymbol{l_b}$ and $\boldsymbol{u_b}$, respectively.

Design variable	Description	$\boldsymbol{l_b}$	$\boldsymbol{u_b}$	Dynamic	Static
n_p	Number of pole pairs	1	6	Yes	Yes
l_2	Stator diameter [m]	0.01	0.3	Yes	Yes
l_1	Stator length [m]	0.1	1	Yes	Yes
N_S	Number of turns per phase	1	40	Yes	Yes
g	Air gap [m]	0.001	0.01	Yes	Yes
α	Winding angle [rad]	$\frac{\pi}{20}$	π	Yes	Yes
g_{r_1}	First gear ratio	1	6	Yes	Yes
g_{r_2}	Second gear ratio	1	6	Yes	Yes
p	Ball screw pitch [m]	0.01	1	Yes	Yes
u_{q_k}	Voltage at design point k[V]	$-u_{\max}$	$u_{\max}$	No	Yes
i_{q_k}	Current at design point k[A]	$-i_{\max}$	$i_{\max}$	No	Yes

The chosen design variables allow one to fully define the EMA model, at least in the simplified form presented in this work. One should note that the design variables in the static approach include the voltages and currents at the design points, since those are needed to satisfy the steady-state dynamics at those points.

4.4. *Overview and Setup*

The dynamic and static optimization approaches were presented, an overview of how they were implemented is shown in Figure 4.1.

Both the static and dynamical optimization approaches were implemented using the same optimizer, Scipy's Differential Evolution [10], based on [11, 12]. A population size of 14 individuals was used, with a maximum of 1000 generations. The chosen weights are given in Table 4.2.

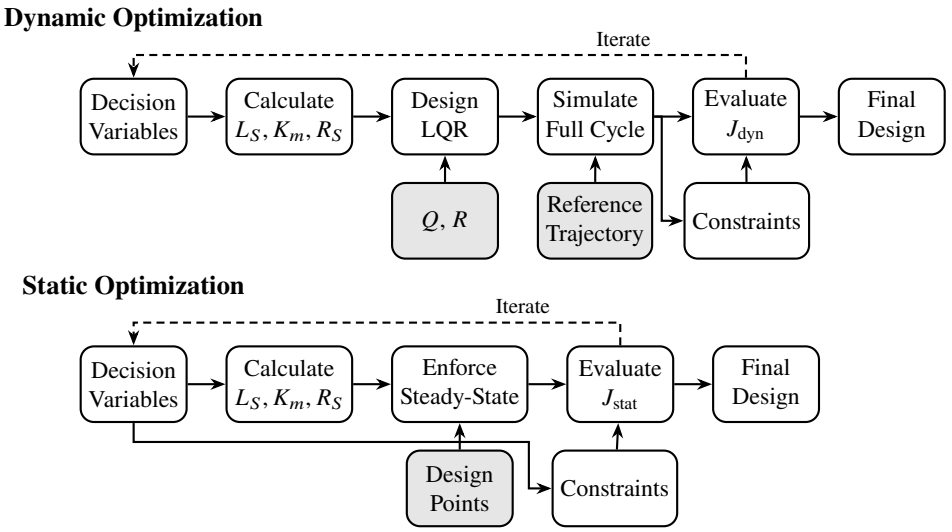

Figure 4.1 Schematic representation of the dynamic and static optimization approaches.

Table 4.2 Weights used in the cost functions and constraints.

Weight	w_1	w_2	w_3	w_4	w_5	w_6	w_7
Value Dynamic	100	$1 \cdot 10^{-3}$	$1 \cdot 10^{6}$	1	$1 \cdot 10^{3}$	N/A	N/A
Value Static	N/A	$1 \cdot 10^{-3}$	$1 \cdot 10^{3}$	N/A	$1 \cdot 10^{5}$	$1 \cdot 10^{10}$	$1 \cdot 10^{5}$

As can be seen in Table 4.2, the weights used in the dynamic approach are different from those used in the static approach. This is due to the different nature of the two approaches, which makes it necessary to tune the weights for each approach separately. The weights were tuned, however, so that the constraints are satisfied in both approaches. It should be noted, however, that the weights were tuned using a simple heuristic approach, and no systematic exploration of the Pareto front was conducted. Thus, the results could be improved further by choosing where in the Pareto front one wants to be, and then tuning the weights accordingly, allowing for a better trade-off between the different objectives.

For the static approach, four design points were considered: maximum torque and speed; half the maximum speed and maximum torque; half the maximum torque and maximum speed point; and one that has an additional torque term to account for the acceleration, where the acceleration was chosen as the maximum acceleration in the drive cycle together with the maximum torque and speed. Those points were chosen after several attempts; they are not only somewhat representative of the drive cycle but also give the best results found in terms of the dynamical performance of the designed EMA.

The chosen drive cycle is shown as the reference position and velocity in Figure 5.1. The drive cycle emulates a simplified crane operation, where a load of $1 \cdot 10^4$ N is lifted to a height of 10 cm, held there for 1 s, and then lowered back to the initial position, where a resting time of 1 s is applied. The load is zero whenever the position is zero, simulating a load being lifted from the ground. The total duration of the drive cycle in the dynamic optimization is 5 s, although it is simulated for 11 s in all figures to show more of the performance. This drive cycle was chosen because it has a wide dynamic range, as is typical for crane applications.

For the dynamical optimization approach, the controller matrices Q and R were chosen as $Q = \text{diag}(5 \cdot 10^1, 5 \cdot 10^1, 1 \cdot 10^6, 1 \cdot 10^2, 1 \cdot 10^4)$ and $R = \text{diag}(1, 1)$, where diag is the diagonal matrix. Those matrices were chosen as a trade-off between performance and control effort.

5. RESULTS

The optimization results shown are selected as the best design found in several attempts. The best design is chosen first by considering the constraints satisfaction, and then by the cost function value. The optimization for the dynamic approach took around 2.94 hours to complete, while the static approach took around 5.1 minutes to complete in the same machine, a standard desktop computer. At this point it must be emphasized that all the solutions found in the dynamic approach were respecting the constraints and had around the same characteristics. In contrast, in the static approach, the constraints are sometimes not satisfied and, even when they are, the characteristics of the solutions vary significantly, which makes it necessary to perform several attempts to find a good design.

The best found designs for both approaches are shown in Figure 5.1, where the position and velocity tracking are shown together.

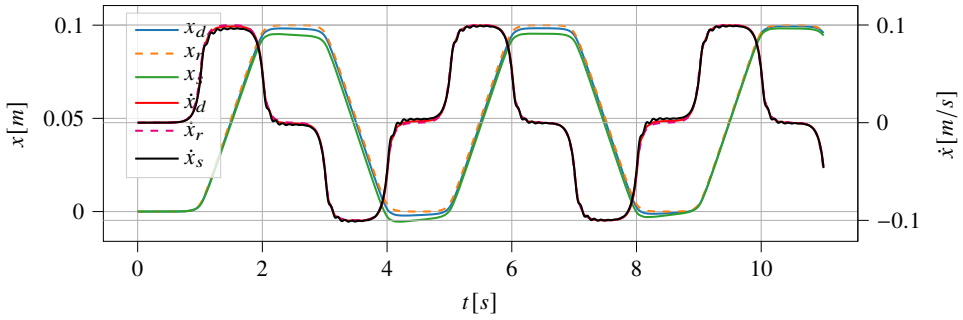

Figure 5.1 Position x and velocity $\dot{x}$ tracking over the drive cycle for both optimization approaches. Within the figure, the reference trajectory is shown with subscript r, the designed EMA using the dynamic approach with subscript d and the designed EMA using the static approach with subscript s.

The designed EMA using the dynamic approach was able to closely follow the desired trajectory, with very small position and velocity errors. The designed EMA using the static approach was also able to follow the desired trajectory, although not as closely. It is important to note that both designs are simulated using the same LQR controller structure with design matrices Q and R defined as in the dynamic optimization approach, yielding the best gain matrix K for each design and allowing consistent comparison. However, it is possible to obtain better tracking performance for the static design by changing the design matrices, although this comes at the cost of increased control effort.

One very important design objective is to choose an EMA that respects the electrical constraints while being able to deliver the needed tracking performance. The current and voltage magnitudes over the drive cycle for both designs are shown in Figure 5.2, where the solid lines represent the designed EMA using the dynamic approach, while the dashed lines represent the designed EMA using the static approach.

As can be seen in Figure 5.2, the designed EMA using the dynamic approach is able to respect the electrical constraints, represented as $u_{\max}$ for the voltage and $i_{\max}$ for the current. $u_{m,d}$ hits the constraint at all points of maximum positive acceleration, while the current $i_{m,d}$ does not hit the constraint at any point. On the other hand, the designed EMA using the static approach is not close to violating any electrical constraints, but the voltage magnitude $u_{m,s}$ is very low compared to the maximum allowed voltage, at the cost of having a higher current magnitude $i_{m,s}$, not ideal for efficiency.

It is important to evaluate the efficiency of the designed EMAs over the drive cycle. The total energy losses for both designs depend on the losses in the PMSM, for which the model only considers the copper losses, and the losses in the ball screw and gears, which are the same regardless of the resulting EMA design since they were defined as having simple constant

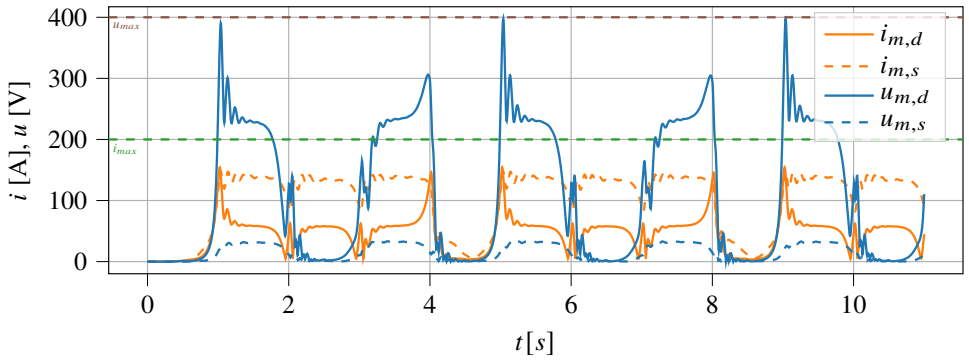

Figure 5.2 Current and voltage magnitudes over the drive cycle for both optimization approaches.

efficiencies. Thus, the only relevant comparison is the copper losses in the PMSM. The total copper losses to complete the trajectory shown in Figure 5.1 are 58 J for the dynamic design and 257 J for the static design, showing a difference in copper losses of approximately a factor of four between the two designs.

A natural question that arises is how the designed EMAs perform outside the drive cycle used in the optimization. This is reasonable to ask since the real world application is very rich in terms of possible trajectories that the EMA might need to follow. To evaluate this, both designs were simulated over a different drive cycle, one that both designs were not optimized for. The new drive cycle is shown as the reference position and velocity in Figure 5.3. This drive cycle is essentially the same as in the previous case, but with half the time to go from the initial height to the final height, thus having twice the velocity.

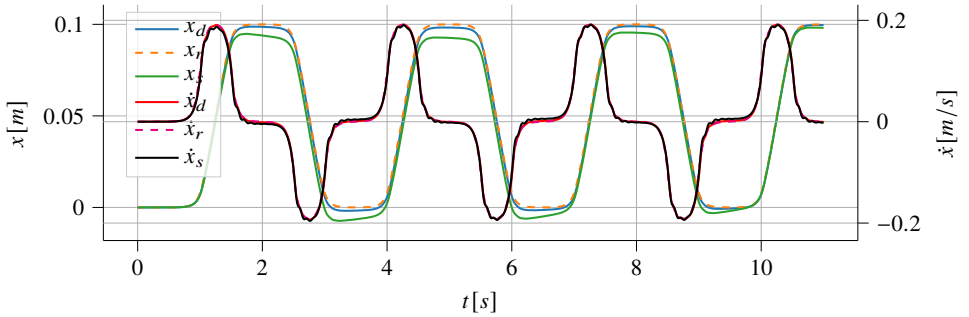

Figure 5.3 Position x and velocity $\dot{x}$ tracking over a different than optimized drive cycle for both optimization approaches. Within the figure, the reference trajectory is shown with subscript r, the designed EMA using the dynamic approach with subscript d and the designed EMA using the static approach with subscript s.

As can be seen in Figure 5.3, both designs have similar tracking performance over the new drive cycle, with the static design now performing even worse at tracking the reference. The currents and voltages over this new drive cycle are, as expected, higher than in the previous case, and for both designs it is exceeded at several points. One could simulate the system with restrictions on the maximum current and voltages, then, instead of the trajectory being followed at the cost of the constraints, the constraints would be kept at the cost of tracking. The former was chosen since it is much easier to implement and gives essentially the same conclusion but from a different perspective. The maximum $u_{m,d} = 1359.99$ V and $i_{m,d} = 274.09$ A for the dynamic design, while for the static design $u_{m,s} = 141.32$ V and $i_{m,s} = 197.47$ A. The total copper losses to complete this new trajectory are 131 J for the dynamic design and 261 J for

the static design. Although the dynamic design became relatively worse in percentage terms, its total energy loss was much lower than that of the static design.

Another major aspect to be considered in the design of EMAs is their diameter, which was considered in the cost function. The diameter, together with the other physical decision variables of both designs, is shown in Table 5.1.

Table 5.1 Design variables of the best found designs for both optimization approaches.

Design variable	n_p	l_2 [m]	l_1 [m]	N_S	g [mm]	α [rad]	g_{r_1}	g_{r_2}	p [mm]
Dynamic	1	0.1	0.99	40	1.32	0.449	1.906	2.18	38.89
Static	1	0.103	0.97	40	9.47	1.53	2.36	4.86	252.23

Table 5.1 shows that the dynamic design has a slightly smaller diameter than the static design, at the cost of having a bigger length. This means that the dynamic design has not only better performance in terms of tracking and efficiency, but also in terms of size. It should also be noted that the dynamic design not only converged to a solution with smaller air gap g, but also to a solution where the operational velocity of the PMSM is much higher, a result of the different gear ratios and ball screw pitch. Both aspects are important in the design of high-performance PMSMs.

In contrast, the static design converged to a relatively large air gap, close to the upper bound of the admissible range. Since the PMSM is being optimized for efficiency, one would expect a solution closer to the minimum allowable g, as observed in the dynamic design. The reason for this behavior is not entirely clear, however, one possible explanation is that the static optimization problem has a larger number of local minima, increasing the likelihood that the optimizer becomes trapped in such regions.

Another important aspect of the results is that l_1, l_2, N_S and n_p were found by the dynamic design approach to be optimal at their bounds, showing that one could obtain better designs if the maximum number of turns and the maximum length were increased. The diameter l_2 was considered in the cost function directly, thus, the fact that the optimizer found the optimal value to be at the bound of l_2 suggests that more efficient designs could be obtained if one were to allow softer restrictions regarding the diameter or by choosing a smaller w_2.

6. CONCLUSIONS

This paper compared two preliminary EMA design strategies for a mobile machinery drive cycle: a dynamic approach that evaluates each candidate design by simulating the full trajectory with a feedback-linearized, LQR-tuned controller, and a static multi–design-point approach that enforces steady-state equations at a few representative operating points. The main finding of this work is not only to reiterate the importance of considering the entire drive cycle in the optimization problem, but also to show that it is possible to do so at a reasonable computational cost by using simplified models and efficient optimal control techniques, allowing the problem to be solved without solving the full OCP, but rather a simpler LQR problem that can be solved efficiently. As seen, although the computational cost of the dynamic approach is significantly higher for one optimization round, the static approach required several attempts to find a marginally acceptable design, making the dynamic approach more efficient in practice.

As discussed, the designs in Table 5.1 are not valid for the actual design of real EMAs, since the model purposely neglects several important aspects that are usually the limiting factors, such as thermal limits, saturation effects and more complete loss models. Moreover, the considered drive cycle is oversimplified and choosing a representative one was not addressed. The main goal of this work is, however, to show the potential of considering the entire drive cycle in the optimization problem without neglecting the dynamics of the EMA, a picture that was clearly shown by the results, where every designed aspect considered was significantly better for the dynamic approach.

The significantly lower losses of the dynamic approach result from the model considering only copper losses: by respecting electrical constraints while tracking trajectories, it finds designs that require lower currents. While more complete models with iron losses would reduce the relative loss difference between approaches, the dynamic approach is expected to remain superior due to its consideration of full EMA dynamics over the drive cycle.

7. Future Work

Future work should address four main areas: incorporating more complete EMA models including thermal limits, saturation effects, and iron losses to enable realistic preliminary designs; validating the simplified optimization-oriented models; comparing the LQR-based control approach against full OCP solutions to assess the optimality gap in this system; and the pareto front of the different designs, that is, how the different weights in the cost function affect the resulting design. This would allow for a better understanding of the trade-offs involved in the design of EMAs for mobile machinery applications. Those improvements would allow much better preliminary design of EMAs, reducing the number of refinements needed using more complete finite element models.

Abstract.

The control of hydraulic motors supplied via long hydraulic lines presents significant challenges, particularly for high-speed operation and loads with high rotational inertia. This study investigates a hybrid hydraulic wire saw attachment equipped with a fixed displacement motor and supplied by two alternative power sources: a constant-flow system driven by a variable-speed internal combustion engine and a constant-pressure system powered by an electric motor with a variable displacement pump. The proposed hybrid configuration combines operational flexibility and mobility with low-noise and low-emission electric operation, while allowing independent operation from either power source. The key contribution of this work is a dual-mode speed control strategy that switches from conventional valve-based flow control during transient phases to direct, valve-less speed control under steady-state conditions. This approach enables energy savings of approximately 13–42% during the steady cutting phase, which accounts for the majority of operating time. Maintaining stable motor speed under varying control modes remains the primary control challenge.

Keywords. Mobile Application, Hybrid machine, Direct Flow control, Construction and Mining Machinery

1. INTRODUCTION

The control of hydraulic motors in construction machinery is a well-established and widely studied topic. However, challenges arise when long hydraulic lines (>20 m) are involved, particularly in achieving precise control of hydraulic motors operating at high rotational speeds (>1000 RPM) and driving loads with substantial rotational inertia. The system analysed in this study is a hydraulic wire saw attachment with a fixed displacement motor implemented as a hybrid configuration, like shown in Figure 1. Hydraulic power is supplied

All Open Access articles are peer-reviewed, distributed under the Creative Commons Attribution-Non Commercial 4.0 International

via two distinct sources: a constant-flow system driven by a variable-speed internal combustion engine, and a constant-pressure system powered by an electric motor coupled with a variable displacement pump. This configuration enables the combination of the mobility and flexibility of an internal combustion engine-powered machine with the low-noise and low-CO_2 emission operation of an electric motor. The saw unit can be operated independently by either system.

Zhongyi Quan [1] and Tianliang Lin [2] have proposed various control strategies for hydraulic motors, including multiple combinations of variable pumps and motors tailored to specific application requirements, with the goal of maximizing energy efficiency and recovery. A particular emphasis is placed on different forms of secondary control strategies. Also Berg and Ivantysynova [3] examined secondary control strategies for hydraulic motors utilizing variable displacement.

In contrast, the hybrid concept examined in this work requires a configuration capable of operating effectively with both constant-flow and constant-pressure supply systems with a fixed displacement motor. In this specific application, energy recovery is not deemed advantageous.

Figure 1 Wire saw attachment cutting, mounted on carrier vehicle including internal combustion engine and electric powerpack at the back

The novelty of the proposed concept lies in the ability to switch between two different speed control modes during operation. For the short, undefined setup and cutting initiation phase, speed control is handled conventionally via a flow control valve. Once steady-state conditions are achieved, the system transitions to direct, valve-less speed control—either by adjusting the internal combustion engine speed or through electric motor control using the swivel angle of the variable displacement pump. This enables energy savings of approximately 13–42% in the steady cutting phase, which typically accounts for over 90% of total operation time. The switching mechanism can be realized using a bypass valve to circumvent the flow control valve, a load-sensing (LS) pressure valve for targeted

pressurization of the compensator, or a control spool with a non-linear characteristic.
The main challenge is maintaining a constant motor speed in accordance with process requirements, where either the combustion engine speed or the pump swivel angle serves as the control variable.

2. SYSTEM OVERVIEW

Figure 2 Hydraulic setup of the saw motor

The hydraulic architecture of the system, shown in Figure 2, comprises a telehandler-mounted attachment equipped with a main valve block and a fixed displacement hydraulic motor, as well as two alternative power units: an internal combustion engine driving a gear pump and an electric motor coupled to a variable displacement axial piston pump. The attachment can be operated independently by either power unit, depending on the availability of an external electric power supply. The decision to combine a constant-pressure system for the electric drive with a constant-flow system for the internal combustion engine was made at an early stage of development. This dual-system approach was necessary because modifications to the existing hydraulic system of the telehandler were not permitted, while the electro-hydraulic power supply was required to be as compact and energy-efficient as possible—requirements that could not be met using a constant-flow system alone.

2.1. Hydraulic Plan

The main hydraulic block is composed of several standard sandwich-plate valves assembled to provide all functions required for operating the attachment. For the sake of clarity and reduced complexity, only the components relevant to motor control are shown in the schematic Figure **3**. The block incorporates an integrated pilot oil supply unit as well as a two-way safety valve.

For the experimental setup, two flow meters and pressure sensors were integrated into the hydraulic circuit: one upstream of the main valve block to measure the pump supply flow to the attachment, and a second upstream of the hydraulic motor. This instrumentation allows the determination of flow and pressure losses across the main valve block by comparison of the measured values.

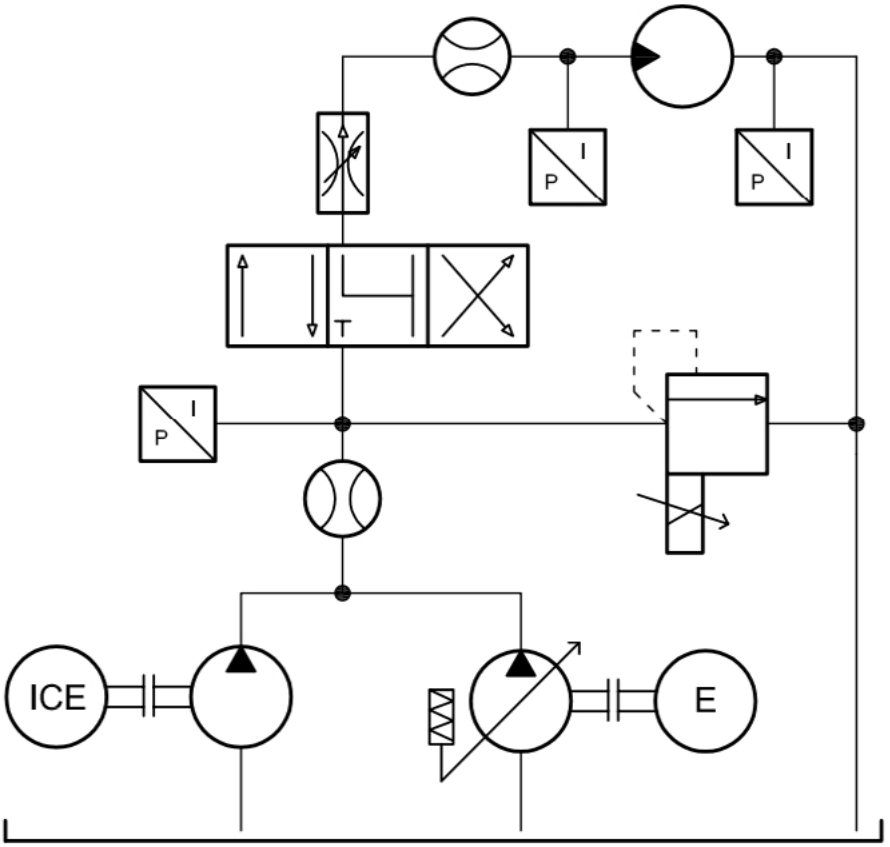

Figure 3 Hydraulic schematic (simplified)

2.2. Control Strategies

First, the hydraulic motor is controlled to reach the target rotational speed required to achieve the desired wire velocity. Second, the feed rate of the wire into the stone is adjusted to obtain the specified motor torque. These target values are predefined and are not the subject of this study. To ensure efficient operation, the hydraulic flow rate and pressure must be supplied in accordance with the required speed and torque demands, while avoiding excess energy provision.

2.2.1. Wire Speed

The wire speed is controlled using a 4/3-way valve equipped with a pressure compensator and a PID controller. This configuration exhibits stable behaviour, as the pressure compensator inherently adapts to pressure fluctuations. The PID controller primarily compensates for leakage and temperature-induced variations and contributes to the attenuation of oscillations. Oscillatory behaviour is a well-known challenge in the control of hydraulic motors driving large inertial loads in combination with long hydraulic hose lengths. During experimental testing with the proposed setup, oscillations were observed but without overshoot. Within the scope of these experiments, it was not possible to clearly distinguish whether the oscillations originated from the hydraulic circuit or from instabilities in the cutting process itself.

2.2.2. Hydraulic supply at constant pressure circuit

Hydraulic flow and pressure are supplied by a variable displacement axial piston pump driven by a three-phase electric motor. The pump is equipped with a pressure controller actuated by an electrically controlled valve, allowing the pump pressure level to be adjusted, while the flow rate is not actively regulated. As a result, the system operates as a pseudo load-sensing configuration. Due to the excessive length of the hydraulic hoses between the pump and the valve block, conventional transmission of a load-sensing signal via a hydraulic line is not feasible. However, under the relatively steady operating conditions encountered during cutting, load sensing is implemented electronically by adjusting the pump pressure based on measured pressures and predefined target values. The pump continuously supplies the flow required to maintain the desired pressure level at the attachment. The pressure difference between the pump outlet and the load pressure is regarded as a necessary and acceptable loss in this configuration.

To eliminate this pressure-related loss, the original pressure-controlled pump was replaced with a flow-controlled pump. The new pump is mechanically identical but is equipped with an electronic controller and a swashplate angle sensor, enabling the implementation of various control strategies purely through software. Load-sensing control can be realized using pressure feedback, while flow and power control are achieved by regulating the swashplate angle and motor speed. To minimize energy losses associated with Δp and to improve stability with respect to oscillations, motor speed is now controlled directly via the pump swashplate angle, while the 4/3-way valve is kept fully open. Consequently, pressure losses are limited to flow-dependent losses, with no additional losses introduced by control valves. Furthermore, the propensity for valve-induced oscillations is significantly reduced, as the valves operate in a fully open state.

2.2.3. Hydraulic supply at constant flow circuit

Hydraulic flow is supplied by a gear pump driven by the internal combustion engine of the telehandler. This pump provides hydraulic power for all machine functions, including boom actuation, stabilizers, and auxiliary attachments such as the wire saw. Consequently, the telehandler is equipped with a load-sensing hydraulic system in which a pressure compensator diverts excess flow to the tank at load pressure. In this configuration, only the pump flow rate and the engine speed can be adjusted. Owing to the operating principle of the circuit, auxiliary attachments must be controlled via the telehandler control valve to

ensure proper functionality. When the flow rate is reduced, the pressure compensator increases the system pressure to its maximum, resulting in unnecessary pressure losses between the actual load pressure and the maximum system pressure.

To mitigate this issue, a proportional pressure relief valve was integrated into the circuit, and the relationship between engine speed and pump flow rate was characterized. By setting the relief valve to a pressure level equal to the load pressure plus a defined Δp, the valve effectively acts as a pseudo pressure compensator. In this operating mode, the telehandler's pressure compensator remains closed, and excess flow is discharged at a lower pressure level. With appropriate adjustment of the engine speed, the amount of excess flow can be minimized, resulting in improved overall efficiency.

To further reduce these losses, an alternative control approach was investigated. This concept, identified inadvertently during testing, involves fully opening the 4/3-way valve while closing the pressure relief valve. Under these conditions, the hydraulic motor rotates at a speed directly determined by the pump flow rate. Provided that the internal combustion engine speed can be adjusted rapidly and accurately, the motor speed can be effectively controlled through engine speed regulation.

2.2.4. Additional hydraulic actuators in the circuit

In addition to the hydraulic motor, the pilot oil supply of the valve block, the wire tension system, and the feed cylinders operate simultaneously. Wire tension is maintained at a constant level by a hydraulic cylinder and therefore requires only the leakage flow of its load-sensing valve. The feed cylinders operate at a comparatively low velocity relative to the hydraulic motor, resulting in negligible hydraulic flow demand.

3. DESCRIPTION OF A STANDARD CUT

Cutting stone with a diamond wire is a comparatively slow process relative to other cutting methods and materials. Feed rates depend on several parameters, including stone type, diamond bead characteristics, cutting width, and wire speed. In the application considered here, feed rates typically range from 1 to 20 cm/min, with an average of approximately 4–6 cm/min. Cutting stones with heights between 1 and 3 m and widths between 2 and 5 m generally requires between 30 min and 3 h, with an average cutting duration of about 1 h.

The cutting process can be divided into three distinct phases, shown in Figure 4. The initial phase corresponds to the start of the cut, during which the wire is not yet fully engaged in the stone due to the rough surface and the absence of a fully developed cutting arc. During this phase, the motor torque is low and unstable until full engagement is achieved and a stable cutting arc is formed, which typically takes approximately 5 min.

The second phase constitutes the main cutting stage and represents the longest portion of the process. During this phase, the wire is continuously fed through the stone under a relatively constant high motor torque with only minor variations. This phase accounts for approximately 90% of the total cutting time.

The final phase occurs toward the end of the cut, when the wire is no longer actively fed because the guide wheels approach the ground. The wire is then used primarily to lower the

cutting arc as far as possible to ensure a clean edge before the stone is separated at the completion of the cut. During this phase, the motor torque decreases continuously to a low level, and the process concludes once only a minimal remaining section is left to be cut, typically lasting a few minutes.

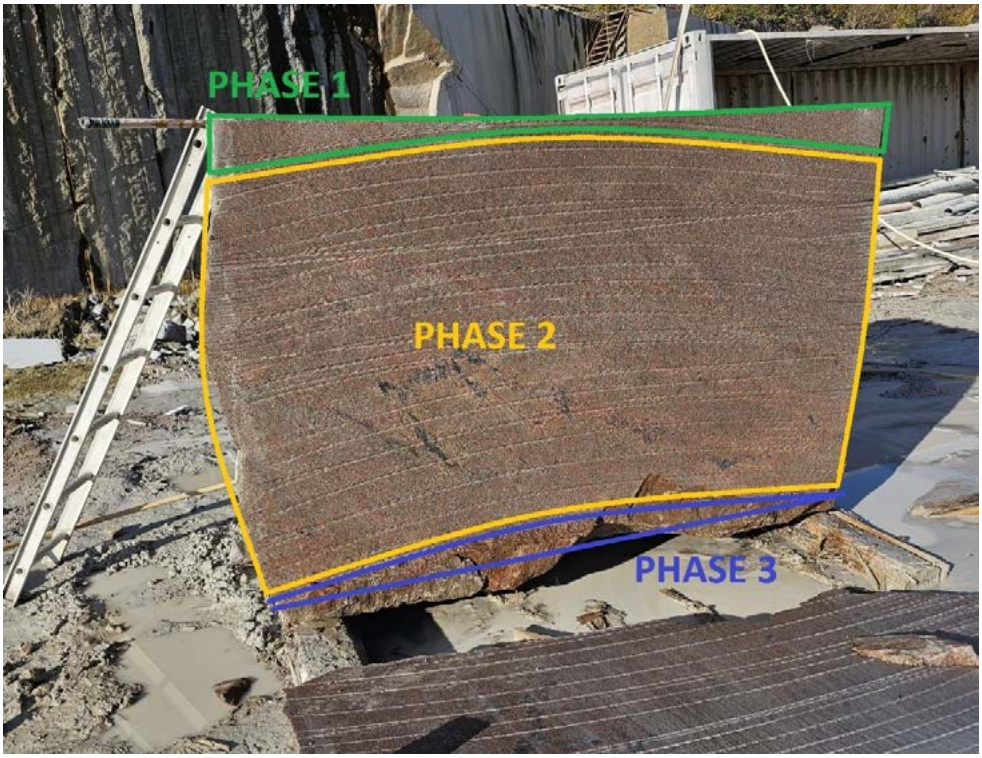

Figure 4 Stone block with the different cutting phases marked

4. TEST AND RESULTS

The experimental investigations were conducted using the same system configuration to ensure maximum comparability. All test cuts were performed on the same stone using the same diamond wire, and switching between the different control modes was carried out during the cutting process to minimize variations in operating conditions.

Due to the inherently irregular nature of the cutting process over time, a comparison based on instantaneous values is not meaningful. Instead, mean values over selected time intervals were used for the evaluation of the results. These intervals were chosen to be representative of typical cutting conditions and were kept relatively short to ensure comparable cutting states. Based on prior experience, these representative periods can be clearly identified within the measured data. The selected intervals are indicated by red and blue dotted rectangles in Figure 7 and Figure 8, and the corresponding mean values are summarized in Table 1. The blue rectangles denote measurements obtained using the proposed control mode, while the red rectangles represent measurements using the conventional control

mode. For improved comparability, all measured quantities were normalized using system-specific reference values p_{ref} and Q_{ref} according to:

$$p = \frac{p_n}{p_{ref}} \quad , \qquad Q = \frac{Q_n}{Q_{ref}} \qquad (4.1)$$

Figure 5 presents the data for the constant-pressure system operating under both control modes. The test sequence began with the proposed control mode, in which motor speed is regulated via the pump swashplate angle. After 175 s, the system was switched to the conventional valve-based control mode. The variable Q_{supply} denotes the flow rate supplied by the pump to the system, while Q_{motor} represents the flow rate delivered to the hydraulic motor. The difference between these values corresponds to pilot oil consumption and leakage flows discharged directly to the tank. The pressure p_{supply} is the main supply pressure measured upstream of the main valve block, p_{tank} is the motor return pressure, and p_{motor} is the load pressure measured at the motor inlet. The motor torque-related pressure p_{torque} is calculated as the difference between the motor load pressure and the return pressure.

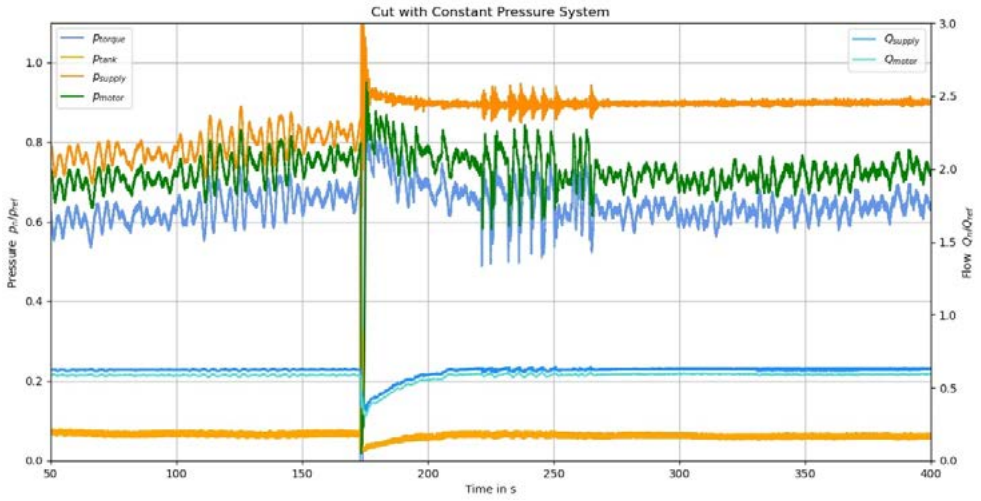

Figure 5 Test with constant pressure system

Figure 6 presents the data for the constant-flow system operating under both control modes. The test sequence began with the proposed control mode, in which motor speed is regulated via the internal combustion engines speed. After 260 s, the system was switched to the conventional valve-based control mode.

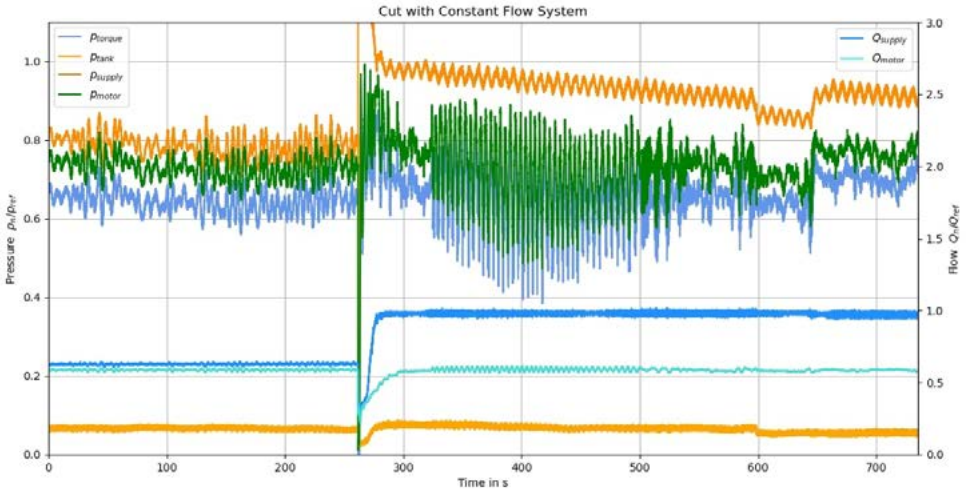

Figure 6 Test with constant flow system

4.1. Test with the constant pressure system

In the following figures Figure 7 and Figure 8, the green shaded areas represent the torque-related values, or equivalently the hydraulic power required for the cutting process. The yellow shaded areas indicate the pressure losses occurring in the valve block and the hydraulic hoses upstream of the motor. It is clearly evident that, after the mode switch, a significantly larger amount of hydraulic energy is dissipated across the pressure compensator. As expected, no significant difference in the flow rates can be observed, since the pump supplies only the flow required by the system, both before and after the change in control mode. The blue shaded areas represent the flow passing through the hydraulic motor.

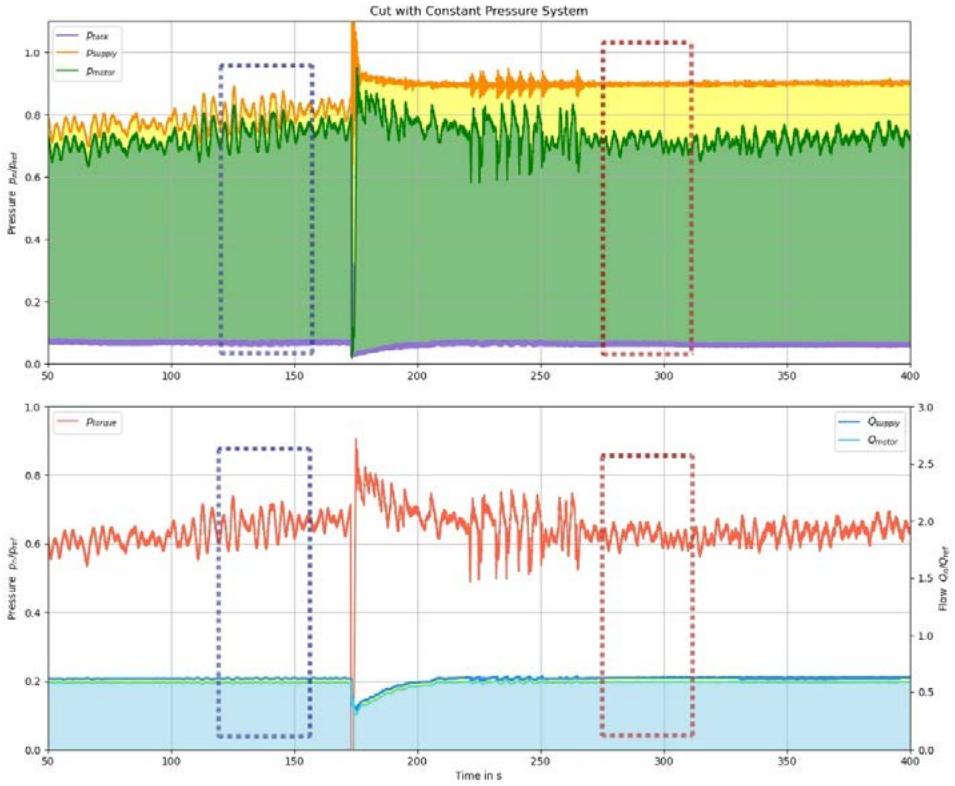

Figure 7 Result of the constant pressure system

4.2. Tests with the constant flow system

For the constant-flow system, the results are generally comparable, with the exception of the flow behaviour. The difference in flow is illustrated in Figure 8, where the yellow shaded area between the flow curves highlights the excess flow. This excess flow results in not only increased losses due to the oil discharged through the pressure relief valve, but also a substantially higher magnitude of loss than anticipated. During the experiments, it was observed that approximately 60% more flow than required was discharged, rather than the expected surplus of around 10%. This discrepancy was attributed to inaccuracies in the calibration of the engine-speed–to–flow characteristic, which therefore requires further refinement.

Because correct calibration could not be achieved at the time of testing, an additional efficiency calculation was performed within this study using the intended target values. This supplementary analysis illustrates the expected system performance under properly calibrated operating conditions.

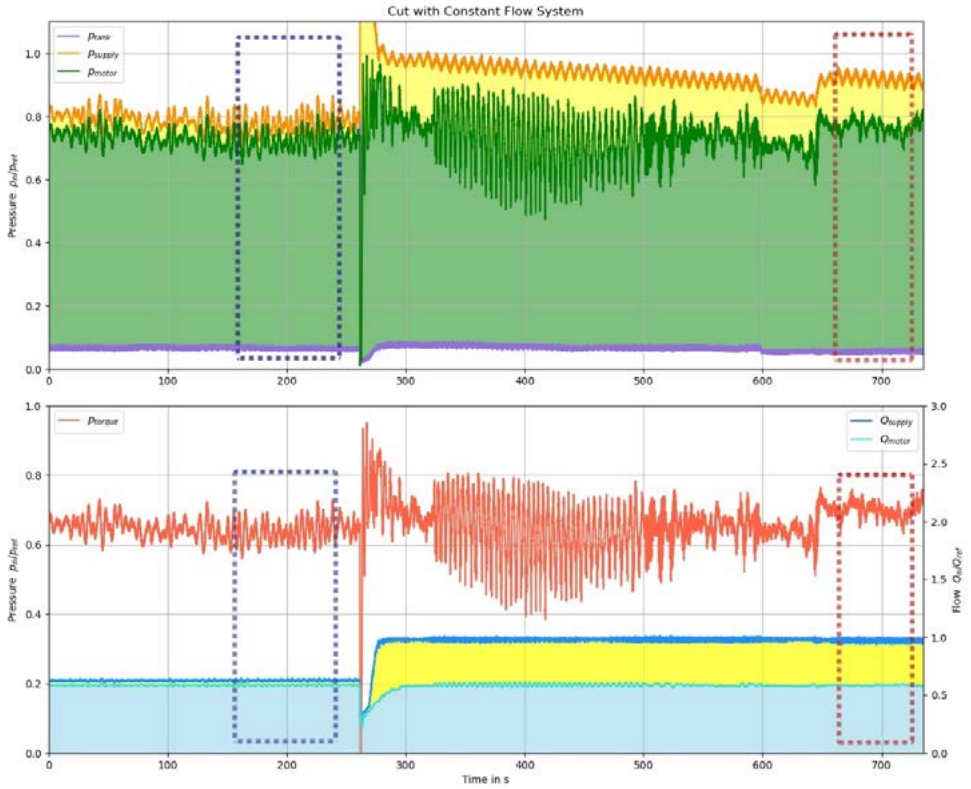

Figure 8 Result of the constant flow system

4.3. Results

To enable a meaningful comparison of the measured results, the converted hydraulic power was calculated based on pressure and flow rate measurements. This approach also allows a direct determination of potential energy savings. Furthermore, it facilitates comparison between different experiments, as all tests were conducted at a single operating point of the system.

4.3.1. Calculation of the results

To determine the total input power P_{in} the hydraulic flow rate and pressure measured upstream of the valve block are used:

$$P_{in} = Q_{supply} * p_{supply} \qquad (4.2)$$

The total cutting power at the motor P_{cut}, including mechanical losses, is calculated using the flow rate upstream of the motor and the pressure difference across the motor P_{torque}:

$$p_{torque} = p_{motor} - p_{tank} \qquad (4.3)$$

$$P_{cut} = Q_{motor} * p_{torque} \qquad (4.4)$$

The overall leakage flow of the valve block Q_{delta}, including the flow through the load-sensing pressure relief valve, is determined as the difference between the flow rates upstream and downstream of the valve block:

$$Q_{delta} = Q_{supply} - Q_{motor} \qquad (4.5)$$

Based on this, the power losses of the valve block $P_{valveblock}$ are calculated as:

$$P_{valveblock} = Q_{motor} * (p_{supply} - p_{motor}) + Q_{delta} * p_{supply} \qquad (4.6)$$

This formulation allows the influence of the compensator state (active or fully open) and the presence of flow through the pressure relief valve to be evaluated. For comparison between control modes, the difference in valve block losses is defined as:

$$P_{valveDiff} = P_{valveblock\ NewMode} - P_{valveblock\ Standard} \qquad (4.7)$$

The remaining losses, which include the return line and return filter losses, are calculated as

$$P_{lossOther} = P_{In} - P_{cut} - P_{valveblock} \qquad (4.8)$$

The efficiency improvement is quantified by the saving factor, defined as the ratio of the reduced valve block losses to the input power:

$$Saving = \frac{P_{valveDiff}}{P_{In}} \qquad (4.9)$$

Table 1 summarizes the calculated results for the comparison of control modes for both the constant-flow and constant-pressure systems. The third column presents the constant-flow system assuming an ideal flow rate under standard control conditions. The green-highlighted cells indicate improvements between control modes in terms of flow- and pressure-related losses, while the grey-highlighted cell denotes an ideally selected reference value.

	Constant Flow		Constant Pressure			Const. Flow improved	
	Standard	NewMode	Standard	NewMode		Standard	NewMode
p_{supply}	0,919	0,783	0,898	0,805		0,919	0,783
Q_{supply}	0,973	0,629	0,627	0,621		0,703	0,629
P_{In}	0,894	0,492	0,563	0,500		0,646	0,492
p_{torque}	0,700	0,642	0,625	0,651		0,700	0,642
Q_{motor}	0,586	0,588	0,592	0,584		0,586	0,588
P_{cut}	0,410	0,377	0,370	0,381		0,410	0,377
p_{motor}	0,767	0,725	0,712	0,742		0,767	0,725
Q_{delta}	0,387	0,041	0,035	0,037		0,117	0,041
$P_{valveblock}$	0,444	0,066	0,142	0,066		0,197	0,066
$P_{lossOther}$	0,039	0,049	0,051	0,053		0,039	0,049
$P_{valvediff}$	-0,378		$P_{valvediff}$	-0,076		$P_{valvediff}$	-0,131
$Saving$	-42,32%		$Saving$	-13,47%		$Saving$	-20,21%

Table 1 Test results

The results indicate that, for the investigated application, between 13% and 42% of the input energy can be saved by employing the proposed control mode. Even with an improved motor-speed–to–flow characteristic, the constant-flow system shows a potential energy saving of approximately 20% of the actual input power when operated with the new control strategy.

The Sankey diagrams provide an additional means of comparing energy losses. In these diagrams, all power flows are normalized with respect to the cutting power P_{cut}, which is used as the reference value. Consequently, the diagrams illustrate the differences in required input power for achieving the same cutting power.

Figure 9 illustrates that, in the constant-flow system under conventional control, approximately 108% of the cutting power is dissipated as losses to achieve 100% cutting power. When the new control mode is applied, these losses are reduced to approximately 17%, indicating a substantial reduction in dissipated energy and, correspondingly, in heat generation within the system.

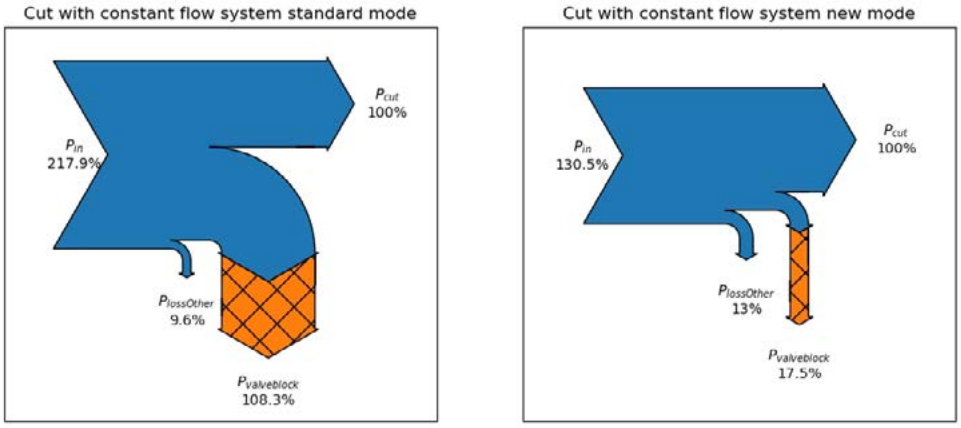

Figure 9 Sankey diagrams for constant flow system

Figure 10 further demonstrates that, for the constant-pressure system, a difference of approximately 20% in input power is required to achieve the same cutting power under conventional control. Both systems exhibit identical results when operated in the new control mode, which is expected, as the valve configurations and functions are identical in this case. In the proposed control mode, hydraulic flow is governed solely by the pumps, while system pressure adjusts according to the motor load.

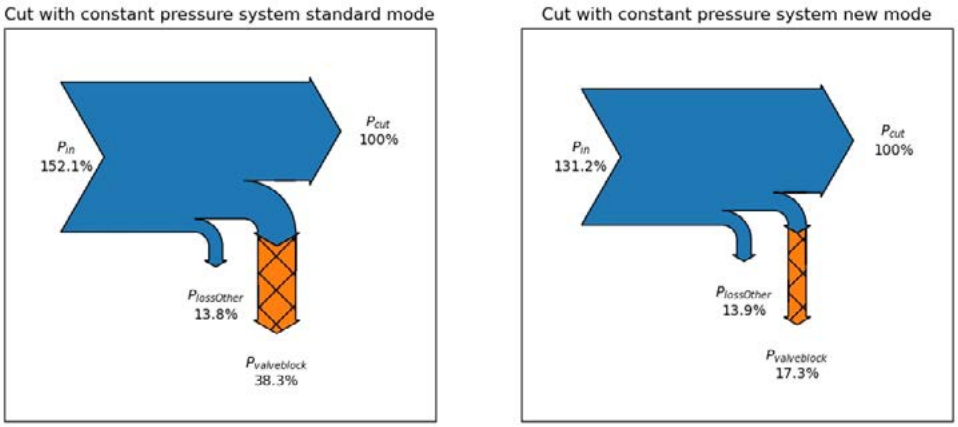

Figure 10 Sankey diagrams for constant pressure system

5. DISCUSSION AND CONCLUSION

The proportion of wasted energy observed in the constant-flow system is relatively high; however, the experiments were conducted on an entirely original system without additional modifications, apart from the integration of the new pump and measurement sensors. Further optimization of this configuration is therefore expected in future work. Nevertheless, even with improved adjustment, the results indicate a substantial potential for energy savings.

Additional improvement measures are conceivable for the investigated system. For example, the electrically driven piston pump could be replaced by a gear pump, and the main valve block could be equipped with a central pressure compensator, similar to an open-loop hydraulic system. Another potential approach would be the use of a variable displacement hydraulic motor capable of directly controlling its own rotational speed. However, the modifications presented in this study were deliberately kept to a minimum and can be implemented without major changes to existing machines. To further enhance system efficiency, other components such as hydraulic hoses and filters could also be reconsidered, as the experiments consistently indicated losses of approximately 13% attributable to these elements.

Further investigations at additional operating points would be beneficial, and the influence of oil temperature should be taken into account. Although the experiments were performed under nearly identical oil temperature conditions, explicitly incorporating temperature effects into the calculations would improve the accuracy of the results.

Digital Twins and AI in Fluid Power: Improving Systems by Connecting Real and Virtual Worlds

Katharina Schmitz and Malte Becker

RWTH Aachen University, Institute for Fluid Power Drives and Systems (ifas), Campus-Boulevard 30, 52074 Aachen, Germany

Abstract.

Fluid power is a widely used drive technology known for its durability, robustness, and cost efficiency, but it faces challenges related to energy efficiency and environmental impact. To address these challenges, the integration of software functions and digital frameworks is gaining importance for improving component performance, system integration, and product development. The integration of data and software within fluid power systems and components enables companies to increase their innovation potential, thereby establishing digital competence as a key determinant of competitive advantage. Consequently, fluid power is evolving into an interdisciplinary research field that combines mechanics, electronics, computer science, and data analytics. Current research focuses on the usage of digital twins across all phases of the product life cycle. As a result, numerous related concepts have emerged, such as digital frameworks and software functionalities that support component and system development while providing additional insights during operation, for example, through soft sensors that derive new variables from existing sensor data.
Despite these advances, the implementation and maturity of digital twin technologies vary significantly between domains. In the field of fluid power, in particular, the extent to which digital twins have been developed and integrated remains an open question. Therefore, this contribution examines the current state of digital twin development in fluid power through selected examples and identifies the key elements that enable interaction between the physical and virtual domains. The contribution shows that, while research already provides solutions addressing individual aspects of digital twins along the product life cycle, a fully integrated approach that connects these aspects is still lacking. These findings underscore the need for common standards and comprehensive frameworks to fully leverage the potential of digital twins.

1. INTRODUCTION

Fluid power is a key drive technology applied across almost all industry sectors. Its main advantages include high durability, robustness, and often cost efficiency in acquisition compared to alternative technologies. Combined with flexibility in system design, these properties enable fluid power to meet the specific requirements of a wide variety of applications. Today, fluid power technology forms a central pillar in heavy machinery, manufacturing systems, infrastructure, and energy production. It is also found in smaller applications, such as medical devices and power tools. [1]

Despite these advantages, the widespread use of fluid power presents notable challenges. Since many applications involve significant energy transfer, fluid power systems contribute substantially to industrial energy consumption and, consequently, to CO_2 emissions. An estimate indicates that the CO_2 emissions from hydraulic machinery account for approximately 5 % of global emissions [2]. For comparison, this corresponds to 2.3 of the global aviation emissions [2], underscoring the considerable potential for improving the efficiency and optimization of fluid power systems. In response, ongoing technological progress increasingly requires the integration of software functions and digital enhancements into products and processes. The effective use of data and information, combined with digital functionalities, is becoming essential for improving component and system performance, as it enables the development of intelligent and optimized systems that contribute to long-term emission reduction. Such advancements can be realized, for example, through the implementation of soft sensors [3, 4] or the digitalization of product development processes [5, 6]. As a result, fluid power is evolving into an increasingly interdisciplinary field, combining expertise from mechanics, electronics, computer science, and data analytics. Current research focuses on approaches such as soft sensors and digital frameworks that aim to enhance the system development process. In this context, the concept of the digital twin plays a central role, representing a fully digital counterpart of a fluid power system or of a component. Against this background, this contribution addresses the following research question: *What is the current development level of digital twins in fluid power?* To answer this question, the concept of digital twins is first defined. Subsequently, selected exemplary research findings related to digital twins in fluid power are presented, followed a brief assessment of the current state of development.

2. DEFINITION OF DIGITAL TWINS

The concept of the digital twin has emerged and is interpreted in various ways [7]. To provide a comprehensive understanding of digital twins, the terminology is first clarified and the interpretation used in this contribution is defined. The origin of the term “twin” can be traced back to NASA’s Apollo program, where engineers replicated the conditions of space missions on Earth [8]. NASA developed an identical physical replica of the spacecraft used in space to simulate mission scenarios on Earth [8]. To reduce the extensive resource requirements of such physical twins and enable their application in earlier stages of development, the idea of the digital twin was gradually introduced [9].

The expression “digital twin” was first introduced by Grieves in 2003, who characterized it as an ideal concept for product life cycle management, connecting physical components with their virtual counterparts through continuous information exchange [10]. In 2010, NASA described the digital twin as a multiphysics simulation model representing a technical system [11]. Since then, numerous definitions of the concept have been proposed, each one

highlighting specific aspects according to the perspective of the respective field or user, such as simulation, life cycle management, or data-driven services.

A general definition that serves as the foundation for this contribution is provided by [7], which describes digital twins as virtual representations of physical entities that are interconnected through real-time data exchange for various applications such as monitoring, design, optimization, maintenance, and remote access. The digital twin serves as a link between the physical and virtual domains. In this context, a digital twin can be understood as the virtual counterpart of a physical object. At the system level, this could include, for example, an excavator in mobile hydraulic applications, a press in stationary hydraulic systems, or a handling machine in pneumatic applications. At the component level, it may represent individual components such as a valve or a pump. Between the physical and virtual worlds, various tasks are carried out that correspond to different phases within the product life cycle (see **Figure 1**).

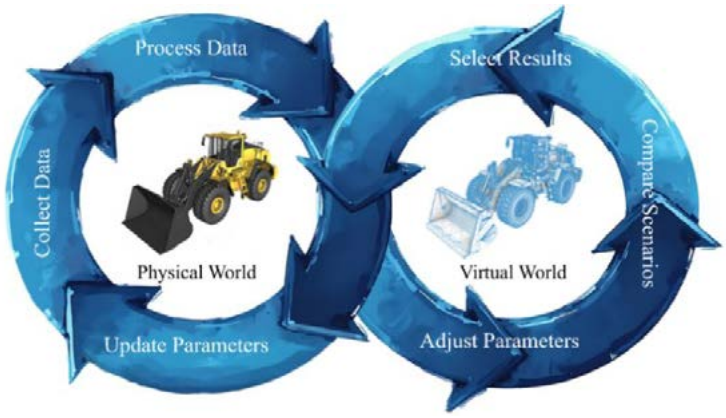

Figure 1: Connecting the virtual and physical worlds using digital twins.

With respect to the product life cycle, several stages can be identified that link the virtual representation to the physical asset. The digital twin facilitates the following steps:

- *Collect data*: Acquisition of data from various sources, such as field devices or sensors, followed by appropriate structuring and organization of the data.
- *Process data*: Transmission of the collected data between devices, specifically from the physical system to the digital twin, and preparation of the data for subsequent analysis. For instance, transferring parameters from the real application into simulation environments.
- *Adjust parameters*: Adaptation of parameters for specific applications, such as the calibration or parameterization of simulation models within the digital environment.
- *Compare scenarios*: Examination of different operating conditions using the digital twin, including parameter studies or evaluation of new configurations, e.g., assessing the performance of a new component.
- *Select results*: Identification and selection of suitable solutions based on scenario analysis, for example, determining an optimal set of parameters for controller settings or system components.

- *Update parameters*: Integration of the optimized parameters into the physical system, thereby closing the feedback loop between the digital and physical domains.

3. UNDERSTANDING THE RELEVANT COMPONENTS OF DIGITAL TWINS

Digital twins should be developed in parallel with product development and interact with the fluid power system during operation. To clearly define digital twins, their key aspects must be specified. This starts with defining data, information, and knowledge, as these constitute what digital twins exchange with real systems. A simplified product life cycle process for fluid power systems then illustrates where digital twins are created and applied. In the following, simulation models are addressed, as they often form the basis for digital twin modeling. Finally, the Asset Administration Shell (AAS) is introduced as an example of an interoperable interface for data exchange.

Data, information, knowledge – Clarification of terms often used synonymously

A continuous exchange of data between the digital twin and its corresponding physical object is essential. Therefore, it is important to establish a clear understanding of the concepts of data and information. However, in practice, the terms data, information, and knowledge are often not clearly differentiated and are frequently used interchangeably. Furthermore, a wide range of definitions can be found in the literature. To ensure conceptual clarity, this contribution adopts the framework proposed by North [12], as shown in **Figure 2**, which provides an overview of these terms along with examples from fluid power.

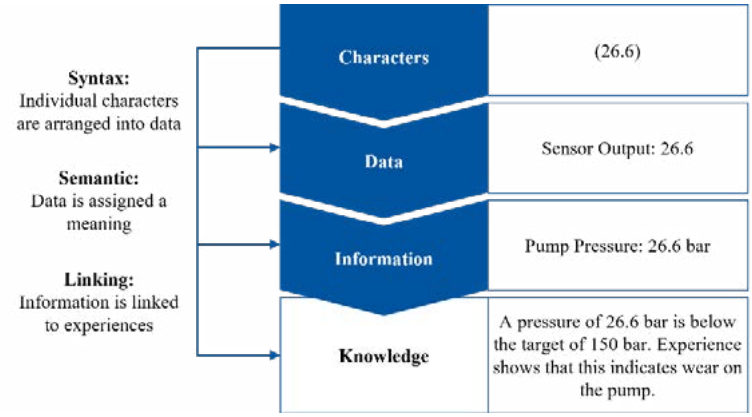

Figure 2: Different between characters, data, information, knowledge according to [12] extended with an example from fluid power.

According to North [12], data is generated through the application of syntactic rules to characters. It therefore represents arbitrary, non-interpreted sequences of symbols, such as a random string of numbers. In the context of fluid power, data can be understood as raw measurements obtained from a real application, for example a sensor output of 26.6. By assigning semantics, data is transformed into information. Information thus refers to data that is embedded within a meaningful context. For instance, interpreted data such as pressure signals from a specific pump (e.g., 26.6 bar). Knowledge, in turn, arises from linking

information with experience. For example, knowing that a certain system pressure is critical for the operation of a hydraulic system, or that a specific pressure value indicates possible pump wear.

To enable a successful exchange between the real system and its digital twin, a shared understanding is essential. The real system and the digital twin must both be able to interpret data in the same way.

Product life cycle – Developing and using digital twins

The product life cycle of fluid power systems, as illustrated in simplified form in **Figure 3**, can be divided into several phases. The division of the phases of the development process is adapted from [13]. The starting point is the requirement phase, where the requirements for the development task are defined and identified. After that, in the initial concept phase, the system layout is designed based on experience and system requirements, resulting in a schematic concept of the system layout. During the subsequent detail development phase, a simulation model is created by integrating component models within a suitable simulation environment. This approach aims to size the components appropriately and determine optimal parameter sets. After simulative optimization, the real system is commissioned. Although parameter transfer to the physical system is still predominantly performed manually, the simulation model continues to support the system during operation. Throughout the product life cycle, it is used for tasks such as efficiency enhancement, process monitoring, and the testing of planned reconfigurations. After the machine's operational phase, various considerations regarding its further use arise during the end-of-life phase. An explanation of various strategies for the further use of a product in context of circular economy can be found in [14].

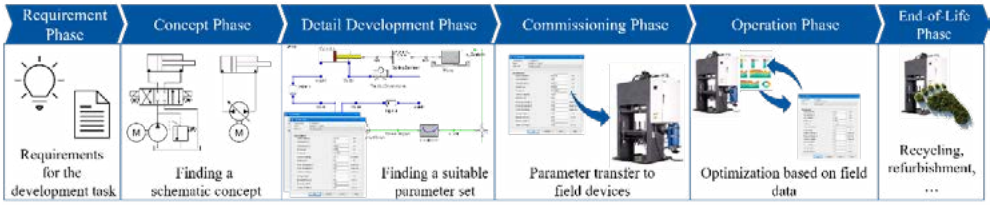

Figure 3: Simplified product life cycle phases.

Simulation models – Foundation for modeling digital twins

Simulation models form the foundation for modeling digital twins. Depending on the required level of accuracy, different types of simulation approaches are employed, as described in [1]. The simulation of fluid power components and systems is an essential tool in product development and optimization. It not only shortens development time but also provides access to parameters that are difficult or even impossible to measure experimentally. Once a model has been created and validated, extensive parameter studies can be performed efficiently and with minimal additional effort. Depending on the level of modeling detail, simulations can range from zero-dimensional to three-dimensional analyses. Furthermore, they can be classified as either static or dynamic, depending on whether time-dependent variations in state variables are considered or only stationary processes are examined. In concentrated (lumped)-parameter simulation, systems are modeled using discrete elements, and this approach is often used for fluid power system

simulation (see **Figure 4**). In contrast, distributed-parameter simulations enable spatial and temporal resolution of state variables and are often used to analyze specific geometries of fluid power components, such as a valve geometry.

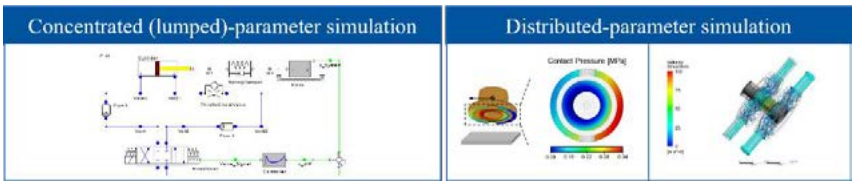

Figure 4: Exemplary representation of concentrated-parameter and distributed-parameter simulation according to [1].

AAS – Interoperable data and model interface

A possibility to transfer data and models through the digital twin is provided by the Asset Administration Shell (AAS). The AAS was developed in cooperation with the "Plattform Industrie 4.0" initiative [15] and the foundational framework of the AAS was published in DIN SPEC 91345 [16]. The AAS concept is becoming increasingly important in fluid power [17]. It serves as a digital representation of an asset, such as a hydraulic valve, enabling Industry 4.0-compliant interaction. It contains comprehensive descriptions of the asset and its associated services within a defined context throughout the entire product life cycle [16].

The AAS comprises submodels that describe an asset by means of SubmodelElements, for example properties or files [18]. Submodels can be standardized into templates to capture the relevant SubmodelElements needed for particular use cases (e.g., the submodel template "IDTA 02023 Carbon Footprint" to provide carbon-footprint-related data of an asset [19]) [18]. Both submodels and SubmodelElements can be annotated with semanticIds, which act as unique identifiers linking to semantic descriptions stored in standardized dictionaries (e.g., ECLASS [20] or IEC CDD [21]) [18]. These semantic references specify the exact meaning of the content contained within the annotated elements. The schematic concept of the AAS is shown in **Figure 5**.

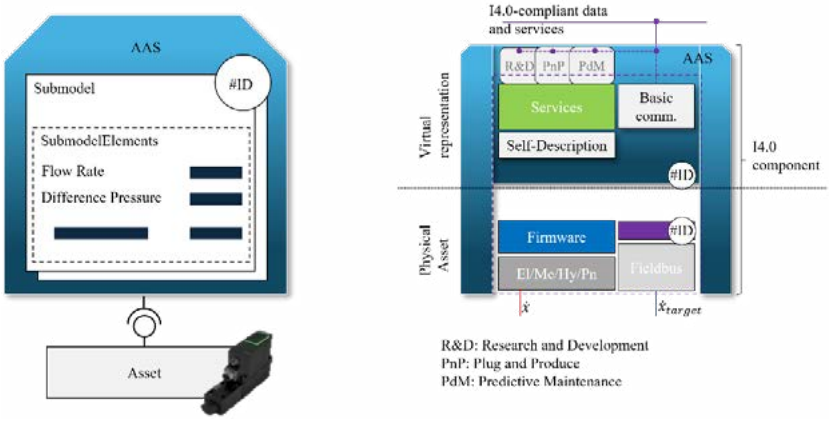

Figure 5: Schematic concept of AAS (left) and exemplary implementation of AAS in the application case of automated commissioning (right).

By providing an interoperable interface for product data and models, the AAS facilitates seamless collaboration among stakeholders, including component suppliers, system manufacturers, and operators, across the fluid power system development process [5]. By employing the AAS, data can thus be exchanged and utilized consistently across different systems and stakeholders.

4. CONNECTING THE VIRTUAL AND PHYSICAL WORLDS VIA DIGITAL TWINS

The following section presents relevant research findings relating to the process steps shown in **Figure 1.**

4.1. Collect data

Collecting and structuring data from various sources, such as field devices and sensors, is a crucial step in the development of digital twins. In addition to conventional hardware sensors, software-based solutions such as soft sensors play an increasingly important role. Soft sensors calculate or estimate process variables using mathematical models or data-driven algorithms instead of direct physical measurements. They are often used to determine variables that are difficult to measure from variables that are easy to measure. Moreover, in the field of hydraulic systems, current developments show a clear trend toward components with integrated intelligence and extended functionality. As a result, soft sensors are gaining importance as they offer a cost-effective way to obtain relevant process information while reducing the need for additional hardware.

One example of soft sensor application is the calculation of volume flow from pressure signals. Measuring the volume flow in fluid power systems continues to pose a major challenge. On the one hand, volume flow sensors are almost invasive sensors and therefore they have an influence on the flow. On the other hand, volume flow sensors are often very expensive, which is why fluid power systems are often designed without them. A virtual flow sensor enables the flow rate to be determined, which in turn makes it relatively easy to draw conclusions about the system, such as calculating hydraulic energy or, for example, detecting leaks at an early stage. Conventional sensors are often unable to detect highly unstable flow conditions due to their slow response times or their dependence on assumptions that only apply to steady, laminar flows, as described by Hagen-Poiseuille's law. By extending the applicability of measurements to turbulent and unstable flow regimes, soft sensors enable condition monitoring in fluid power systems. In addition, a soft sensor can also functionally improve the informative value of conventional sensors.

The development of a virtual volume flow sensor is shown in [3, 22], where the sensor was developed based on Hagen-Poiseuille's law to calculate the transient flow conditions of the volume flow. Theoretical models for transient, laminar, turbulent, and compressible flows were developed and validated by one-dimensional and three-dimensional simulations as well as experimental tests. The results showed that the soft sensor can measure transient volume flow and is well suited for practical industrial applications (see **Figure 6**).

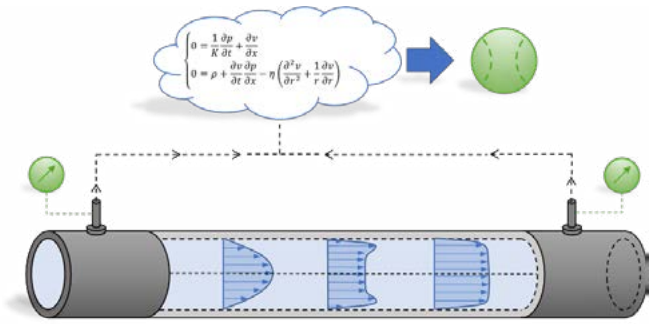

Figure 6: Schematic design of virtual volume flow sensor. The volume flow is calculated based on measured pressure signals.

Another example of the use of soft sensors is the flow calculation, based on the force of the electromagnetic valve actuator. The development of such a sensor is shown in [4] and the concept is illustrated in **Figure 7**. The approach aimed to develop a methodology for volume flow estimation on direct-actuated valves with solenoids for constant pressure systems. This approach provides a cost-effective, software-based sensor solution. By detailed modeling of the valve, inherent disturbances can be considered and thus the volume flow through the valve can be inferred from the electrical variables of the actuator as well as the armature position.

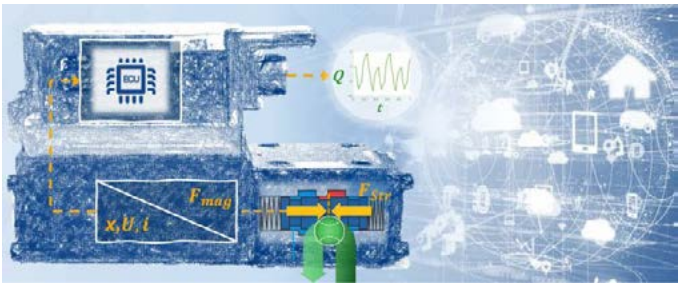

Figure 7: Schematic concept of virtual volume flow sensing, based on the force of the electromagnetic valve actuator.

In addition to soft sensors, there are other possibilities for data collection. One example is shown in [23], where simulation-based and measured data sets are used to train a condition monitoring algorithm based on machine learning. The approach is illustrated in **Figure 8** using the example of a hydraulic press. Machine learning is applied to identify patterns related to system failures (e.g., external and internal leakage). For this purpose, a database is built from both physical and virtual machines (simulation model). Subsequently, feature detection is performed, and machine learning is used to train the algorithm to recognize these features. In this research, the required amount of data and the combination of simulated and real data are also investigated. However, most algorithms are not designed to handle raw machine data directly and therefore require the data to be compressed and transformed into a smaller set of representative features. While several coding toolboxes aim to simplify feature generation through generic feature extraction methods, this work presents an enhanced procedure for automatically refining and selecting features. Moreover, an

approach for condition monitoring based on neural network is shown in [24]. The study shows that a feed-forward neural network can reliably identify different operating states of a pneumatic system based on vibration, pressure, and position data. It also becomes clear that even low-cost sensors enable reliable vibration-based condition monitoring, thereby supporting the industrial adoption of such maintenance strategies.

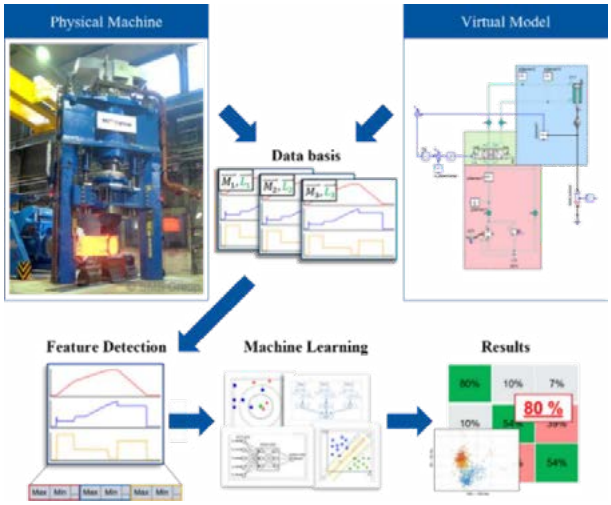

Figure 8: Collecting data from different databases to train a machine learning-based condition monitoring algorithm.

Another example of data collection for condition monitoring is given in [25]. This contribution proposes a cost-effective condition monitoring method for axial piston pumps using a single low-budget sensor capable of capturing multiple fault indicators. Data from various sensors operating under different conditions were used to detect faults such as valve plate cavitation, slipper wear, and axial clearance using machine learning algorithms.

4.2. Process data

Once the data has been collected, it is transferred between devices, specifically from the physical system to the digital twin, and prepared for analysis. For example, parameters can be transferred from the real application into simulation environments. The AAS provides an interoperable interface for data, models, and related information (see **Figure 9**). Consequently, within the development process, a variety of stakeholders such as component suppliers, system manufacturers, and operators can be seamlessly integrated. At the same time, heterogeneous data sources become accessible in a standardized and interoperable manner. By employing the AAS, data can thus be exchanged and utilized consistently across different systems and stakeholders. AAS is already being used in some industry-relevant use cases, an overview of which is given in [17]. In particular, within the domain of fluid power, several research activities are already being conducted in the context of simulation-based development and parameterization [5, 26, 27], and in the field of automated commissioning [28].

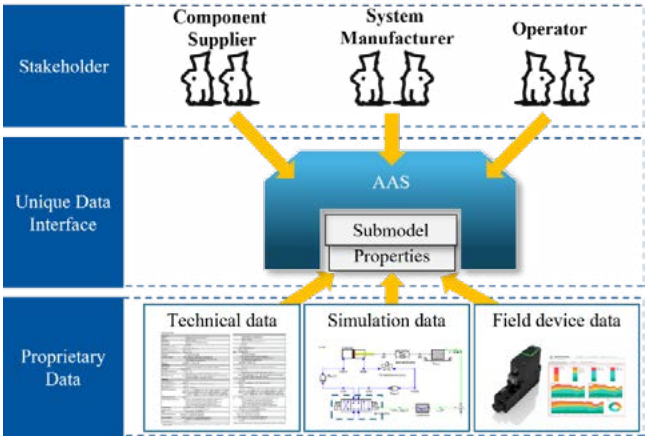

Figure 9: Integration of AAS into the product life cycle to enable a unique data interface.

4.3. Parameter adjustments

After the data is transferred, it is adapted for use in a virtual environment, for example for engineering applications. Adapting parameters to specific applications, such as parameterizing simulation models within a simulation environment, represents a key step in the development process. One example of parameter adjustment occurs during the detail development phase, as described in [5, 26] and illustrated in **Figure 10** and **Figure 11**.

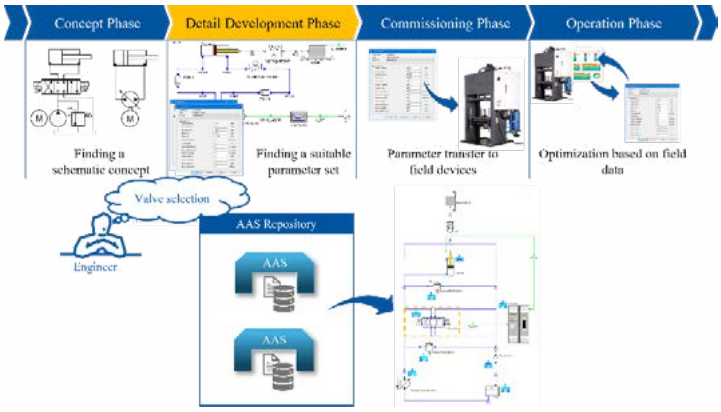

Figure 10: Exemplary use case for parameterization simulation models via AAS.

Engineers traditionally select components and set initial parameters manually by consulting various sources such as websites and data sheets, a process that is time-consuming and prone-to-errors. For example, an engineer may need to select a new valve and verify whether it has the correct size. This task usually involves clarifying the requirements and parameterization of the simulation with the relevant component data. This process can be made significantly easier using AAS.

The automatic component selection and parameterization of the simulation is described in **Figure 11** with more detail below.

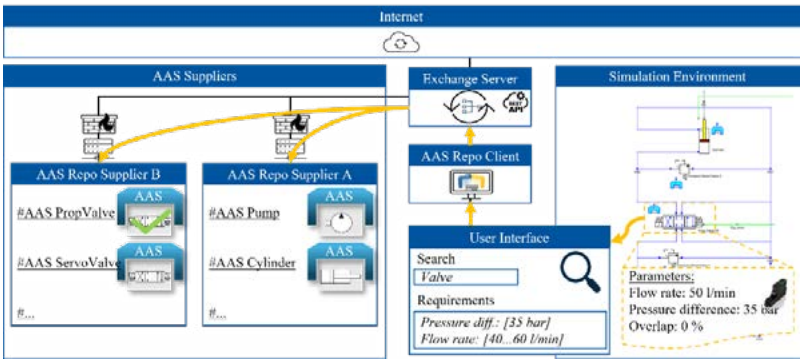

Figure 11: Parameter adjustment in the simulation-based development process.

A workflow is illustrated in which simulation data are adjusted based on parameters provided by the AAS. To enable this, a framework was developed that allows the parameterization of simulation models via the AAS. The framework is implemented using an HTTP REST API and considers manufacturer-specific safety requirements. The framework supports component selection by enabling searches in AAS Repositories provided by manufacturers to identify components that meet the desired requirements. The framework allows the definition of query criteria such as component type (e.g., valve or pump) and technical requirements (e.g., pressure difference and flow rate) specified as exact values or ranges. In the example considered in **Figure 11**, the engineer searches for a valve to ensure that the hydraulic press meets its functional requirements. Based on preliminary calculations, the engineer estimates the valve specifications, such as a nominal pressure difference of 35 bar and a flow rate of 40 to 60 l/min. Another example of adjusting parameters is shown in [29]. The contribution presents an approach for the identification, tuning, and verification of digital twins in hydraulic control systems. Another approach to parameter adjustments is presented in [30], which demonstrates a self-optimizing fuzzy PID controller for the independent control of the speeds of two non-identical electric motors. An example in the pneumatic area is shown in [31]. This contribution shows a concept for modeling and simulating the fluidic behavior of pneumatic vacuum generators. To increase the accuracy of the simulations, the approach uses instance-specific data rather than just object-specific data for the respective asset. The model and data are integrated into the digital twins of the pneumatic vacuum generators so that they can be combined with other components to represent digital twins of complete vacuum handling systems.

4.4. Scenario calculation and comparison

After parameterizing the engineering applications, such as simulation models, various scenarios are calculated and compared according to the engineering objectives. Finally, a suitable configuration is selected. Therefore, parameter studies are carried out for testing new configurations, for example evaluating the performance of a new component in a hydraulic system, finding suitable settings for a controller or testing different designs of slippers in hydraulic pumps. An example of scenario analysis is shown in [32] where displacement-controlled hydraulic systems are analyzed as an energy-efficient alternative to conventional valve-controlled systems in construction machinery. Another example is shown in [33], where different geometric designs of slippers for axial piston machines are

investigated. After the scenario comparison, suitable configurations are selected, such as an optimal set of parameters for a controller or the best design of a slipper. Therefore, tools are being researched that enable fast calculation of scenarios and allow efficient comparison of the results. Examples include [34, 35], in which a framework of fast computation of lubricated contacts using PINNs was developed. Conventional simulation tools are often time-consuming for extensive parameter studies and scenario comparison. Accurately representing all possible operating conditions requires many simulation cases, and in some applications, near real-time performance is even necessary for control tasks. Although extensive research has been conducted in this area, further efforts are particularly needed to accelerate calculations through AI-based approaches such as PINNs and neural networks, as well as in uncertainty management and cross-domain and cross-scale simulation.

The identified configurations and parameters are then made available again and can be used to adjust the real machine. At this stage, there is potential for an automatic transfer of parameters to the real application using tools such AAS. In **Figure 12** an overview of scenario calculation and comparison is shown. This process can be accelerated using AI-based simulation frameworks.

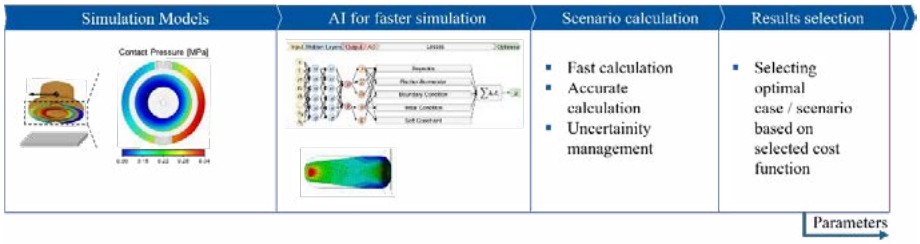

Figure 12: Scenario calculation and comparison with AI-based accelerated simulation.

Moreover, in [36] an optimization framework for hydraulic hybrid vehicles is presented. The paper introduces a simulation-based optimization approach for assessing a series hydraulic hybrid vehicle transmission, demonstrating that numerical optimization enables exploration of a wide design space and reveals trade-offs between component sizing and control strategies. This framework builds on the simulation-based optimization methodology originally introduced in [37]. Therefore, various scenarios defined by the design parameters of the hydraulic components are analyzed and systematically compared.

4.5. Update parameters

Feeding the optimized parameters back into the physical system closes the information loop between the digital and physical domains. By applying these updated parameters, the system operates more accurately and reliably, improving controllability, ensuring smoother performance, and enhancing overall output. At the same time, optimizing energy efficiency reduces energy consumption, resulting in a more sustainable and cost-effective operation. An example of updating parameters is presented in [38], where deep reinforcement learning (RL), an emerging branch of machine learning, addresses complex nonlinear optimal control problems through data-driven, trial-and-error learning. In this contribution, a deep RL controller is applied to a hydromechanical system, an inverted pendulum on a cart with a hydraulic drive, demonstrating a comprehensive framework that enables training in simulation to swing up and balance the pendulum. Another example is shown in [39], where

mobile off-highway machines are equipped with sensors that continuously record data such as position, inclination, power, and information about surrounding obstacles for analysis. Through sensor data fusion and modeling, this information can be enriched with geospatial data to generate semantic insights about the environment. As a result, a digital twin of the surroundings can be created, supporting geodata-based processes like digital construction planning or terrain analysis. Despite these research findings, much work remains to be done from both a scientific research perspective and an industrial standpoint. Transforming the available information into tangible benefits is a complex challenge, yet it is essential to fully realize the potential of digital twins. **Figure 13** summarizes the potentials of connecting data from real and virtual world, e.g., for the optimization of the machine controller.

Figure 13: Transferring parameters from the virtual to the real world.

5. CONCLUSION

Fluid power is a key technology applied across various industries but continues to face challenges in energy efficiency, environmental impact, and digital integration. Digital twins provide a promising approach to address these issues. However, the extent of existing research in this field remains unclear. Therefore, this contribution addressed the research question: *What is the current development level of digital twins in fluid power?* To answer this question, the term “digital twin” was first derived from scientific literature. Moreover, key aspects for understanding a digital twin were identified and explained, including, for example, simulation as a physical modeling of reality and the AAS as an example for a model and data carrier. Subsequently, this contribution presents relevant exemplary research findings from the field of digital twins in fluid power.

This contribution points out the significant progress made in recent years regarding concepts and solutions for various aspects of digital twins in fluid power. In addition, there are very advanced research activities related to collecting data with digital methods, for example using machine learning or the development of soft sensors. Moreover, there are research activities concerning process data and data adjustment, especially regarding the use of the AAS. Furthermore, in terms of scenario analysis and comparing scenarios, there are increasing activities focused on using PINNs to accelerate simulations and to enable an easy comparison of different scenarios. The identified research activities underline that there are many ongoing efforts in each sub-area of the digital twin process. Building on recent

advances, future research should focus on developing a unified and holistic framework for digital twins in fluid power.

Biographies

Katharina Schmitz studied mechanical and chemical engineering at RWTH Aachen University and Carnegie Mellon University, Pittsburgh (USA) and graduated 2015 as Dr.-Ing. at RWTH Aachen University. Since 2018, she is full professor at RWTH Aachen University and director of the Institute for Fluid Power Drives and Systems (ifas). In addition, she is Vice Dean of the Faculty for Mechanical Engineering at RWTH Aachen, a position she holds since 2020. Prof. Schmitz's awards and honors include several best paper awards and 2023 IMechE Joseph Bramah Medal award.

Malte Becker obtained his Master of Science degree in Mechanical Engineering from RWTH Aachen University. Since 2021, he has been working as a research associate at the Institute for Fluid Power Drives and Systems (ifas) at RWTH Aachen University. His research focuses on the Industrial Internet of Things (IIoT) and Systems Engineering. Since 2025, he has been serving as Chief Engineer at ifas.

Next Generation Valve Actuation Platform

Dr.-Ing. Dirk Wroblewski

Danfoss Power Solutions, Nordborgvej 81, DK-6430 Nordborg, Denmark

Email: dwroblewski@danfoss.com

Abstract.

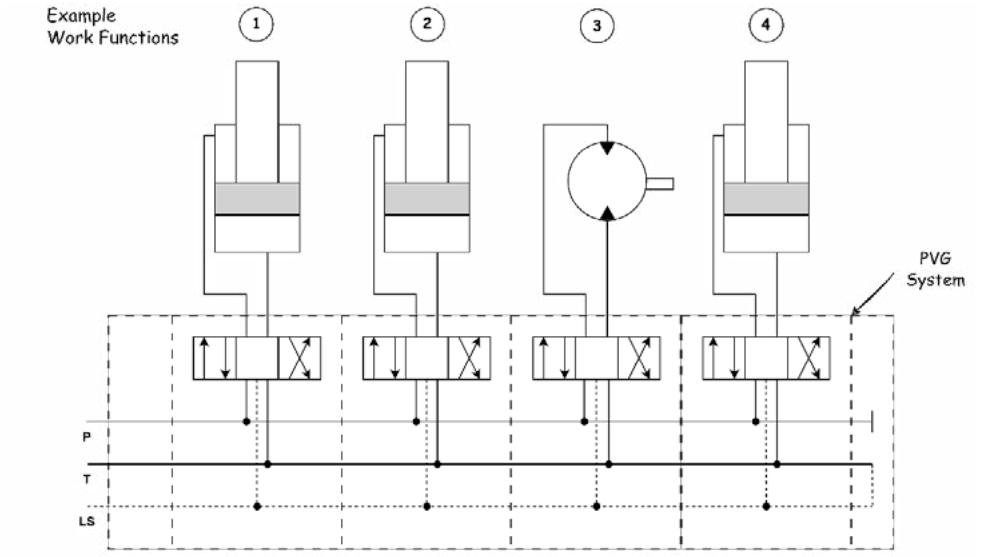
Danfoss is going to develop a new generation of valve actuation platform for our PVG system. Featured with integrated sensors, enhanced connectivity, memory scalability, etc., it allows the creation of actuator variants customized to the different needs of the application systems. This paper will focus on the modular concept, and key features of this next generation actuation platform. One element of it is the voice coil driven pilot valve actuator. This is an important technology for highly advanced work function control tasks to create application performance driven by software design elements in favor of performance driven by mechanical design elements. This paper presents a design study with the goal to demonstrate the ability to design a cost-effective voice coil actuation for a PVG valve. The preliminary performance and key characteristics of the actuator will be discussed in this paper.

Keywords. pilot valve, voice coil, electro-hydraulic control valve, mobile machines.

1. INTRODUCTION

The quest to achieve seamless control of pressure and flow rate in fluid power systems has undergone major development in the past decades. Back in the 80's the industry shifted from mechanical/hydraulic controls to electro-hydraulic controlled proportional valves. These systems emerged as a cost-effective alternative to servo valves, enabling stepless control of pressure and flow rate via electrical signals.

To improve the performance of proportional valves, relative to the performance of servo valves, the manufacturers added linear variable displacement transducers (LVDTs) to proportional valves in order to sense the spool position. The output signal from the LVDT was used to calculate the difference between where the main spool was supposed to be and where it actually was, and that difference was passed on to modulate the pilot valve in an effort to position the main spool to achieve the desired output based on the input [1]. This simple, yet efficient closed loop control principle enabled machine builders and system integrators to make easy integration, i.e. plug 'n play of high performing control valves.



In 1988 Danfoss launched the PVG32 (Proportional Valve Group) series, a modular control valve system designed for mobile machinery. The system's concept was novel at the time

All Open Access articles are peer-reviewed, distributed under the Creative Commons Attribution-Non Commercial 4.0 International

Classified as Business

and offered a flexible, load-sensing directional control valve, designed for advanced electrohydraulic control. Over time, Danfoss and others have evolved electro-hydraulic valve actuation with microcontrollers, fault monitoring, integrated sensors, software-controlled options, and CAN bus communication to meet versatile requirements in a broadening application range for electro-hydraulic controlled proportional valves. Concurrently the PVG system has grown with adding new frame sizes, each demanding new variants or series of electro-hydraulic actuation.

Contrary to common assumption, the requirements for different work functions in many applications are far from uniform. The ability to configure a proportional control valve stack, serving versatile work functions, with valves and actuation technology tailored to the actual demand, provides scalable yet cost-efficient solutions to the machine builders to meet the individual value proposition of each work function. As a result, modular valve systems with flexible valve actuation technologies play an important role in helping machine builders to design a control system that is optimally customized to their applications, both in terms of cost and technology.

High Level Work Function Requirements	Proportional Control	Proportional Control	Proportional Control	ON-OFF Control
	Sensor controlled	Joystick. controlled	Joystick. controlled	Joystick. controlled
	Flow Rate: High	Flow Rate: Medium	Flow Rate: Medium	Flow Rate: Low

2. MODULAR VALVE ACTUATION PLATFORM

As customer needs and technology evolve, so must the solution. Therefore, Danfoss is going to develop a new generation of valve actuation platform for our PVG system. It is a new hardware & software platform, fully modularized on electronic hardware and software domain, to support the prospective expansion of our proportional control valve portfolio. The new hardware & software platform addresses the most important needs of an increasingly growing variety of control valves.

Scalability: Product architects need to be able to easily add or remove components (e.g., drivers, sensors, actuators) without redesigning the entire system. Scalability in the design will support future upgrades and expansion.

Reusability: Modules (software blocks, hardware units) should be able to be reused across different product development projects, to reduce development time and cost.

Flexibility: The platform should support the customization of product variants. Flexibility in the design ensures the platform can support a wide range of applications from simple to highly complex applications.

Standardization promotes consistent design practices and interfaces and provides a common, well-known appearance to the system integrator / application engineer. Standardization enables easier integration with application systems. In short: If one knows a single product variant, one knows them all.

The core of the new platform will be a new microcontroller family with scalable memory to accommodate growing software, lockstep core technology and built-in self-tests (BIST) to increase fault coverage capabilities. Lockstep core technology is a mechanism where two processor cores run in perfect synchronization, executing the same instructions at the same time. Their outputs are continuously compared, and if a mismatch occurs, it signals a hardware fault. The external watchdog monitors, among other test points, the MCU's program sequencing ability with a question-response approach and disables power supply to the driver circuit via the safety switch. Secure Boot is a security feature designed to ensure that a device boots using only software that is trusted by the manufacturer. It helps protect against malware and unauthorized software running during the boot process. It supports compliance with security regulations (e.g. CRA).

A completely new software architecture will be developed, that exploits the microcontroller's capabilities but is still abstracted well enough to support the modular approach. The architecture will be designed with different peripheral and application specific layers. The layers will be vertically permeated by modular software components with well prescribed interfaces.

The microcontroller supports various analogue & digital input devices for application sensors, CAN Classic & CAN FD interfaces, plus Ethernet interface for future, data-hungry applications. On the actuation side the hardware & software platform primarily supports both solenoid and voice coil technology to control the associated pilot valves. But the electro-mechanical valve actuation technology can also be applied to this new platform to support the transition from mechanically actuated control valves to electrically actuated control valves.

Classified as Business

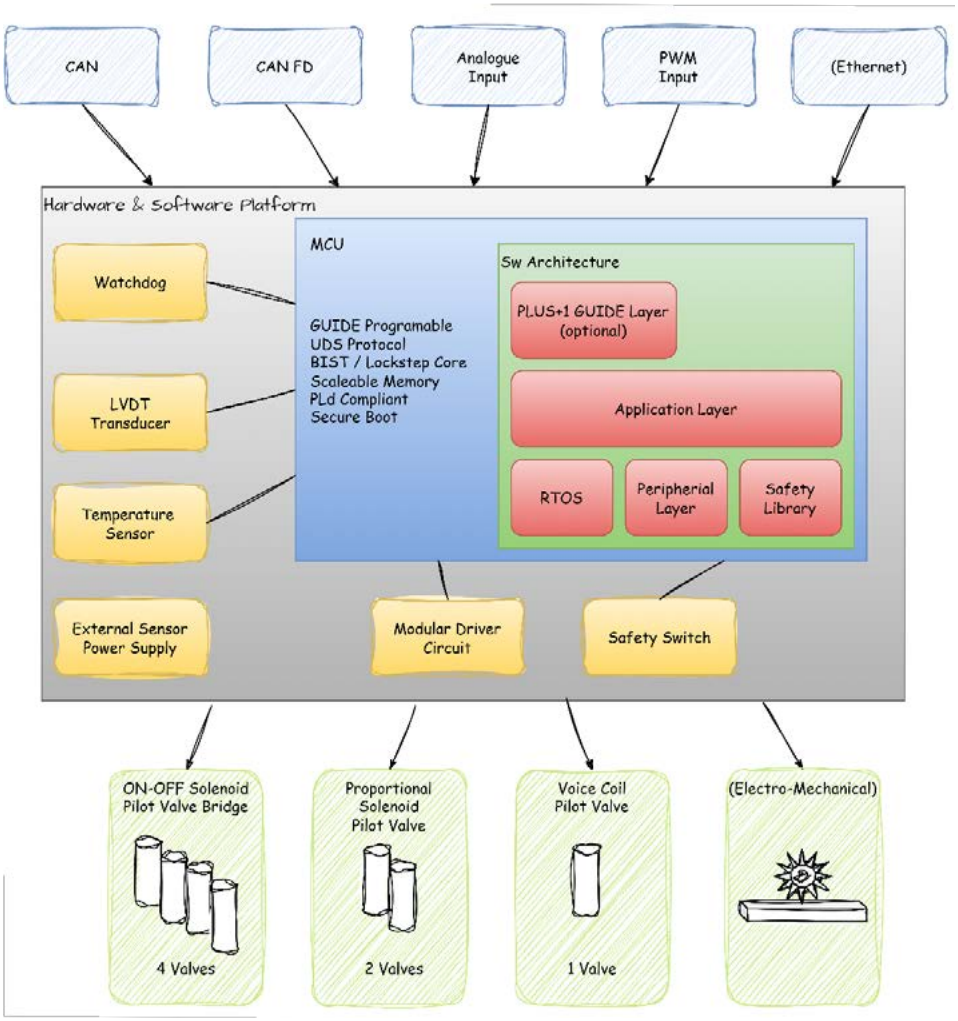

Figure 2. New PVG Valve Actuation Platform.

The platform will be designed to reach PL=d compliance (acc. ISO 13849) for application-level safety function **Safe Stop**. This means that whenever a safety-critical event occurs, i.e. overload situation, the boom movement must be safely stopped and an unexpected start-up from the rest position must be prevented. This platform supports these requirements by selecting highly reliable components and extensive diagnostics. The operation of the on-board electronics and the control valve is continuously monitored. If a failure is detected, the on-board electronics sends an error message on the CAN bus to the machine control unit and concurrently de-activates the solenoids via the integrated safety switch.

The interfaces and basic capabilities will be backwards compatible with current Danfoss PVE actuation series; however, we expect control performance enhancements due to increased microcontroller capabilities that would allow the implementation of sophisticated valve control algorithms. This new platform supports free combinations of input and actuation technology according to the upcoming demand and associated value proposition.

Classified as Business

For example, aside from conventional solenoid bridge technology with a classical CAN interface, Danfoss could also offer voice coil driven actuation with pressure or other application sensors. Or it could combine it with free programming space for customers.

All these technologies could be available in the same PVG valve system; individually tailored to the specific value and needs of the respective work function.

3. NEW FEATURES

The new platform provides a couple of new capabilities and features with the aspiration to be prepared for increasing integration, data exchange and control performance objectives.

Enhanced Control Valve Capability refers to offering new PVG features in addition to existing ones.

- Improvement on valve control through the implementation of advanced robust control techniques. In particular, the compensation of the inherent cold oil behaviour is a long-cherished desire.
- Integrated sensors for pressure, temperature and spool position can be utilized for detecting the work function's integrity, i.e. predictive maintenance, or they can be used to optimize the work function's control system.
- Realization of machine learning techniques to capture knowledge of highly skilled machine operators and transfer that knowledge into control logic to make it available to all machine users.

PLUS+1® GUIDE is a graphical software development environment from Danfoss, designed to simplify and accelerate the creation of control systems for mobile machinery. The tool is based on graphical software programming enabling users to develop their own individual work function application. When this development environment becomes part of the valve controller, customers will benefit from its close proximity to sensors and work functions in the development of their own intelligent solutions. This programable space is optional to the embedded application firmware.

CAN-FD (Controller Area Network – Flexible Data-rate) is an enhanced version of the original CAN protocol, designed to meet the increasing demands of modern automotive and industrial systems. It can handle larger and faster data exchanges, which are essential for modern, data-intensive applications. For instance, the controller software can be downloaded up to 5x faster than using classical CAN interface. CAN-FD nodes can coexist with classical CAN nodes, but classical CAN nodes cannot interpret CAN-FD frames.

Automotive **Ethernet** is a specialized version of Ethernet adapted for use in vehicles. It supports data rates from 10 Mbps to 10 Gbps, ideal for streaming large data frames, needed for advanced applications like autonomous driving.

Today it is not yet clear what kind of value Ethernet can offer to work functions. Eventually the move of centralized machine control functions to de-centralized machine control architectures might foster the use of Ethernet. A potential use case is the facilitation of many advanced, data dependent functions into a single valve system controller, servicing a whole valve stack. For example, this controller might process camera data as feedback signal for a given work function control task. When data bandwidth is no longer a constraint, many more options will become apparent.

4. WHY VOICE COIL?

One element of the prospective valve actuation platform is the pilot valve with so called voice coil technology. Danfoss has already developed such a technology in conjunction with the development of CMA / PVX valves. These proportional control valves are known for their independent metering edge technology, their electronic load pressure compensation and superior controllability. They are well recognized by customers, but since they were developed independently, they do not benefit from the scaling and modularity of the PVG platform. On the other hand, the PVG platform does not benefit from the opportunities that the voice coil technology can offer.

The voice coil driven control valve achieves much higher dynamics, similar to servo valves, which enables them to react much more precisely and much faster to sensor signal induced valve commands. Features that were previously provided hydro-mechanically can now be provided by a software-enabled control function that uses sensor feedback and can be configured, tuned, and automatically adapted.

It is exactly the flexible control valve configuration by means of software that is appreciated by the customers. In the end it is the voice coil technology that enables significant gains in controllability/productivity beyond conventional pilot valves. For example, load pressure oscillations or the limitation of load pressure can be effectively controlled by voice coil driven control valves. **Figure 3** shows likewise the load pressure with / without active damping while lifting of a particular load. Actively dampening the load pressure oscillations contributes to stabilizing the work function acceleration, leads to decreased flow ramp-up time, to increased flow rate and operator comfort. Electronic load pressure limitation utilizes the full maximum load potential by precisely adjusting the port pressure by the control valve. All in all, these gains contribute to increasing the productivity of machines.

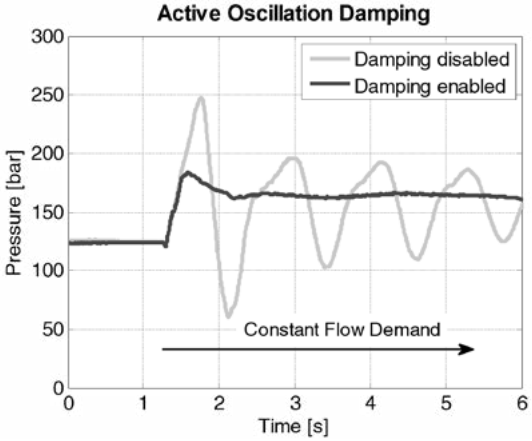

Figure 3. Effect of Active Oscillation Dampening. [2]

Voice coil driven valves also contribute to creating more energy efficient hydraulic systems. They provide the ability to switch the valve state very rapidly during energy regeneration or recuperation scenarios. These often require a fast redirection of the energy flow from one port to another, without interfering with the work function control.

5. BASIC IDEA OF THE VOICE COIL

So, what is this "voice coil" all about? Voice coil principle is based on the Lorentz force. It is the force experienced by a moving charge in a magnetic or electric field. This principle is widely commercialized by electric motors but also in speakers that convert an electrical signal into a corresponding sound. Hence, the name voice coil. The magnetic component of the force is greatest when the direction of motion of the charge is perpendicular to the magnetic field lines, and zero when the charge moves along a field line. It always acts perpendicular to the direction of motion of the charge and to the magnetic field lines.

When a wire of length L is exposed to a magnetic field and carries a steady electric current I, each of the moving charges in the wire experiences the force. For a straight, stationary wire in a uniform magnetic field, this force F is given by

$$F = I \cdot L \times B \qquad (1)$$

where B is the magnetic flux density. The force is proportional to the coil wire length, the flux density and the coil current. The force direction will change when reversing the coil current. **Figure 4** illustrates the principle.

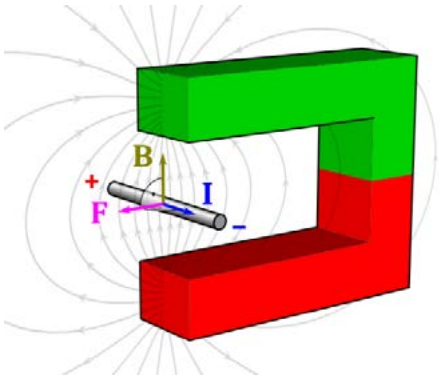

Figure 4. Lorentz force on a current-carrying wire exposed to a horseshoe magnetic field. [3]

This principle can be utilized by attaching a pilot valve to a moving coil and exposing the coil to the field of a permanent magnet. Due to the ability to reverse the coil force by reversing the current direction, the coil and pilot valve can move in both directions from a center position. A single 4/3 pilot valve can be designed to control a single main spool.

In contrast, traditional solenoids generate force in a single direction only, regardless of the current direction. Here, the solenoid force is generated by decreasing the magnetic circuit's reluctance (i.e. increasing inductance). Increasing the inductance happens when the solenoid's exerting force element, the armature, minimizes the air gap in the circuit. This movement happens independent of the coil's magnetic field polarity. Thus, these solenoid valves operate unidirectionally per given coil. However, in addition to the productive magnetic field created in the axial direction, a secondary (and unproductive) force is also created on the armature in the radial direction. This causes the armature to move laterally and stick to the solenoid body, introducing friction.

Classified as Business

Although the physics between armature and body is understood and minimized by surface coating means, this influence still generates significant friction and produces significant hysteresis in the solenoid valve behaviour. This inherent hysteresis decreases control valve resolution and reduces control valve dynamics. Both effects put proportional solenoid valves to a technologically inferior position against voice coil driven valves.

6. DESIGN STUDY

Despite the known performance advantage that voice-coil technology provides to hydraulic valves, one limitation has historically been a relatively higher cost. In this paper we reveal a design study, where we have built an experimental prototype with the goal to demonstrate the ability to design cost-effective PVG actuation utilizing the voice coil principle. See **Figure 5** and **Figure 6**.

Figure 5. Design study for voice coil driven PVG valve actuator.

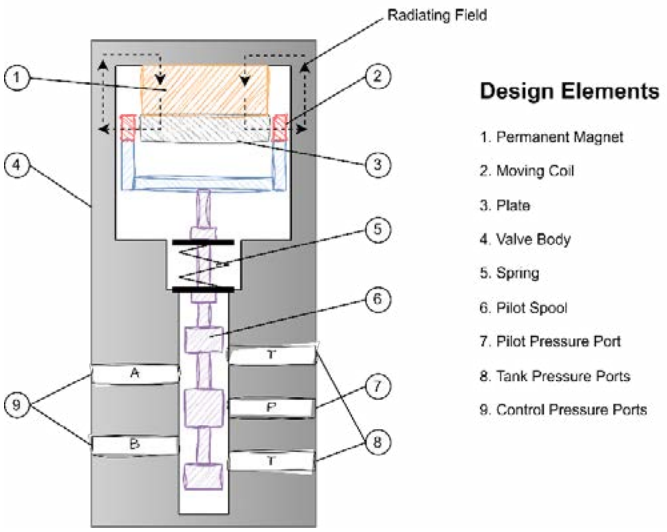

Figure 6. Sketch of the voice coil driven pilot valve. The moving coil is placed in the air gap where the magnetic flux density is highest.

Classified as Business

This proof-of concept consists of a permanent magnet (1), a moving coil (2), a valve body (4) and the pilot valve (5, 6, 7, 8, 9). The permanent magnet is assembled with a plate (3) to guide the magnetic field. The magnetic field radiates out of the plate, runs through the coil and enters the valve body. From there it travels through the valve body back to the permanent magnet.

The moving coil is connected to the pilot valve's spool. It is obvious that backlash is not allowed. The coil runs "wet", exploiting the oil bath to function as a heat sink. The coil wires are guided through a valve body opening (not displayed) to the ambience. There they are connected to the on-board electronics.

Further, the friction level of the moving parts must be low and predictable. The low clearance between spool and valve housing enables unambiguous defined bearing for the spool/moving coil assembly. The axial position of the spool/moving coil assembly is defined by a pre-loaded spring. To yield a high dynamic it is important to design the moving elements as light weighted as possible. The valve body offers hydraulic connection to pilot pressure, tank and two control pressure ports. Both control pressure ports are connected to either control chamber of the PVG main spool.

By applying a current to the coil, the spool moves out of the center position to connect pilot pressure with one of the control pressure ports. While the one control pressure port is connected to pilot pressure, the other one is connected to tank. And vice versa for reverted coil current.

As the pilot pressure travels into one of the PVG's main spool chamber, the main spool will move away from its neutral position. Once the main spool approaches its target position the logic reduces the coil current in order to reduce the pilot valve opening from pilot pressure to control port. Reducing the valve opening leads to adjusting the control chamber pressure so it will match the main spool spring force at particular main spool position. The pilot valve spool takes a position where all acting forces, such as coil force, spring force, friction, etc., are in equilibrium. Thus, holding a permanent PVG main spool position to meter a steady fluid flow to the work function requires the application of a permanent coil current.

When the coil is de-energized the pilot spool moves under the influence of the spring force to the center position at which the control pressure ports are connected to tank, and the PVG's main spool will return to its neutral position.

The law of the Lorentz force provides guidance in sizing the design elements to optimize the coil force to given space constraints. To identify the individual design element's sensitivity to the coil force, we have conducted numerous finite element simulations to calculate the coil force for a given design iteration. These simulations confirmed the underlying basic principles which have been discussed before.

The typical coil force characteristic is depicted in **Figure 7**. The force curve is fairly constant, where the force itself depends primarily on the coil current and much less on the coil position. In contrast, the armature force of proportional solenoids depends both on current and armature position. This is very important for the control understanding of any electro-hydraulic valve. Because the electric current induced force, whether voice coil or solenoid, is the control signal used to induce a dedicated reaction based on the control logic input. To achieve the desired closed loop control performance of the PVG valve the actuator

Classified as Business

force must be capable of precisely controlling the piloting power. Controlling the piloting power means the actuator force must find equilibrium with other force components in the pilot valve, like spring force, flow force and friction forces. For perfect controllability it is necessary that small current changes lead to small and immediate force changes, and that alternating current adjustments are not obscured by hysteresis effects.

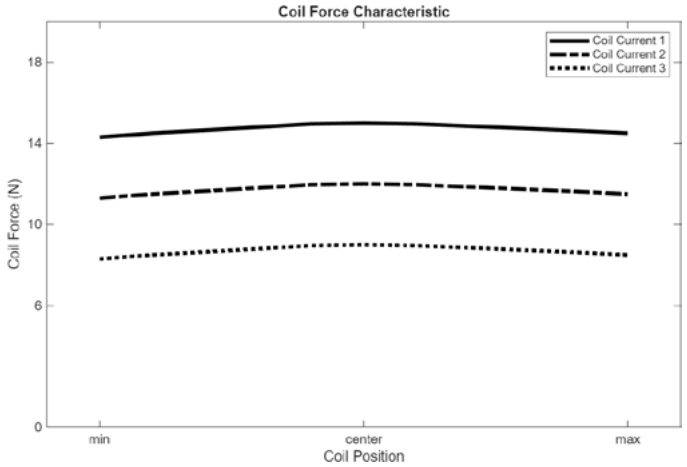

Figure 7. Simplified typical coil force characteristics for various coil currents.

Voice coils have a distinct advantage over solenoids because their force characteristics—being bi-directional, low-hysteresis, and proportional to the coil current—allow for quick and precise adjustments to find the next pilot valve position.

7. TEST RESULTS

The presented voice coil feasibility study was mocked together with a LVDT transducer to control a PVG32 valve. Functional tests carried out in the lab showed encouraging results. The voice coil valve was operated at Δ13 bar pilot pressure. The oil and valve components are heated at 50 °C to represent typical operational oil viscosity conditions. The focus for the lab test has been on tracing the spool position based on given commands.

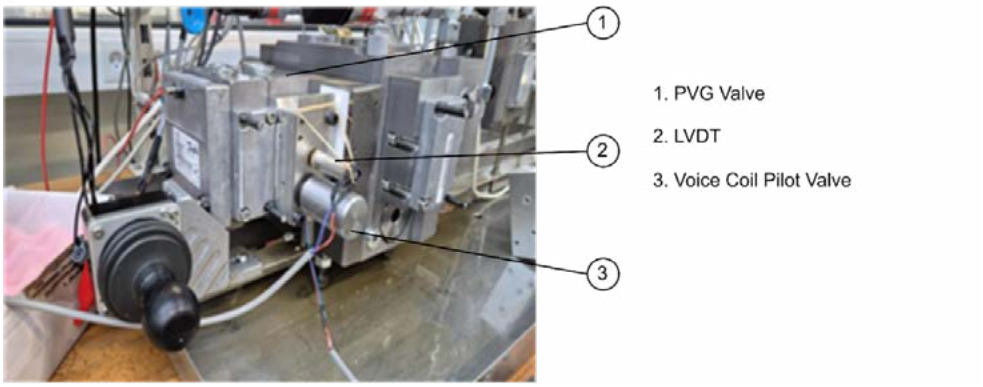

Figure 8. Proof-of-concept demonstration in the lab.

Classified as Business

Figure 9 shows the steady state characteristics of spool positioning. It plots the actual spool position over the demanded spool position, showing how much the spool position deviates from the command for almost steady command. The spool command undergoes a sweep from neutral to max stroke and back to neutral within 25 sec.

Figure 10 shows the step response characteristic. It plots the demanded and actual spool position as functions of time, showing how quickly and accurately the spool position gets adjusted to the dynamically changing command value. The response time is evaluated at 95% of the reached steady-state spool position.

Figure 11 shows the frequency response characteristic, describing how robustly the control valve reacts to alternating setpoint commands. The frequency response is characterized by two subplots: The magnitude plot, showing the amplitude attenuation, and the phase delay plot, showing the phase delay of the spool position in regard to its setpoint. A negative magnitude indicates the spool position oscillation is reduced, i.e. dampened, and the phase delay increases by increasing setpoint alternation frequencies. The set point alternation is configured as a sinusoidal signal with a bias of 50% nominal spool stroke and an amplitude of 25% nominal spool stroke.

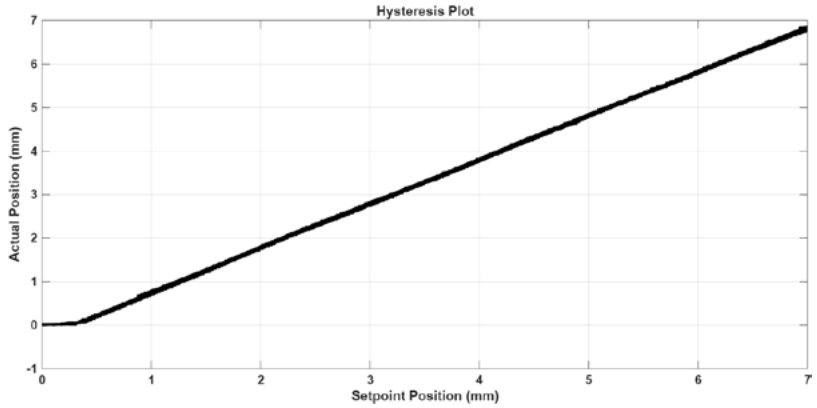

Figure 9. Steady state characteristic for the closed loop main spool position control.

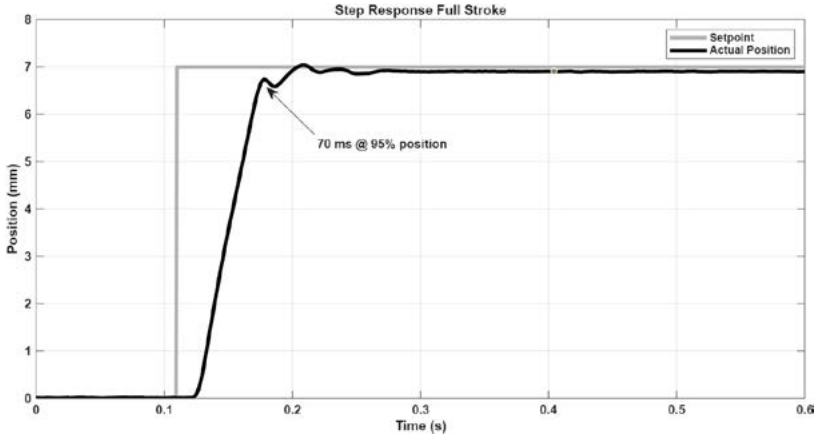

Figure 10. Step response characteristic for the closed loop main spool position control.

Classified as Business

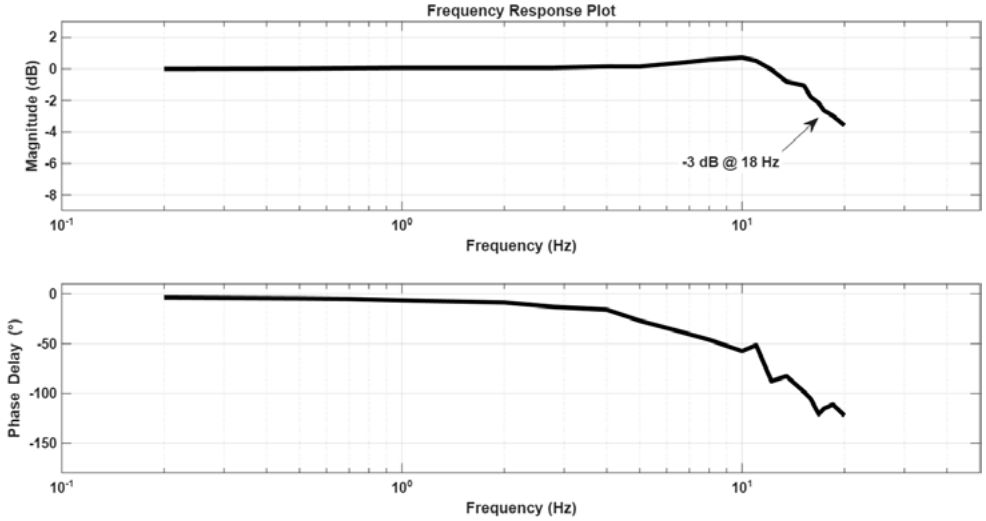

Figure 11. Frequency response characteristic for the closed loop main spool position control.

As can be seen in the figures, the PVG valve displays almost zero hysteresis and almost zero noise for the spool position control. The test results above reveal a deadband around neutral position which is attributed to the imperfect LVDT and control calibration. Besides this, the graph proves that the valve does very well in converting small and slowly changing incremental setpoint changes. The full-stroke step response of 70 ms, with little oscillation or overshoot, is noteworthy. This dynamic capability is underpinned by an impressive frequency response of approximately 18 Hz.

These test results of the feasibility study confirm the anticipated superior spool controllability of the voice coil technology. On a particular note, the frequency response data suggest that such a control valve is well-suited to be integrated into sensor- and software-controlled work functions.

8. SUMMARY

Danfoss is developing a new modular hardware and software platform for its PVG valve system to support future expansion and increasing variety in proportional control valves. The hardware and software platform emphasizes:

- **Scalability**: Easy addition/removal of components without full redesign.
- **Reusability**: Shared modules across projects to reduce cost and time.
- **Flexibility**: Simplified customization for diverse applications.
- **Standardization**: Consistent design and interfaces for easier integration.

Pilot valves are tailored to the work function's individual value proposition with free combinations of input and actuation technologies, supporting advanced control logic and customer-specific programming.

Classified as Business

Low-cost voice coil technology is one element of Danfoss' future valve actuation platform. It significantly improves machine productivity, energy efficiency, and control precision, positioning it as a superior alternative to conventional solenoid-driven valves. It offers:

- **High Dynamics & Precision**: Performance comparable to servo valves, enabling faster and more accurate response to sensor-driven commands.
- **Software-Based Flexibility**: Facilitates the transition from mechanical-hydraulic features to software-enabled controls, improving customization and productivity.

Danfoss conducted a design study with the goal of demonstrating a cost-effective PVG valve actuator using voice coil technology**.** Functional tests carried out in the lab showed encouraging results. These confirm excellent controllability and dynamic performance of voice coil technology.

Abstract

Electromagnets are one of the key components in modern hydraulic systems, enabling precise and efficient control of hydraulic valves. The use of electromagnets in hydraulic valves offers several advantages, including fast response times, high forces with low power consumption and reliable linear motion. A disadvantage is that they only move in one direction, hence two electromagnets are required for full fluid control of 4/3 valves, which means two coils and, among other things, double control wiring. This disadvantage can be overcome by using a push-pull electromagnet, which can move in either direction depending on the polarity of the supply voltage.
This paper presents a study of push-pull electromagnets and the usage in various hydraulic valves to replace the standard two-coil solution.

The push-pull electromagnet consists of a setup with permanent magnets together with discs made of magnetically soft material. The armature is housed in plastic sleeves that allow it to move smoothly.

Keywords: Push-pull electromagnet, Hydraulic valve, Electromagnetic actuator, Bidirectional motion, Coil reduction, Mobile and industry hydraulics

1. INTRODUCTION

In the field of modern hydraulics, key requirements are not only reliability and precise control but also energy efficiency and component compactness. Traditional designs of electromagnetic actuators for 3-position hydraulic valves often employ two separate coils, one for each directional function. While this solution is tried and tested, it brings certain disadvantages, larger structural volume and more complex wiring.
An alternative to this classical approach is the use of a so-called push-pull electromagnet, which enables control of both directions of armature movement using a single coil with polarity reversal. This concept offers potential for design simplification, reduction of energy demands and optimization of system response. The paper will describe the functional principle of the push-pull electromagnet, its advantages compared to the traditional solution and practical aspects of its implementation in hydraulic applications.

All Open Access articles are peer-reviewed, distributed under the Creative Commons Attribution-Non Commercial 4.0 International

2. PRINCIPLE OF THE PUSH-PULL ELECTROMAGNET

The push-pull electromagnet utilizes a reversible magnetic field to achieve movement of the armature in both directions. By changing the polarity of the supply voltage, both the “push” and “pull” effects can be realized. This makes it possible to replace two coils with a single one, reducing the number of components and simplifying the valve design.

The armature of the electromagnet consists of strong permanent magnets combined with discs made of magnetically soft material. The armature is mounted on plastic sleeves that allow smooth movement.

Although the push-pull principle is well known, it is rarely used in the field of oil hydraulics. Most electrohydraulic valves still rely on conventional single-direction electromagnets or a pair of coils for bidirectional movement. In contrast, the push-pull configuration is commonly applied in other areas, such as pneumatics, precision mechanics, automation, and drives for non-oil hydraulic systems (e.g., water hydraulics). These applications take advantage of the ability to generate bidirectional motion with a single coil to simplify design, reduce weight, and increase dynamics. As a result, the push-pull principle has proven effective where fast response or compact design are essential.

3. DESIGN SOLUTION AND PATENTED INNOVATION

One of the primary technical challenges in using a push-pull electromagnet for hydraulic applications is hysteresis – caused by the difference in magnetic behaviour during current switching on and off – which can adversely impact the accuracy and repeatability of the valve control. During the development of a new type of actuator, an innovative solution was proposed and patented, enabling active influence on hysteresis through a refined armature design.

The armature of the push-pull electromagnet consists of a series of magnetic and permanent elements arranged in a specific configuration: magnetic disc – permanent magnet – disc – magnet – disc. A key feature of this design is the variability of the diameters of the magnetic discs at the front and rear ends of the armature (Figure 3.1). By adjusting these diameters, the magnetic field distribution can be purposely influenced, thereby controlling the magnitude of hysteresis within the system.

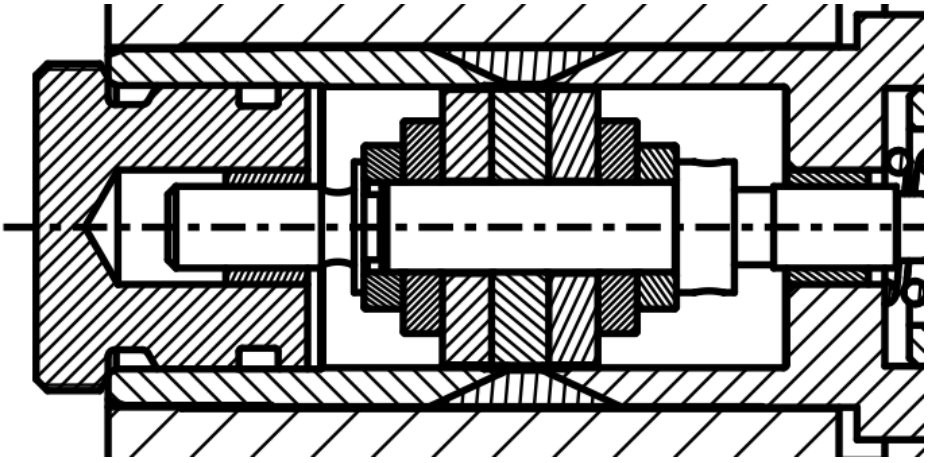

Figure 3.1. – Asymmetric armature design

Figures 3.2 (uncompensated hysteresis) and 3.3 (compensated hysteresis) illustrate an exemplary effect of hysteresis compensation. As seen in the uncompensated case, the valve opens abruptly without any sign of proportionality and remains fully open until the polarity of excitation changes; then it jumps to the opposite side and, with a slight indication of proportionality, stays open until the excitation ends, after which it closes. With hysteresis compensation, these abrupt changes in opening are eliminated, and the valve behaves proportionally throughout the entire operating range and for all pressure levels.

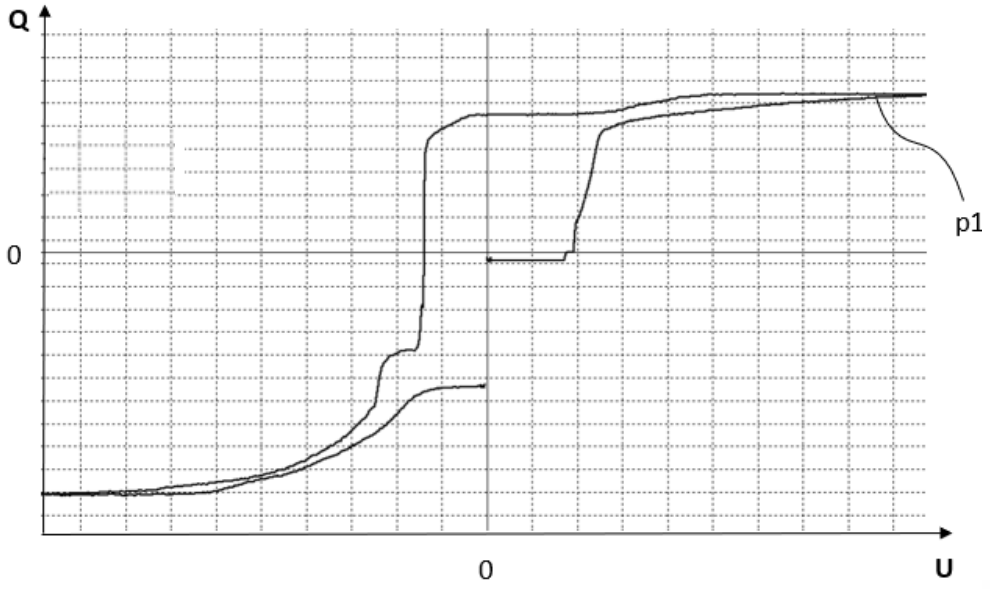

Figure 3.2. – Hysteresis of an indirectly controlled valve without hysteresis compensation (pressure p1)

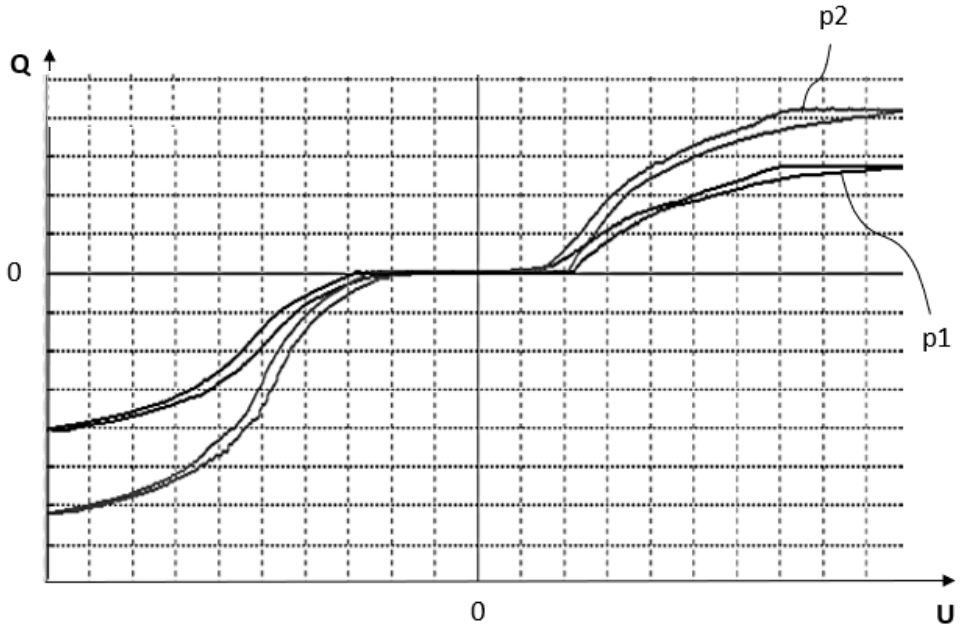

Figure 3.3. – Hysteresis of an indirectly controlled valve with hysteresis compensation (at pressures p1 and p2)

3.1. Advantages Compared to Two-Coil Systems

Overall dimensions of the valve are reduced, allowing it to be used in applications where the two-coil version cannot be installed due to space limitations.

The usage in CETOP valves opens up other possibilities for this type of valve, such as the possibility of mounting a position sensor on the spool and using its sensor output, either as a feedback function or as a safety function.

There are numerous additional to this technology:

- **Reduced material consumption** – Eliminating the second coil means less copper, plastic, and insulating materials. Copper mining and plastic production are energy-intensive processes with high CO_2 emissions, so using fewer of these materials directly improves the ecological footprint of manufacturing and supports circular economy principles.

- **Lower energy demands** – Push-pull systems operate with a single coil and optimized magnetic flux control, which reduces current load and idle-state losses.

- **Smaller carbon footprint** – Lower material and energy consumption during both production and operation significantly reduce emissions throughout the entire life cycle. Optimized hydraulic systems can achieve emission reductions over their lifetime, especially when combined with intelligent electronics and regenerative control strategies.

- **Longer component life and less waste** – Fewer parts mean fewer potential failures, reducing maintenance frequency and the need for spare parts. This not only saves costs but also reduces industrial waste, contributing to sustainability goals.

- **Economic competitiveness** – In addition to environmental benefits, simplified design reduces assembly time, wiring complexity, and storage costs. Combined with lower energy bills, this represents a significant advantage in total cost of ownership for OEMs and end users.

3.2. Challenges of Integration into Control Systems

One of the main obstacles preventing wider adoption of push-pull electromagnets is the need to adapt control systems for bipolar control. Although most modern control systems already support polarity reversal or can easily implement it through a simple firmware update, the use of push-pull electromagnets in the hydraulic sector is not common.

The key factor, therefore, is awareness and cooperation with system integrators [1].

4. CASE STUDIES AND APPLICATIONS

Push-pull electromagnets can be applied both in stationary equipment and in mobile hydraulics, for example in agricultural machinery, construction equipment, or mining systems. Thanks to their compact dimensions and high reliability, they are ideal for environments with high vibrations and limited space. In some applications, they have also proven effective in systems requiring fast response and low energy consumption. The proportional valves were controlled by the EL7-IA3 electronics [2], which is specifically designed for use with valves equipped with push-pull electromagnets.

4.1. Tested Applications

4.1.1. Electromagnetic Direct Operated Screw-In Valve (SD2E-A4/H3)

Successful implementation of a bidirectional push-pull electromagnet has been achieved on the originally two-coil, electromagnetically operated screw-in valve SD2E-A4/H3 (Figure 4.2.). The valve is designed for installation in a standard A4 cavity, 3/4-16 UNF thread. An example of the valve used in an application where it controls the direction of fluid flow and thus the direction of actuator movement - or stops it - can be seen in Figure 4.1..

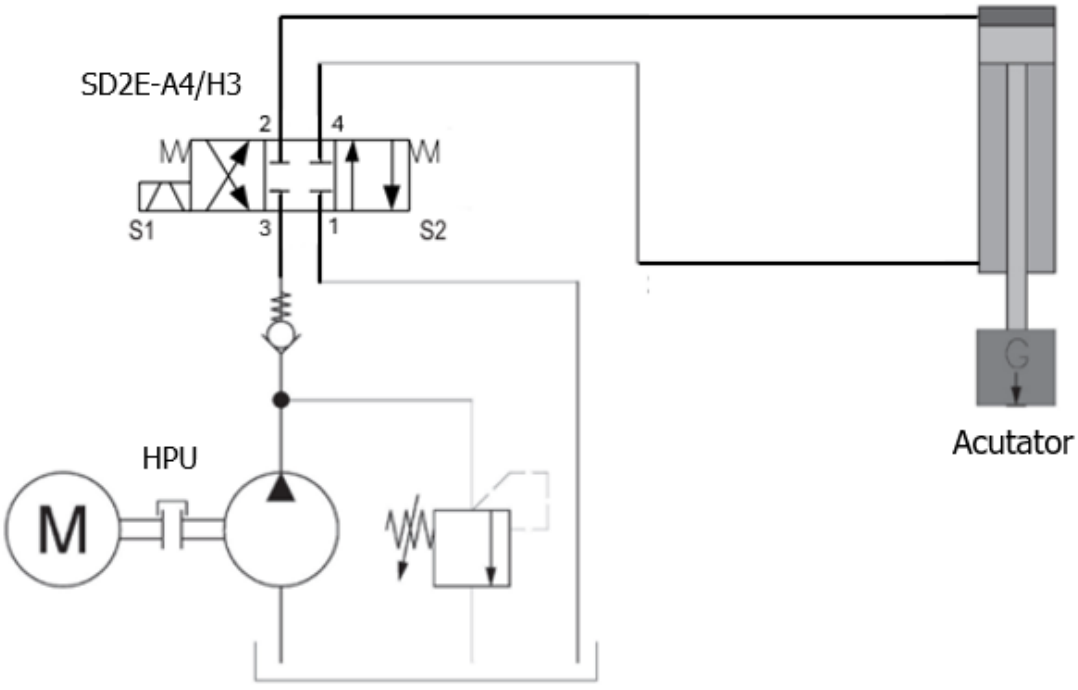

Figure 4.1. Example of using the SD2E-A4/H3 valve in a hydraulic circuit

Comparison of the original design and the new solution with a push-pull electromagnet, Figures 4.2 [2] and 4.3. The hydraulic part of the valve, including the spring and shims, is identical for both types; the push-pull version has a special chamber in the control system for integrating components from the standard two-coil version.

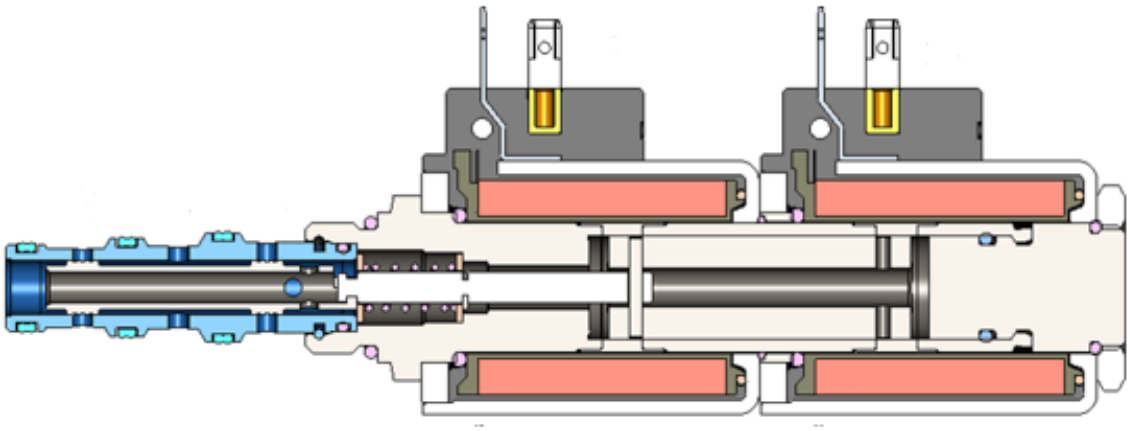

Figure 4.2. – SD2E-A4/H3

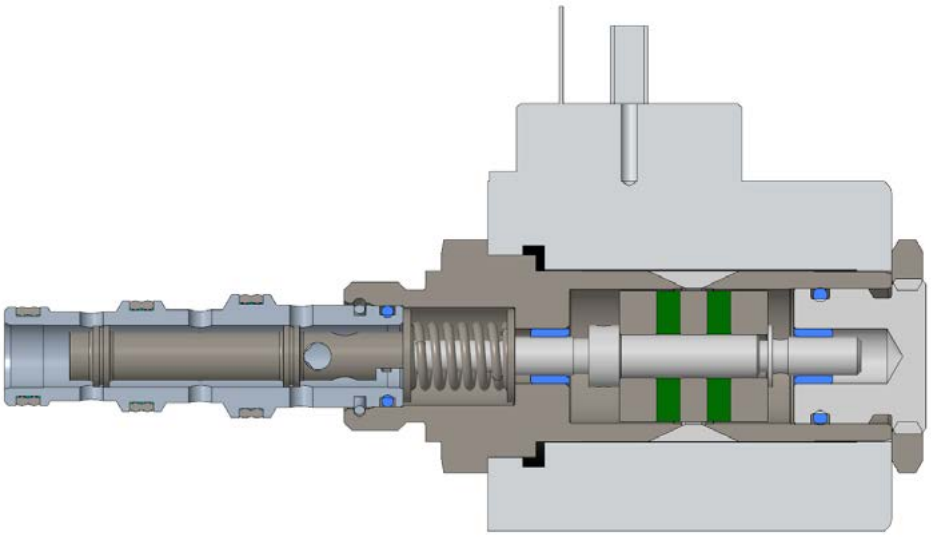

Figure 4.3. – SD2E-A4/H3 with push-pull electromagnet

The valve was tested with different spool types (thus with the effect of different flow forces). A full-fledged replacement – that means same power limits – for the standard version with two coils could successfully be proven.

4.1.2. Electromagnetic Direct Operated Proportional Valve (PRM2-063Z11/15)

A directly controlled proportional CETOP valve (Figure 4.4), combined with a push-pull electromagnet, exhibited significant hysteresis (Figure 4.5), which would need to be reduced, for example, by using electronics and internal feedback from the spool position.

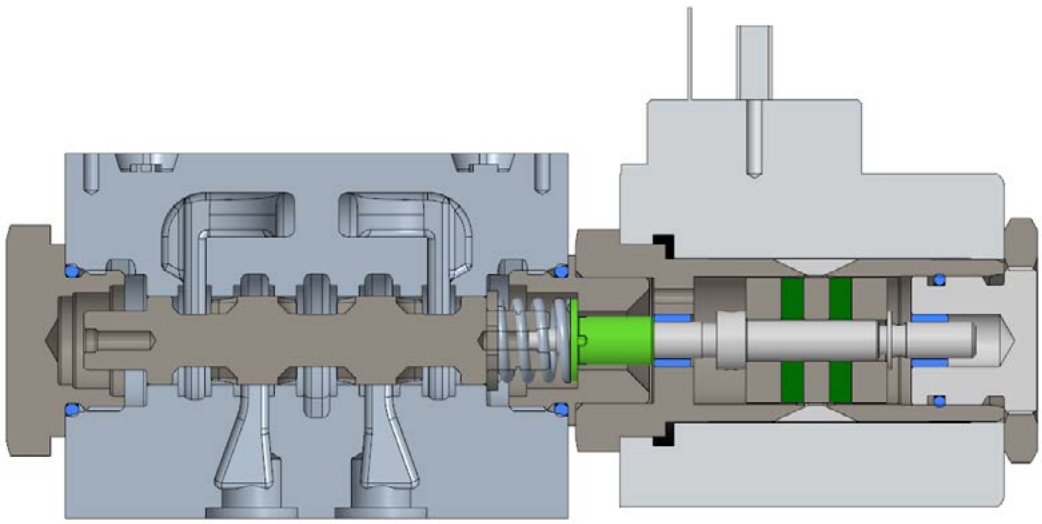

Figure 4.4. – PRM2-063Z11/15 with push-pull electromagnet

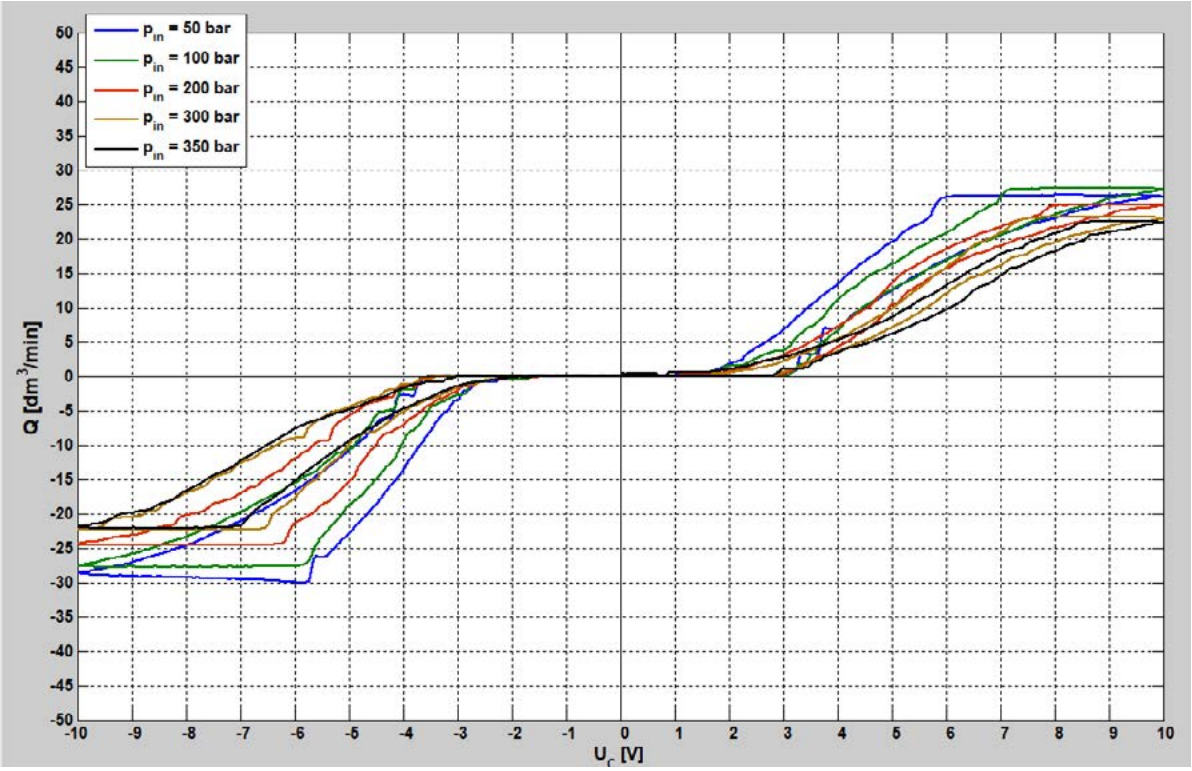

Figure 4.5. Flow curves of the PRM2-06 valve with a push-pull electromagnet

4.1.3. Electromagnetic Pilot Operated Proportional Valve (PRM8-063Z11/15)

Valves that are particularly suitable for the use of push-pull electromagnets are pilot operated valves (Figure 4.6.), because the principle of the pilot and follow-up spool [3] compensates for the lower force of the push-pull electromagnet compared to the two-coil design. Thanks to the indirectly controlled spool, equivalent performance to the two-coil variant can be achieved, even with the lower available force of the electromagnet. At the same time, this type of valve allows hysteresis reduction using an armature with discs of different diameters (Chapter 3). Hysteresis and performance of the valve modified in this way are then identical to the two-coil version (Figure 4.7.).

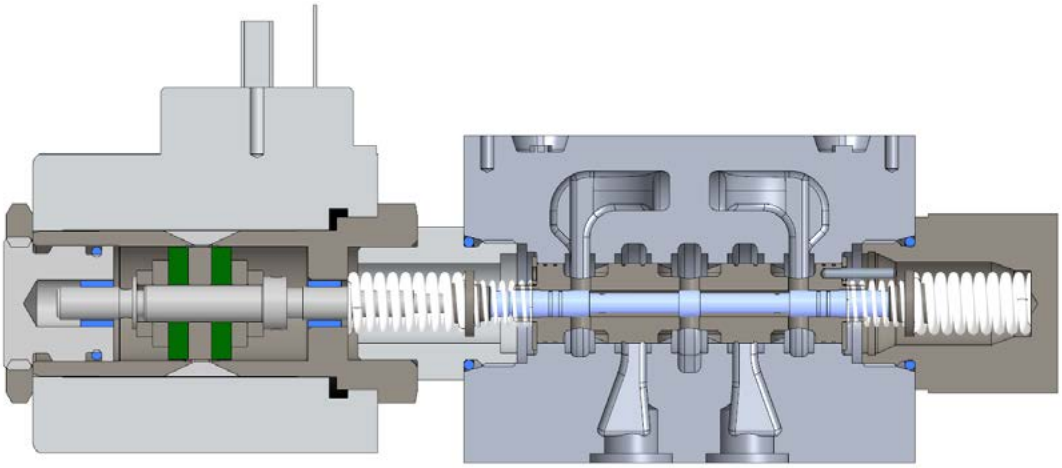

Figure 4.6. – PRM8-063Z11/15 with push-pull electromagnet

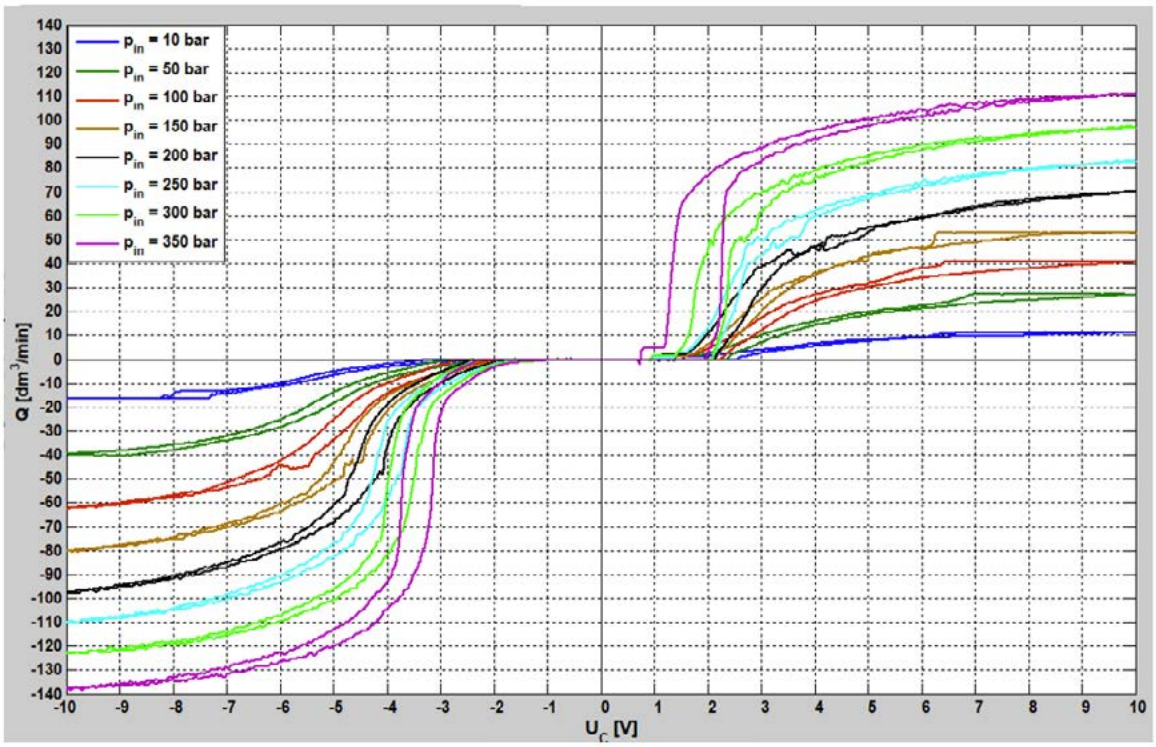

Figure 4.7. Flow curves of the PRM8-06 valve with a push-pull electromagnet

5. CONCLUSION

Push-pull electromagnets represent an interesting, modern, efficient, and environmentally friendly solution for controlling hydraulic valves. Thanks to successful tests, case studies and the patented design solution, their full-scale deployment in industrial practice can be confirmed. The remaining challenge is awareness and cooperation with integrators, but the potential of this technology is significant. Their ability to provide fast response, high performance, and reliable linear motion is essential for automation and safety applications. Their broader adoption depends on overcoming communication barriers between component manufacturers and system integrators.

Abstract.

This article presents a recuperation concept for an industrial gearbox test bench. The concept of hydraulic testbench was realized in the past already, the fully automated system is a new technology. Here the concept is presented witch combines to the hydraulic circuitry and the control technology implementation.

Keywords. Recuperation, Gear Box, Multiple variable control, efficiency optimization, Open Source control software

1. INTRODUCTION

The test bench presented here is a combination of classic industrial hydraulics and modern control technology. The test bench has been developed as a research and development test bench. It offers a very high degree of flexibility both in the design of test sequences and in the selection of test specimens for industrial and mobile gearboxes as well as drivetrains or hydraulic motors. The basic concept can be seen in Figure 1.

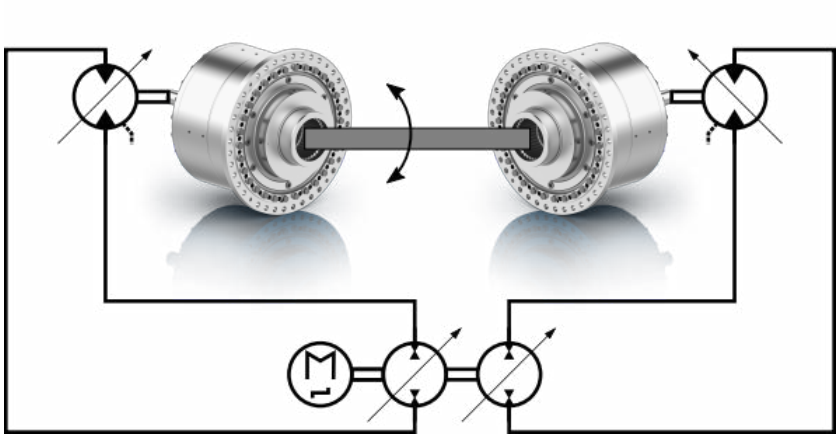

Figure 1: Figure 1: Concept of the Test Bench

An asynchronous motor operated by a frequency converter drives two identical A4V pumps that are installed in tandem. Type A6V hydraulic motors are installed on the test gearboxes. The two test gearboxes are braced against each other, with one gearbox operating as a speed-controlled drive and the second gearbox as a torque-controlled brake.

The test bench allows tests to be carried out on a variety of different purposes. Its main tasks are:

- Investigation of thermal behavior
- Identifying mechanical efficiency
- Investigation of wear and fatigue behavior
- Measuring vibrations and noise
- Testing new materials, manufacturing processes, and lubricants
- Testing gearboxes, hydrailic motors or complete drive trains

2. TEST BENCH DESIGN

When designing the test bench, the focus was on energy efficiency and flexibility in addition to suitability for the planned test specimens. For this reason, automation does not rely on ready-made solutions from component manufacturers, but rather on an open source solution. The EtherLab [1] project offers numerous functions that are used here.

The selection of hydraulic components is based on the performance data of the gearboxes. Typical input speeds of 1500 to 2500 RPM are required, which are then also applied to the output of the test setup due to the back-to-back arrangement. The torques can exceed 3000Nm and the transmitted power can range up to 600kW. With a gearbox efficiency of around 97,5% each, this results in a maximum waste heat output of about 60 kW.

These key data were used for the design of the pumps, motors, and gearbox cooling system [2]. Figure 2 shows the entire test bench; the soundproof enclosure and the hydraulic container are not shown.

Since this is a research and development test bench, the hydraulic connection options are designed to be very flexible. Figures 3 to 5 show three examples of frequently used arrangements. For large test specimens, the two built-in main pumps can be operated in parallel, see figure 3. However, two load tests can also be run simultaneously on smaller gearboxes, figure 4. Free-running tests with no load can be performed on up to four test specimens simultaneously, figure 5. Mixed operation between the operating modes is also possible.

All auxiliary functions, such as control oil pressure supply, filtration, temperature control, housing flushing, and feed and flushing functions, are implemented via separate systems. These systems are working independently of the main pumps.

The feeding of the closed hydraulic circuits is temperature-controlled in order to minimize the demand for feed oil. For this purpose, oil is taken from the low-pressure section [3] via a proportional throttle, and the pressure-controlled feed oil supply pushes fresh oil through accordingly.

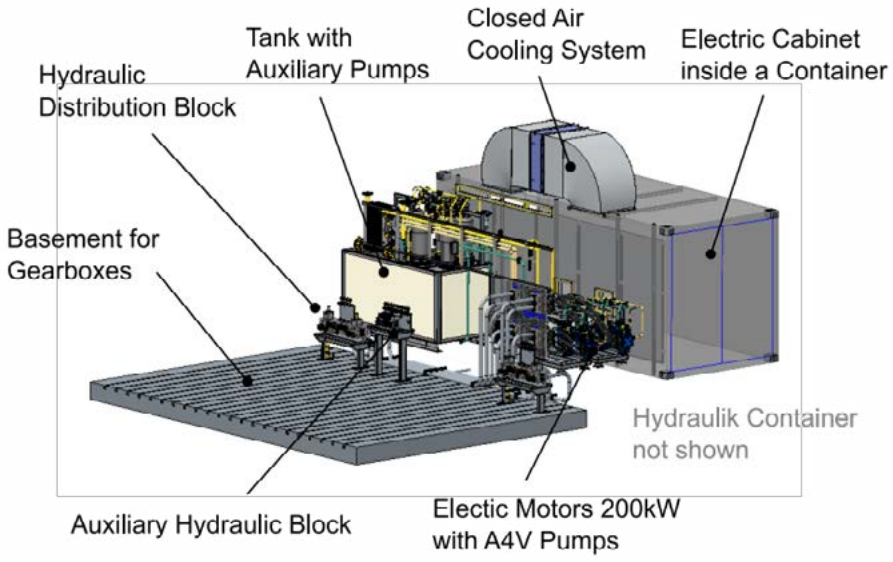

Figure 2: Test Bench Overview without Specimen

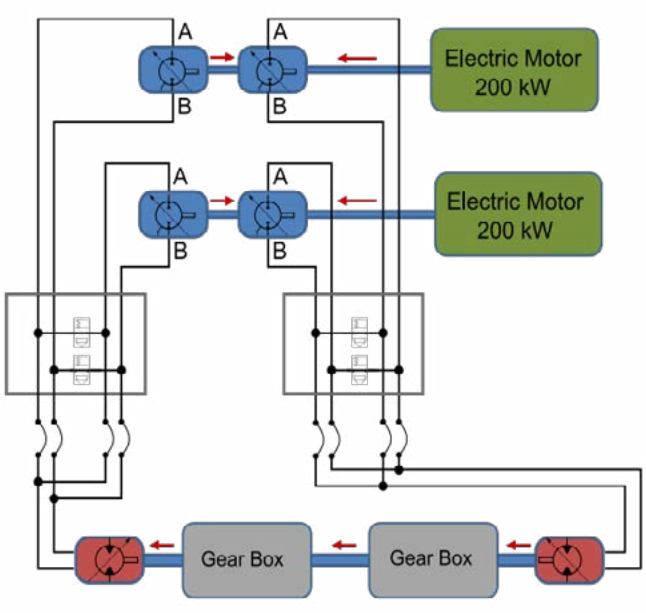

Figure 3: Parallel Pumps operating for big Specimen

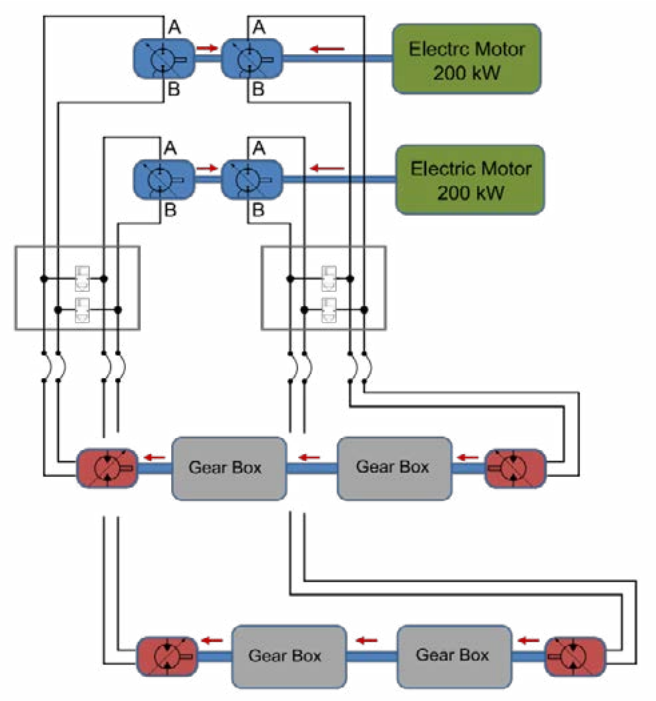

Figure 4: Configuration for two Tests at the same Time

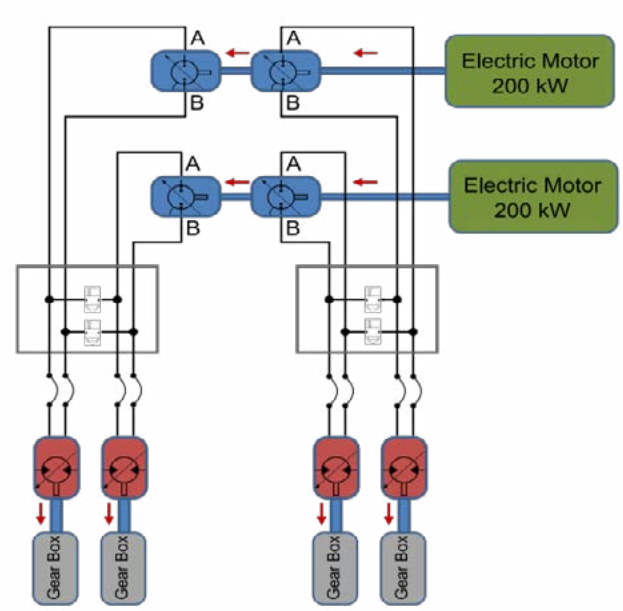

Figure 5: Multiple Specimen in free running Mode

3. EFFICIENCY OF A TEST BENCH

What is the efficiency of a test bench in which all of the energy used is ultimately dissipated as heat? For the test bench implemented here, the definition shown in the image was chosen in order to implement an optimization strategy.

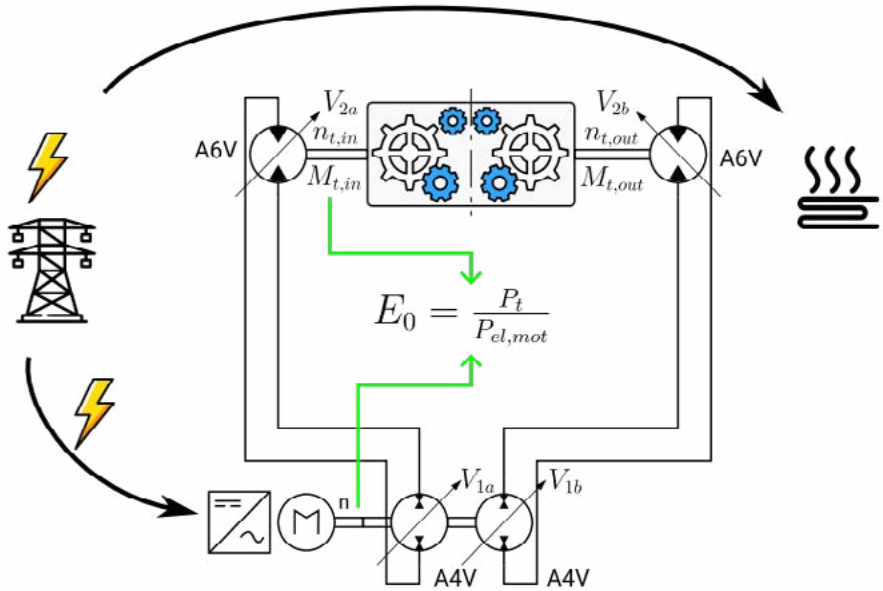

Figure 6: Definition of Efficiency at the Test Bench

Efficiency is defined as the ratio between benefit and effort and is defined here as the ratio between the mechanical input power in the test specimen and the active power used in the electric pump drive.

$$E_0 = \frac{\eta_{A4Va}\eta_{A6Va}}{1-\eta_{geara}\eta_{gearb}\eta_{A6Vb}\eta_{A4Vb}\eta_{A4Va}\eta_{A6Va}} \quad (1)$$

Since many hydraulic adjustment units operate in series in this test bench, each individual efficiency level has a very strong influence on the overall efficiency. The overall efficiency can be determined using the equation 1 and is in the order of magnitude of 1,5. This means that the power flow through the gearboxes can be about one and a half times greater than the electrical power input. If the components are not operated at their optimum operating point, the overall efficiency drops significantly. A deterioration of around 2% in a single component reduces the overall efficiency by around 10%.

4. CONTROL SYSTEM

The entire automation of the test bench, including all auxiliary systems, is implemented using the open source tool kit EtherLab®. EtherCAT® is used as the fieldbus system, which easily allows sampling rates better than 1 kHz, even for large systems. As shown in the figure, the control system for the main functions is cascaded.

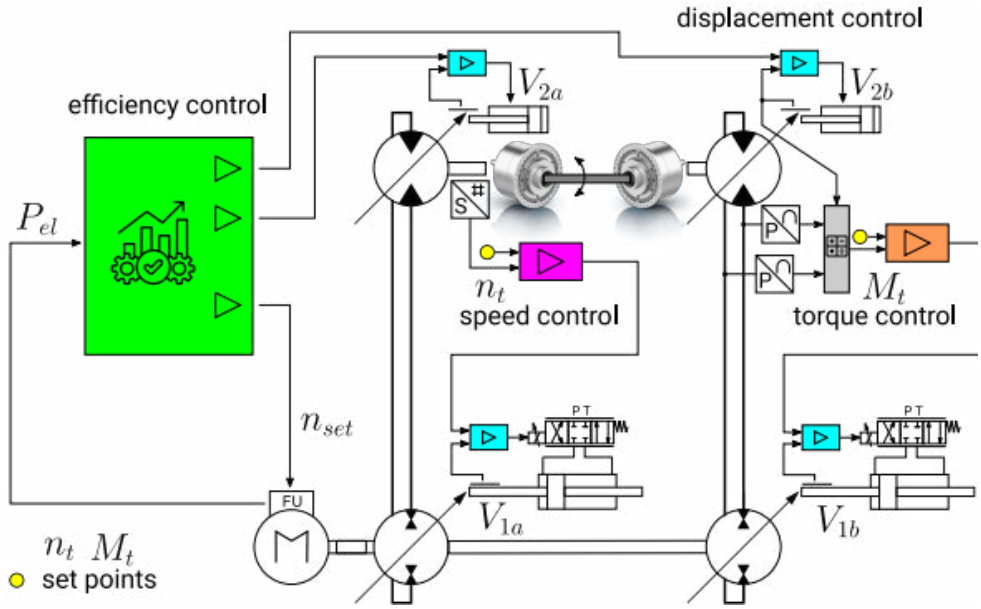

Figure 7: Structure of the Control System

All units with variable displacement have a subordinate swivel angle control loop [5]. The setpoints for this control loops are generated in the higher-level control loops for the input speed n_t and for the torque M_t.

The efficiency of displacement units is highly dependent on their operating points. The operating points are largely determined by the pressure, speed, and swivel angle. The general relationship [3] is shown in the figure 8. Looking at the basic efficiency curves helps to set a good starting configuration. On the drive side, the desired test speed at the gearbox input determines the ratio of the displacement volumes at a given drive speed of the electric motor.

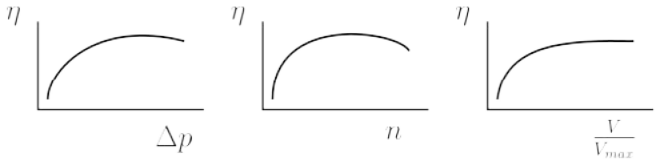

Figure 8: Efficiency and Operating Point

A mathematical description of these relationships, which are mostly determined experimentally, is only possible to a limited extent and is not useful due to the large number of different configurations. Instead, an evolutionary method is used here for the efficiency controller in order to achieve the most efficient overall operation.

Since the test runs last several hundred hours, there is enough time for optimization to implement a robust, i.e., slow algorithm. This algorithm uses small increments when changing the available control variables V2a, V2b, and n. Taking the operating limits into account, the speed of the drive is changed as long as the efficiency increases. The displacement volumes of motors V2a and V2b are then manipulated. The algorithm for increasing efficiency is activated by the operator during a test run and then runs automatically. The algorithm stops when no further improvement can be achieved by changing the control variables.

5. CONCLUSION

The test bench presented here combines the capabilities of classic hydrostatic drives with modern automation technology. The control concept with higher-level efficiency optimization and detailed improvements in the area of auxiliary functions has resulted in a system that is unique in this form.

It offers a high degree of flexibility in test design as well as a high degree of robustness through the use of high-quality components.

This investment in the Witten development site will help to secure expertise in industrial gear manufacturing in the long term and develop new technologies.

Siegfried Rotthäuser

was born in Essen in early 1961 under the sign of Aquarius. After attending school and completing his military service, he studied general mechanical engineering at RWTH Aachen University from 1981 onwards and then worked as a research assistant at the IHP under Prof. Wolfgang Backe. After obtaining his doctorate, he founded the engineering firm IgH in 1993 together with Dr. Torsten Finke († 2025), where he continues to serve as managing director and board member within AXXERON Technologies.

Nico van de Sandt

born in Bocholt on December 8, 1971, studied mechanical engineering at RWTH Aachen University between 1993 and 1998 and then worked as a research assistant at the Institute for Machine Elements and Machine Design. He received his doctorate in 2004, specializing in rolling bearings and lubrication. From 2003, he held senior development positions in the gearbox industry. Since December 2015, he is head of R&D for gearboxes for mobile and industrial applications at ZF Industrieantriebe Witten GmbH.

Next Generation Fixed Displacement Pumps for Electrified Mobile Applications

Patrick Fischer[1], Adrien Gambet [1], Shanmukh Sarode[2], Howard Zhang[2]

Abstract.

Electrification of mobile machinery imposes new demands on hydraulic components, notably higher operating speeds, greater power density, and stricter noise requirements. This paper presents developments in the next generation of Parker fixed displacement pumps – gear, bent axis, and vane – designed specifically for electrified applications. We introduce a pragmatic low complexity gear pump approach retaining straight teeth while leveraging advanced manufacturing methods for higher shaft speeds at acceptable costs. For bent axis pumps, we demonstrate an integrated ripple chamber that reduces flow ripple yielding multi-decibel reductions in system noise while valve plate and suction channel refinements enable significant higher self-priming speeds, up to 17% depending on the displacement. The next generation vane pump incorporates tribological coatings for higher pressures and exceptional self-priming speed capabilities. Virtual and physical validation qualify the proposed concepts. Finally, the paper outlines a novel approach to integrate these pumps into ePump architectures while keeping modularity.

Keywords. Hydraulic pumps, electrification, fluid power electrification, fixed displacement pumps, noise, efficiency, integration, semi-integration, ePumps.

1. Introduction

Electrification is reshaping mobile fluid-power systems by removing the masking effect of Internal Combustion Engines (ICE) on one hand and by driving demand for higher power density due to batteries reducing available space and target weight for the hydraulics. As a result, hydraulic pumps – the primary flow sources in these systems – must deliver higher shaft speeds while meeting increasingly stringent Noise, Vibration, Harshness (NVH) requirements, higher efficiency while becoming smaller and lighter. Traditional pump designs, optimized for ICE-driven platforms, are therefore being re-evaluated for the new constraints imposed by electrified architectures. Although variable piston pumps dominate the hydraulic pump markets, fixed displacement units remain foundational in many mobile

All Open Access articles are peer-reviewed, distributed under the Creative Commons Attribution-Non Commercial 4.0 International

applications. However, the shift to electric prime movers alters the trade space for pump selection and optimization. Recent literature reports a broad spectrum of hydraulic pump concepts under investigation for designing electrified flow sources (ePumps), including vane, internal and external gear, bent axis piston, axial piston and radial piston designs to address the abovementioned requirements. Concurrently, to achieve the required power density of electrified mobile applications, system level integration considerations become more important as well, e.g. Integrated ePumps (IEPs).

This paper focuses on next generation fixed displacement pumps tailored for electrified mobile machinery, more specifically for open circuit work functions. Section 2 reviews the state of the art, summarizing the electrification-driven requirements and surveying relevant pump technologies. Different ePump integration levels are explained. Section 3 presents design concepts and validation results for the proposed next generation gear, bent axis, and vane pumps. Section 4 outlines a novel approach of integration for ePumps by combining modularity of non-integrated and the advantages of highly integrated ePumps. Section 5 summarizes the present contribution to provide an outlook on further research needs.

2. State of the Art

2.1. Mobile application perspective: Electrification leaves less space for hydraulics

Fischer et al. [1] provide an extensive overview on the state of the art, challenges and chances of electrification for hydraulic pumps and their operating limits. They summarize key literature dealing with different layouts of electrified mobile applications (centralized vs. de-centralized hydraulics as dealt in Casoli et al. [2]) and their maturity in terms of whether it is a phase/generation 1 electrification (pure conversion of existing ICE application as explained by Myers [3]) or a fully de-centralized layout in phase/generation 3 systems with one dedicated Electrohydraulic Pump (EHP) or ePump per function (as outlined by Nagel & Zhang [4]). Overall, it appears that the more electrified and de-centralized the hydraulics in the application are, the lesser space is available for the hydraulics due to increased electrical content.

2.2. System perspective: EHPs with higher power density

Both variable and fixed pump technologies have their use-cases in today's applications. This applies also to tomorrow's electrified mobile applications as well. While the Electric Motor (EM) has the flexibility of variable speeds, a Hydraulic Machine (HM) – this more generic term will be used in the following to consider multi-quadrant operation and not only pumping operation – using fixed displacement would require many and high accelerations and decelerations for the pump to implement an electric Load-Sensing (eLS) functionality. Using variable displacement technology adds mechanical complexity, though it provides an additional degree of freedom, as the flow can not only be adjusted by varying the EM's speed, but also through adjusting the displacement within the pump, e.g. through Electronic Displacement Control (EDC). Those fewer accelerations and deceleration of the pump's, its drivetrain and the EM's inertia enable efficiency optimized operating strategies as outlined by Myers [3]. Since the focus of this paper is fixed displacement technology, variable displacement pumps will not be further detailed. Ultimately, the choice for the technology depends on many factors to be weighted, the work function and the desired duty cycle to be performed.

In both cases however and as described by Fischer et al. [1] electrification demands more integration to compensate for decreasing available space in the mobile applications as well as tougher requirements to the target weight of hydraulics, as batteries occupy the bulk of the vehicle's size and increase vehicle weight accordingly. One first step for moderate integration is the direct coupling of EM to the HM as proposed by Cailteux [5] and Pelz et al. [6]. Having this direct connection instead of a coupling allowing compensation of misalignments and/or damping oscillations in circumferential direction requires however specific lubrication solutions for the splines to avoid fretting corrosion and ensure appropriate durability over lifetime. [1]

In the context of Parker's SMART Electrification portfolio (refer to [7]), pumps directly connected to Parker electric motors are referred to as Configured ePumps. Despite having the advantage of direct coupling with appropriate spline lubrication, Configured ePumps are highly modular, as they feature a broad spectrum of different pump technologies, displacements and power ranges as well as motor types, featuring not only Parker's GVM but also its NX motor both as low (LV) and high voltage (HV) versions. They can further be combined with Parker's Global Vehicle Inverter (GVI, refer to Parker Hannifin [8]), depending on the voltage level. Another direction is a more consequent type of integration, which can be seen on Figure 2.1, called Integrated ePump (IEP).

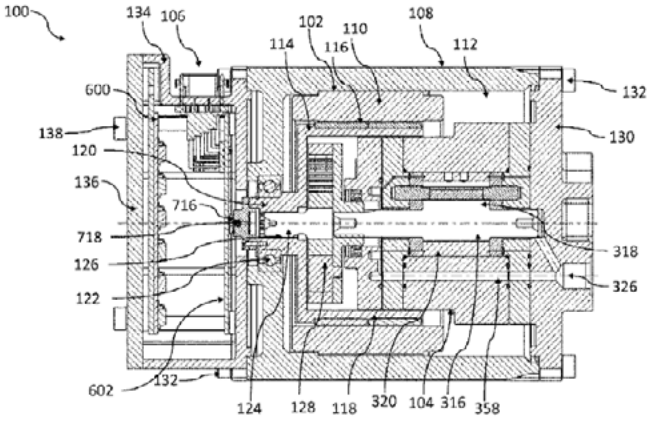

Figure 2.1: Integrated ePump (IEP) with Planetary Gearset (PGS) acc. to Zhang et al. [9]

There are multiple approaches on how to integrate HM with the EM, as a recent publication by Heeger, West & Ericson [10] outlines. The authors describe systematically whether HM and EM are axially or radially stacked and then whether the HM is direct-driven or gearbox-coupled. Combinations are also presented, e.g. radially integrated gearbox and HM. In related work, Lindh et al. [11] demonstrated a gearbox-coupled configuration connecting a bent axis pump with a permanent-magnet motor and examined the feasibility and performance of hydraulic-oil based cooling strategies for the motor. Ponomarev et. al [12] integrated a permanent magnet synchronous machine with a bent axis piston pump. The thesis also explores use of hydraulic fluid to cool the electric motor. Pietryzk et al. [13] investigated the potential of implementing high speeds at the EM with a Planetary Gearset (PGS) between EM and HM for a high-power density Electrohydraulic Actuator (EHA). Gadiyar et. al [14] designed a single casing integrated axial flux electric motor with a radial

piston pump unit, allowing a reduction in the overall package volume and removing shafts, bearings, and bearing seals. Along the same lines, Sarode [15] have designed and experimentally validated an integrated fixed displacement axial piston machine with a permanent magnet electric motor. These single-casing motor–pump integrations enable highly compact packaging well suited to electrified mobile machinery. In the concept of Figure 2.1, the HM and the gearbox no. 128 are radially integrated into the EM's rotor no. 114. With that, a concept like the gearbox type of integrated ePumps from Heeger, West & Ericson [10] arises and has in addition a motor controller no. 106, which is also integrated axially with joint cooling system. This approach of combining hydraulic pump, electric motor, gearbox, and inverter represents one of the most highly integrated ePump architectures considered in this work, delivering a compact package and an in-situ thermal management solution.

2.3. Component perspective: Higher speed and low noise pumps

While the previously mentioned integration reduces size of the ePump thus weight, it appears that if each of those sub-components is as well optimized itself towards higher power density, a further optimized application size and weight is enabled. Hence, it becomes crucial to increase Self-Priming Speed (SPS) of HM to reach higher speeds for higher flows, compensating for a smaller and lighter pump with lower displacement. The displacement is a key factor defining the torque needed to drive a HM in pump mode at a certain pressure, as depicted in the following basic formula (refer to Ivantysyn & Ivantysynova [16]):

$$T_P = \frac{\Delta p \cdot V_{D,P}}{2 \cdot \pi \cdot \eta_{hm}} \qquad (2.1)$$

At a given pressure differential Δp, reducing the displacement $V_{D,P}$ of a pump compared to a reference with lower SPS, it appears, that the needed torque T_P is significantly lower, assuming the hydromechanical efficiency η_{hm} staying constant. This drives secondary downsizing potential for the EM connected to the HM, since – as outlined by Schweigert et al. [17] – the required torque has the main influence on the size and hence the costs of an EM, which is – amongst others – one of the drivers of high-speed concepts for EHPs.

A wide variety of hydraulic pump architectures are employed in ePump designs: Sarode et al. [18] systematically compared several ePump configurations that combine commercially available hydraulic pumps to meet the demands of a representative mobile-hydraulic application. The study evaluated drive-cycle efficiency across four utility drive cycles and benchmarked mass, volume, cost, and power density for each architecture. By providing this generalized, utilization-based comparison, the work offers a practical guideline for selecting appropriate ePump architectures in electrified mobile hydraulic systems. These conclusions inform trade-off decisions when matching pump architecture to application requirements e.g., favoring bent axis designs where power density and efficiency are paramount, gear solutions where cost and simplicity dominate and vane where noise needs to be reduced.

Indeed, while external gear pump technology is cost-efficient and robust, it is usually rather loud at higher speeds and pressures, when having straight teeth. Using helical teeth for a more continuous meshing of the gears brings advantages in terms of NVH behavior. Transitioning to alternative profile geometries (e.g. trochoidal) instead of conventional involute profile allows to reduce dead-volume hence reduces flow ripple as outlined for example by Morselli [19] or Zhao & Vacca [20]. The latter ones discuss a Continuous-

Contact Helical Gear Pump (CCHGP) design combining both helical teeth and alternative profile geometries yielding improved NVH behavior. A more complex overall pump design compared to straight teeth gear pumps is usually resulting, as then either complexity increases in the design by adding balancing features or in the manufacturing by adding a double-helical gear layout (e.g. Morselli [21]) similarly to herringbone gears. Despite external gear technology, internal gear technology can also be used in medium pressure areas, typically being less noisy than external straight gear technology.

Vane pump technology operating in medium pressure often features a symmetric layout in circumferential direction, hence it is radially balanced, reducing nominal loads on the shaft compared to other technologies with a similar displacement. In addition to that, vane technology is rather quiet and offers great NVH behavior, due to a different operating principle bringing however disadvantages in terms of robustness and overall efficiency. [1]

Ultimately, bent axis pump technology typically offers best-in-class efficiency, however at the price of higher noise emissions inherent to its operating principle. Further details on advantages and disadvantages of each pump concept and type can be looked upon at Vacca & Franzoni [22], Sarode et al. [18] or Fischer et al. [1].

3. Next Generation Fixed Displacement Pumps for EHPs

3.1. Next Generation Gear Pumps for Electrified Applications

3.1.1. Concept and/or design

As mentioned in section 2.3, novel gear pump designs using helical teeth to enable lower noise may become more complex as they need special features to ensure equalization of the axial forces generated by the helical angle. The proposed design here features minor changes on today's gear pumps having straight gears, i.e. major process and quality improvements of the critical tribological interfaces, that cannot be detailed further due to confidentiality reasons. Those modifications enable achieving best-in-class efficiencies for straight gear pumps as well as improved durability at higher speeds, hence higher SPS.

3.1.2. Virtual and/or physical validation and limitations of this study

An exemplary SPS assessment performed for the 14cc sample can be seen in Figure 3.1 (left). The SPS gain potential for different displacements is outlined in Figure 3.1 (right).

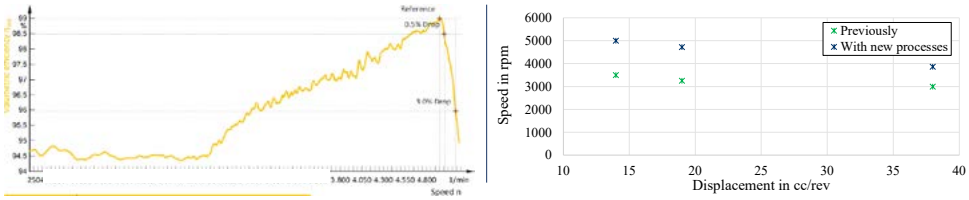

Figure 3.1: Exemplary SPS measurement at 200 bar and 0.8 bara inlet pressure (left) and SPS comparison before and after using the new manufacturing processes (right)

However, it must be acknowledged that those SPS gains are currently purely based on the formal definition of SPS. Additionally, the product maturity is at an A-Sample stage, hence a full endurance validation is to be performed. This will give more insights into the

practically reachable SPS, whether this value can be driven continuously, intermittently or is just to be considered as a peak value.

3.1.3. Exemplary use-case related to mobile electrification

Since this new process is in A-Sample stage, there are currently no real use-cases demonstrating its advantages in mobile applications being in the field. However, any cost-sensitive electrified application where the noise performance with straight gears is acceptable, but an increased SPS is required while benefitting from the robustness and simplicity of a gear pump could be applicable.

3.2. Next Generation Bent Axis Pumps for Electrified Applications

3.2.1. Concept and/or design

The next generation bent axis pumps features an integrated Ripple Chamber (RC), which is novel for this type of pump. It has been applied to both the F1 truck pump, making it the F1e and the heavy-duty F12 pump, making it the F12e (refer to Parker Hannifin [23]). While the RC is integrated in the end cap of the F1e, the RC on the F12e is integrated into the barrel housing. The RC lowers significantly the flow ripple, hence also the dB(A) noise emissions in the lab but yields even more noise reduction potential in real applications. Additional design improvements on valve plate and suction channels increase the SPS by up to ≈ 17%, depending on the developed displacement of the F12e.

3.2.2. Virtual and/or physical validation and limitations of this study

The optimizations have been firstly virtually conceptualized and validated by means of Computational Fluid Dynamics (CFD) and then physically validated through extensive, physical testing, covering all typical qualification demands. It must be highlighted, that as opposed to the gear pump improvements described in section 3.1, for those new bent axis pump series F1e and F12e, full qualification took place. This includes a very demanding Steady-State Tests (SST), where a factor of the maximum pressure is applied – increasing the pressure beyond maximum pressure – and the pump is operated at the same time at the increased SPS for the whole testing duration covering several weeks. The SPS values of the F12 vs. the F12e having passed this demanding duty-cycle are on Figure 3.2 (right).

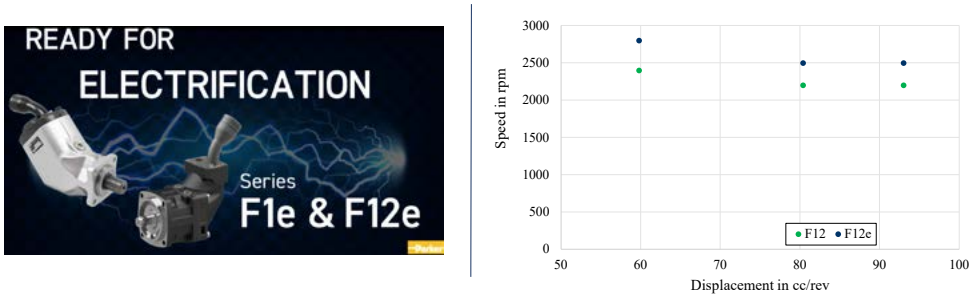

Figure 3.2: The new F1e and F12e series (left) and exemplary validated SPS values of the F12e vs. F12 pump versions at 1 bara inlet pressure (right)

There are no known limitations to this study at this stage, as the product has passed in C-/D-Sample maturity both all internal lab validations as well as the field testing successfully.

3.2.3. Exemplary use-case related to mobile electrification

The F1e has been tested on a truck application (tipper) to be compared to the standard F1. To avoid disruption of running operation where the measurement took place, it was not possible to compare on the same layout F1 vs. F1e during tipping operation. This can be seen in Figure 3.3 (left) where using the F1e, it appears that parasitic noises dominate further away from the pump compared to the same analysis with the F1. Hence, this made the F1e measurement look worse, than it actually was, though still achieving an improvement compared to the F1. The F12e however could be measured in exactly the same refuse truck side loader application to enable a side-by-side comparison. Representative measurement results can be seen on Figure 3.3 (right), showing excellent noise emission reductions.

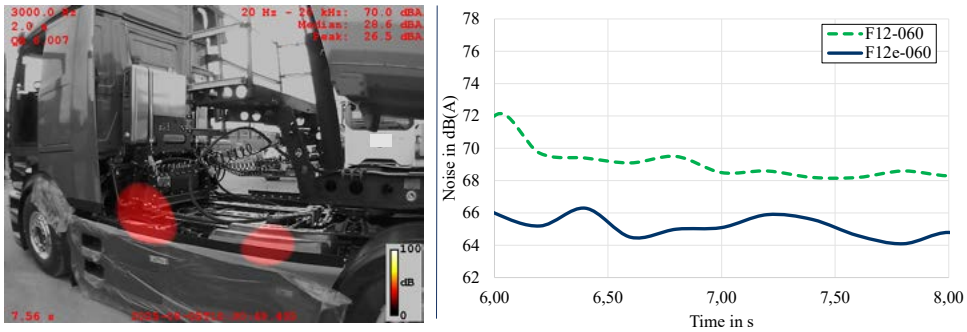

Figure 3.3: Exemplary F1e (left) measurements with acoustic camera during tipping operation and F12 vs. F12e noise measurement (right) results with acoustic camera performed on a refuse truck (ejection beam in operation at driver side)

In both cases, the external truck operators mentioned that they perceived significant noise improvements when switching from the F1 to the F1e and from the F12 to the F12e, which shows a real gain from psychoacoustic perspective in addition to the measurements results.

3.3. Next Generation Vane Pumps for Electrified Applications

3.3.1. Concept and/or design

Vane pumps are typically medium pressure pumps, but they still can reach higher pressures than today. Parker's new T8mini (refer to Parker Hannifin [24]) features 280 bar continuous pressure, while allowing 300 bar intermittent. This is made possible – amongst other changes – through novel coatings on the critical tribological interfaces between pressure and rear plates that interface with the rotor side faces. Additionally, a novel design of the port plates and housing in conjunction with additional radial holes in the cam profile enable excellent filling behaviour, yielding exceptional SPS performance. Together with a simpler mechanical design – for instance 10 instead of 12 vanes – the hydromechanical efficiency of this pump as well achieves highest levels. This enables a new breakthrough of overall efficiency for vane technology compared to the already rather high efficiency of the T7

series. The T8mini reaches on all his cam profiles enabling $V_{D,P} = 6 \ldots 12\ cc/rev$ an SPS of 4,800 rpm at 0.8 bara. [24]

3.3.2. Virtual and/or physical validation and limitations of this study

The T8mini has been conceptualized by means of virtual validation (e.g. 1D-Simulation) and detailed using modern CFD simulations, e.g. to improve filling behaviour as described in Jeganathan et al. [25] and high volumetric efficiencies. The standard validation program in lab environment has been performed, e.g. from performance measurements (efficiency), noise emissions in reverberant rooms as well as high-pressure and endurance tests. Additional tests have been performed to meet special requirements demanded in new applications, e.g. BEV trucks both in on- and off-highway applications. Here, tests with high-viscosity oils (e.g. ISO 680 oils) were performed to reach kinematic viscosities of $\nu \approx 5{,}000\ cSt$ to simulate the effect of cold temperatures < 0° C. It must be mentioned that such tests do not replace specific in-vehicle tests at such low temperatures, nevertheless, they provide good-enough insights on cold-start capabilities of the pump. The test layout for this specific lab test can be seen on Figure 3.4 (left). Tests have been performed both in standard configuration (Figure 3.4, right) as well as submerged in the oil tank (not shown below).

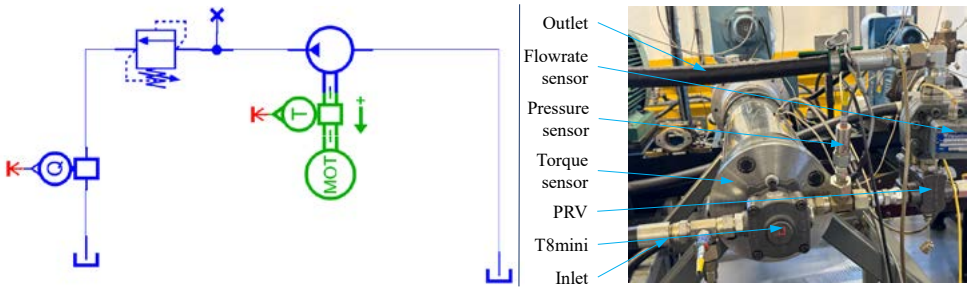

Figure 3.4: Hydraulic scheme & standard testing of T8mini at high viscosity

The submerged variant considered the intended layout in the final application by mimicking the application's oil tank volume and showed particularly good heat-up behaviour of the oil as well as an even better subjective noise assessment due to the surrounding oil, damping noise emissions. Ultimately, submerged pumps typically yield improved suction performance. As those investigations have been performed for a specific displacement of the T8mini and at a B-Sample maturity, further investigations are to be done for C-Samples at multiple displacements and also yielding higher production volumes.

3.3.3. Exemplary use-case related to mobile electrification

Since the T8mini has been optimized towards high-speeds and higher pressures, the detailed characterization at combinations of low speeds (≤ 1,000 rpm) at low pressures (≤ 50 bar) as well as high-speeds (> 4,000 rpm) at low pressures (≤ 50 bar) was not in the initial scope of the development. Nevertheless, special tests have been performed to check compliance with requirements demanded for an auxiliary low pressure 24 V ePump for On- and Off-Highway BEV Truck applications. Here, the T8mini's high-speed and cold-start capabilities as well as its resistance against high pressures spikes were key to achieve the high-power density, low noise, low envelope size and weight requirements as well as reliability for such a heavy-

duty application. While the B-Sample featured a bell housing between the Brushless Direct Current (BLDC) motor with integrated motor controller rated for 1.85 kW (refer to Figure 3.5), the C-Samples have been designed featuring a direct connection. The potential of axial space saving resulting by that can be seen in Figure 3.5. Further reduction of envelope size however requires more extensive integration, that will be outlined in the next section.

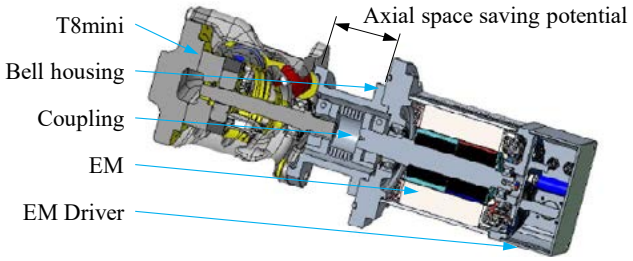

Figure 3.5: T8mini HM as 24 V auxiliary EHP for HV BEV Trucks, here in B-Sample maturity with moderate integration (still using a bell housing with coupling)

4. Discussion: A Novel Approach to EHP Integration

4.1. Limitations of increasing solely the pump's power density

The previous section demonstrated that with nowadays development tools like Computer Aided Engineering (CAE) – more specifically CFD – further advancements can be done on existing pump technologies, to increase their power density or to develop new pump generations. Increasing the SPS while improving the NVH behaviour at the same time enables reducing the pump size. In other words, assuming a certain flow Q_P is required from the application's perspective, if the pump's SPS n_P can be increased, its displacement $V_{D,P}$ can be subsequently reduced, as it can be seen in the following basic formula:

$$Q_P = n_P \cdot V_{D,P} \cdot \eta_{vol} \qquad (4.1)$$

If an intermittent flow of around 160 l/min is required, with the standard F12-060 for example, the requirement could not be reached without boosting the inlet, and it would be needed to take the next bigger size, i.e. the F12-080. With the F12e-060, this flow could be met through the increased SPS (refer to path a) in Figure 4.1) assuming the same volumetric efficiency η_{vol} for F12 and F12e at those different speeds: A significant reduction in displacement, hence pump size would be enabled. Another option would be, to maintain the F12-080 and operate it at lower speed to achieve similar flow Q_{des} at reduced noise (refer to path b) in Figure 4.1). However, having this example in mind, the HM downsizing remains marginal, compared to the size of the EM that typically represents the bulk of the EHP's size, weight and costs. Additionally, the speed limiting factor often being the HM's SPS, it remains difficult to operate the EM frequently in its efficiency optimum areas that typically are at higher speeds.

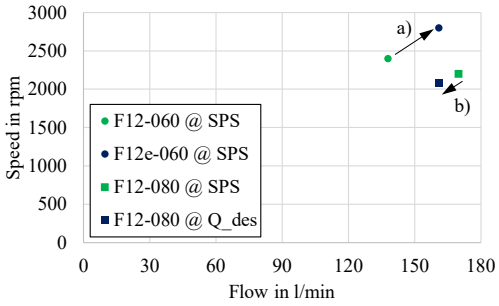

Figure 4.1: Exemplary calculation study to assess benefits and limitations of SPS increases

4.2. Semi-integration: High power density EHPs that can remain modular

One approach to tackle the beforementioned challenge to match HM and EM speeds, is to add a gearbox between EM and HM. The added complexity, losses and costs of the gearbox can only be justified, if the EM's downsizing is such, that from system perspective the overall efficiency remains constant or even improves through operating the EM in more efficient areas of its maps. Additionally, the system costs should ideally be lower than before. While Heeger, West & Ericson [10] showcase most possibilities to combine HM, EM and gearbox in Figure 4.2 (concepts (a) to (e), there may be another option (f) (Figure 4.2, below) that may appear counterintuitive at first sight.

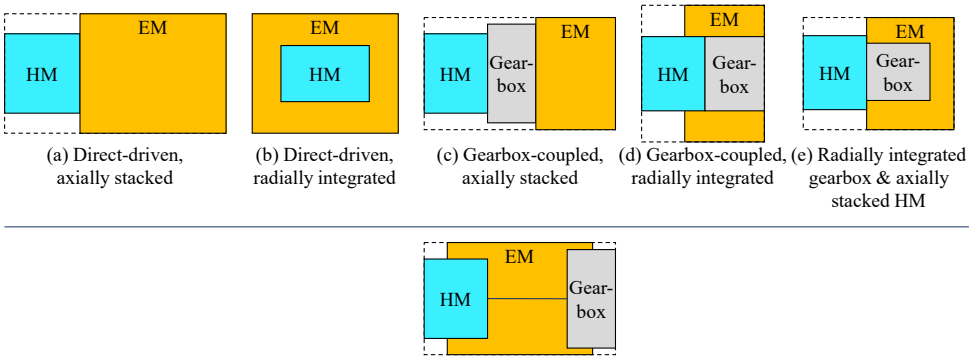

Figure 4.2: Concepts for combining Hydraulic Machines (HM) and Electric Motors (EM) into electro-hydraulic energy converters according to Heeger, West & Ericson [10] (left, with concepts (a) to (e)) and novel approach (f) for semi-integration (patent pending)

This option is to deliberately separate the gearbox and HM from the EM, so that both are arranged on opposed sides of the EM. This requires a through-shaft going through the EM which subsequently needs to have a hollow-shaft rotor and resolver design to have the gearbox connected to the HM. What appears to be more complex and costly at first sight, brings a lot of advantages as such a layout still enables a certain degree of integration, while offering more flexibility for modular design of the overall system and its components: Hence it can be referred to as "semi-integrated" EHP concept. The advantages of such an unconventional approach to integration are the following:

- Easier scalability of the outer diameter of the EM, while keeping the possibility to scale the EM in axial length. This gives additional flexibility for the design of a modular system comprising certain EM, HM and gearbox variants.
- The EM's rotor diameter can be much smaller, as it is not necessary to integrate gearbox and HM inside of the rotor, hence the only limiting factor of the EM's inner diameter is the very moderate diameter of the through-shaft. This is essential for high-speed EM concepts that require small diameters.
- The radial dimensions of HM and gearbox are less limited in radial direction than in other integrated concepts, offering additional possibilities to improve the scalability of those components to increase modularity of the EHP system.
- An oil cooling of the EM's rotor can easily be implemented via the through-shaft and/or the hollow rotor shaft, if a common oil sump between gearbox and HM is possible.
- If a common oil sump between gearbox and HM is chosen, the through-shaft layout extends the size of the oil sump, enabling using the oil sump as integrated tank.
- The through-shaft further enables integration of features to compensate radial and axial misalignments between gearbox and HM.
- In case a Planetary Gearset (PGS) is used as a gearbox – which has the benefit of highest power density and radially equalized forces – the overall EHP is fully co-axially arranged (concentric). This simplifies design of housing parts and provides an axially extending layout, that is beneficial if the radial extension of the available space is limited. Also, such a co-axial design supports a common part strategy.
- Gearbox and HM can be assembled nearly at the same time in parallel on each side of the EM, which reduces assembly time.
- Gearbox and HM can be dis-assembled and/or serviced independently from each other, which also eases maintenance, if required.

Such a concept is shown schematically in Figure 4.3 (i) using a 2-stage PGS on the left side with high PGS ratio, that is partly fitted under the windings of the EM. The HM is to be thought of a cartridge type of pump, that can be either of fixed or variable displacement type and can have 1- to 4-quadrant-capability, or any in-between step, depending on the requirements. The suction side of one or both pumps can be fed through the oil sump of the system or be led to an external tank. The outlets can be separated or together, depending on the application.

Another variant with only one minimal change can be seen in Figure 4.3 (ii). Here the only difference is that the hollow gear of the PGS stage I is connected to the carrier of the PGS stage II. This enables a lower ratio with only a minor modification of the PGS, supporting a common parts strategy.

Using only stage I of this same PGS – consistently driving common parts strategy – enables a further reduced ratio, that may be sufficient for intermediate displacements, see Figure 4.3 (iii).

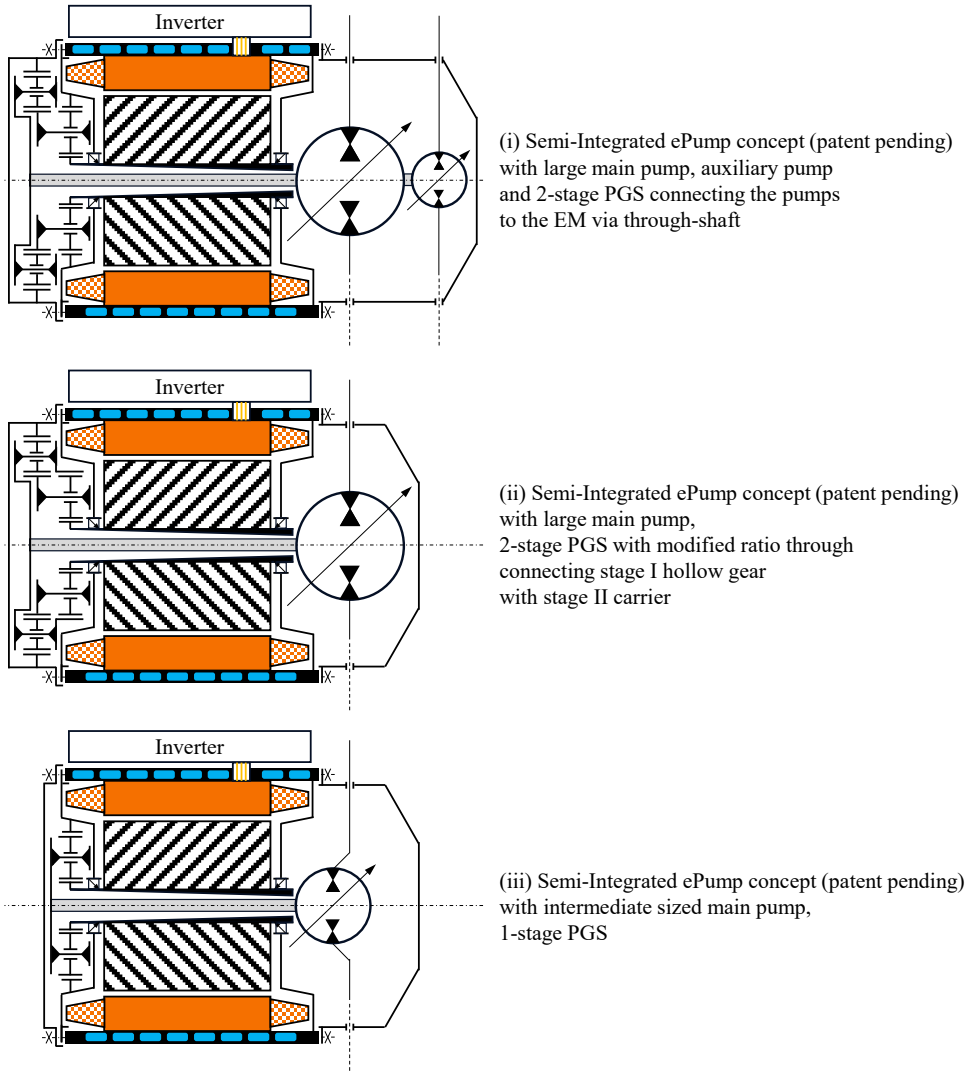

Figure 4.3: Semi-Integrated ePump concept and exemplary variants (patent pending[1])

Further variants can be thought of, e.g. increasing torque capacity of the PGS through increasing either the number of planets, their width, or both together. Changes in the teeth numbers with or without addendum modifications enable slightly modified ratios. The schematically indicated position of the inverter is deliberate, as being on top allows proximity to the EM, shortening connection distances on one hand. On the other hand, having it not axially integrated ensures that gearbox and HM can be radially scaled. Ultimately, the use of a gearbox does not only limit itself to be used to allow higher speeds hence higher efficiencies at the EM (EM "high-speeding") but may also be used to lower or

[1] A patent application covering aspects of this work has been filed; details will be available upon publication of the application.

at least keep the pump speed constant for purpose of à posteriori noise reduction in mobile applications particularly sensitive to noise emissions (HM “low-speeding”).

4.3. Potential limitations to tackle when dealing with semi-integration

While the abovementioned approach for semi-integration is rather new and shows considerable advantages on many aspects, it brings also new challenges with it that need to be further investigated. Certainly, achieving the right balance between integration and modularity represents one of the biggest challenges. Adding a gearbox will increase inertia, which may be a limiting factor for highly dynamic applications. Depending on the lubrication concept, using a mono-fluid for the gearbox and the hydraulics might require compromises on either one of those sub-components’ performance. Choosing separate, dedicated fluids on the other hand would complexify the sealing and eventually the assembly concept. All those aspects need to be investigated both theoretically and experimentally before implementation of semi-integration.

5. Summary

The present contribution shows advancements in the development of the next generation fixed hydraulic pumps for electrified mobile applications, more specifically for electrified open circuit work functions. In a first step, the current state of the art summarizes chances and challenges of electrification for hydraulic pumps. A main takeaway is, that due to increased need of space for batteries on HEV and BEV, the hydraulics need to be more power dense than ever to compensate a bigger portion of the vehicle’s weight being accounted by the battery. Additionally, noise emissions of hydraulic pumps need to be reduced, being not masked by ICE noise anymore. In a second step, a moderate approach outlines, how to achieve those development targets from pump perspective presenting three examples of Parker’s eReady pumps from lowest to highest degree of modifications: A new combination of manufacturing processes enabling higher SPS on gear pumps; an integrated ripple chamber in the new bent axis pumps F1e and F12e to reduce flow ripple, hence noise and further optimizations to increase SPS to up to 17% and ultimately a completely new generation of vane pumps designed for electrification. System level considerations have then been performed to reflect on the shown pump’s power density improvements and to enable even higher density of EHPs. A novel approach was presented – that tries to reconcile high integration and high modularity – described as “semi-integration”. Further research is needed in terms of endurance validation of the outlined SPS improvements for gear pumps as well as on the design and implementation of the outlined modular EHP system leveraging semi-integration.

Abstract.

Regenerative pumps are capable of generating high pressures at relatively low flowrates, making them suitable for applications such as electric vehicle cooling systems and cleaning systems for autonomous vehicle sensors. However, their nominal efficiency remains relatively low. The objective of this study is to improve the understanding of how the channel geometry influences the internal flow and performance of regenerative pumps, with particular emphasis on the empirical coefficient of the analytical model. A regenerative pump prototype with variable channel geometry was designed and manufactured. The channel height and width were modified while maintaining a constant side-channel area to enable direct comparison among configurations. The hydrodynamic characteristics, including pressure-flowrate and efficiency-flowrate curves, were experimentally measured. Based on both CFD simulations and experimental data, the empirical coefficients of the analytical model developed by Badami and Mura [1, 2] were estimated, and the corresponding performance predictions were analysed.

Keywords. Regenerative pump, side-channel pump, internal flow, regenerative pump geometry.

1. INTRODUCTION

Pumps can be classified into three main categories: centrifugal pumps, axial pumps and volumetric pumps. Centrifugal pumps use the centrifugal force generated by their rotor to project the fluid outward into the volute and toward the outlet. These pumps can produce high flow rates but have small pressure differential between the inlet and outlet (Figure

All Open Access articles are peer-reviewed, distributed under the Creative Commons Attribution-Non Commercial 4.0 International

1.1(a)). Axial pumps have similar characteristics but can generate higher flowrate (Figure 1.1(b)). In contrast, volumetric pumps rely on a variation in volume to draw liquid through the inlet and discharge it through the outlet. They are more efficient at high pressure and large flow rates (Figure 1.1.(c)).

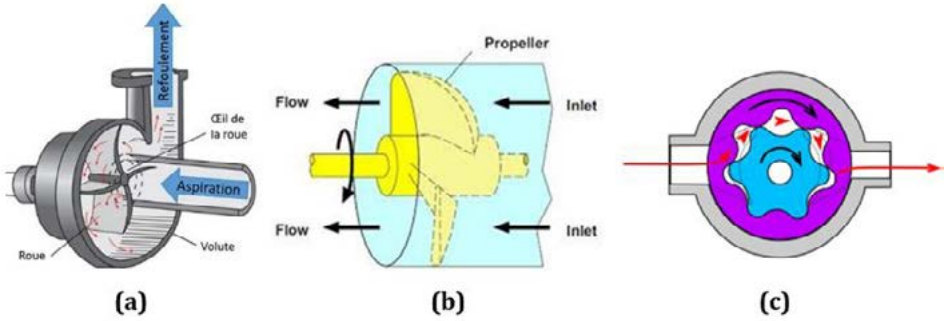

Figure 1.1. Centrifugal pump (a), Axial pump (b) and volumetric pump (gerotor pump) (c)

The pumps described above do not operate efficiently under conditions of low flowrate and high pressure. Regenerative pumps, which combine characteristics of both centrifugal and positive displacement machines, are well adapted to such operating regimes. Applications such as cleaning sensors on autonomous vehicles require compact pumps capable of generating high pressure at low flowrates with good efficiency, conditions for which regenerative pumps are particularly suitable. Introduced in the 1920s by Siemen and Hinsch [3], these pumps are currently used in fluid transfer (oil and gas, boiler feed, cooling and refrigerant systems) and can also be used in mixing and misting applications.

One advantage of this type of pump is its simple design. Its rotor consists of a central bore used for the mounting on a rotating shaft and a series of radially distributed blades around the peripheral surface (Figure 1.2). The symmetry and regular distribution of the blades ensure that the rotor is balanced which minimize vibration and wear. The housing of the pump has a side channel integrated along its inner circumference, aligned with the blades of the rotor (Figure 1.3). It plays a crucial role in the pump operation, that will be explained later. Another key feature of the housing is the stripper, which is a component that separates the inlet and the outlet sections of the pump. This part ensures that the leakages from outlet to inlet are minimal thus improving pump performance.

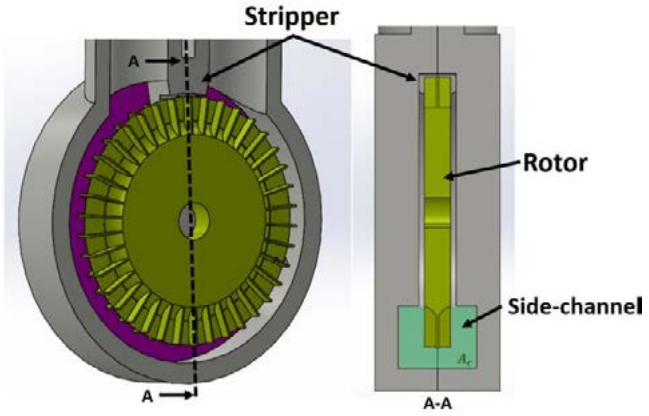

Figure 1.2. Regenerative pump basic design

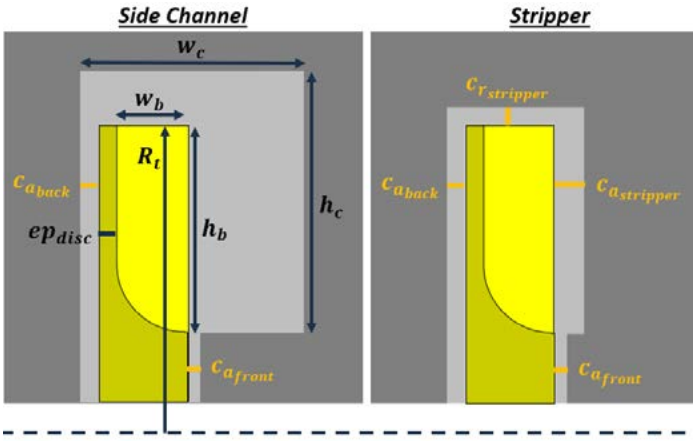

Figure 1.3. Regenerative half-pump geometric parameters

The flow within such a pump is complex and three-dimensional (Figure 1.4). Initially, the fluid enters the pump and is transported by the rotor to the outlet of the housing. Observing from a radial cross-section aligned with a blade, one can also identify a flow referred to as "regenerative" (Figure 1.5). During this flow, the fluid enters at the inner radius of the blade, and the rotation of the wheel increases the fluid's energy. Subsequently, the fluid moves into a channel where various physical phenomena convert a portion of the gained energy into pressure. These phenomena will be explained later. The fluid then returns to the inner radius of the wheel, and the cycle begins anew.

This flow behaviour has been validated by numerous experimental studies and numerical simulations [4-9]. A notable advantage associated with this flow behaviour is the pump's pulsation-free operation. Another advantage is that regenerative pumps are less prone to cavitation compared to centrifugal or volumetric pumps, the gradual increase of the fluid pressure along the pump circumference minimizes turbulent zones that could lead to low-pressure areas. However, regenerative pumps are not immune to cavitation, as shown by

Senoo [4]. This flow behaviour also allows the pumping of liquid/gas mixtures, as gas bubbles are thoroughly mixed with the liquid, breaking down larger gas pockets and evenly distributing the gas within the liquid.

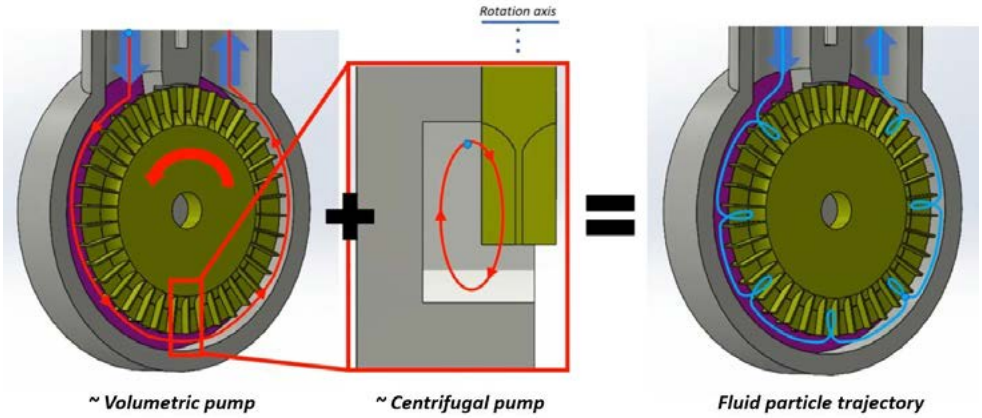

Figure 1.4. Internal flow inside of a regenerative pump

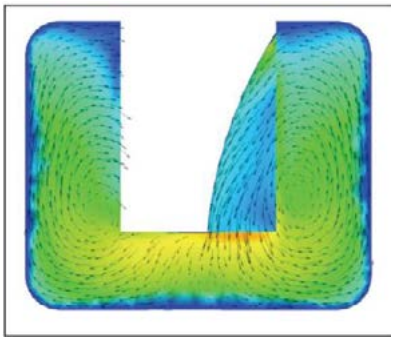

Figure 1.5. Flow inside of the side-channel of a regenerative pump [9]

To predict the characteristic of a regenerative pump, the development of models is essential. Multiple theories have been developed that try to predict the performances of regenerative pumps.

One of these theories is the Momentum Exchange Theory (MET) which was introduced in the 50s by Hopkins and Wilson [5, 6]. In this theory, the mechanism responsible for the pressure generation is the transfer of momentum between the impeller blades and the fluid. The momentum energy imparted to the fluid by the impeller blades propels the fluid to the tip of the blades. Upon entering the pump channel, the fluid's momentum energy is partly converted into pressure through interaction with the turbulence generated by the fixed wall of the outer diameter. Nevertheless, MET is not without limitations. Turbulence mechanism responsible for the pressure rise are simplified and their modelling rely on the use of empirical coefficient. The model then requires experimental data to give accurate results.

The model also relies on several idealized assumptions about flow conditions which can introduce deviations from the actual pump performance.

Since this initial work, several research groups have extended and refined the model [1, 2, 10]. Notably, it has been established that the flowrate in regenerative pumps is strongly influenced by the cross-sectional area of the side channel. Consequently, following definitions for the dimensionless flowrate φ and pressure coefficients ψ of regenerative pumps have been proposed:

$$\varphi = \frac{Q}{UA_c} \quad ; \quad \psi = \frac{2\Delta P}{\rho U^2} \tag{1.1}$$

Here, Q and ΔP are respectively the flowrate and pressure differential between the inlet and the outlet of the pump, A_c the cross-sectional area of the side channel, U the blade tip tangential velocity and ρ the fluid density.

φ and ψ are dimensionless performance coefficients that enable consistent comparison across pumps of varying sizes and rotational speeds. In this study, the definitions given in eq. (1.1) are employed to evaluate and contrast pump configurations featuring different side-channel geometries. By expressing the flowrate and the pressure generated by the pump in nondimensional form, these coefficients isolate the intrinsic dynamic behaviour of each design, allowing performance trends to be interpreted independently of scale or operating conditions.

The paper first introduces the analytical modelling of regenerative pumps. The experimental setup and the tested pump configurations are then described, followed by a presentation of the experimental results. Using both experimental data and CFD simulations, the empirical coefficients of the analytical model are determined and applied to predict pump performance. Finally, a comparison between the predicted and measured efficiency curves is conducted to evaluate the accuracy of the analytical model.

2. REGENERATIVE PUMP MODELLING

The model presented in this section was originally developed by Badami and Mura in 2010 [1] based on Wilson et al. work [6].

To determine the pressure coefficient of the pump, the momentum equation is applied to the fluid in the side-channel:

$$\frac{dK}{dt} = T_p + T_w \tag{2.1}$$

Where K is the angular momentum of the fluid, T_p is the torque associated to the increase in pressure along the pump circumference and T_w is the torque linked to the effect of the shear forces on the side channel walls.

By assuming that the fluid is not compressible and that the torque T_w is proportional to the square of the mean velocity in the channel, equation (2.1) can be rewritten as:

$$Q_m \rho \left(R_t C_{u_2} - r_1 C_{u_1}\right) = A_c r_c \Delta P + \frac{1}{2} K_p A_c r_c \rho u_c^2 \tag{2.2}$$

With R_t the radius of the tip of the impeller, r_c the mean radius of the side channel, r_1 the mean radius of the inlet meridian flow stream at the impeller as defined in Figure 2.1, A_c the cross-section of the side channel, Q_m the recirculation flowrate, C_{u_1} and C_{u_2} the tangential components of the absolute velocity at the entry and exit point of the blades and K_p a coefficient used to model the losses linked to the friction forces on the side channel wall.

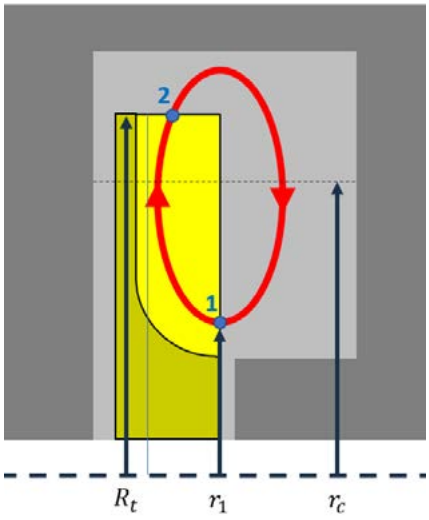

Figure 2.1. Mean flow streamline

the non-dimensional pressure coefficient ψ of the pump can then be determined from equation (2.2):

$$\psi = 2\left(\frac{Q_m}{A_c U}\right)\left(\frac{r_1}{r_c}\right)\left(\frac{R_t}{r_1}\frac{C_{u_2}}{U} - \frac{C_{u_1}}{U}\right) - K_p\varphi^2 \tag{2.3}$$

With φ and ψ the non-dimensional flowrate and pressure coefficients as defined in equation (1.1) and U the tangential velocity of the tip of the blades.

The mean radius of the inlet flow of the impeller can be estimated using the following equation:

$$r_1 = R_t - kh_b \tag{2.4}$$

Where h_b is the height of the blade (Figure 1.3) and k is an unknown coefficient. Badami & Mura use a value of $k \approx \frac{2}{3}$.

Assuming that the angular velocity of the fluid in the side channel is constant along the pump circumference:

$$\frac{C_{u_1}}{U} = \frac{U_{c_1}}{U} = \frac{r_1}{r_c}\varphi \quad ; \quad \frac{C_{u_2}}{U} = \frac{U_2}{U} - \frac{\Delta U_2}{U} = \left(1 - \frac{\Delta U_2}{U_2}\right) \tag{2.5}$$

Here, $\frac{\Delta U_2}{U_2} = \sigma$ is a slip coefficient that considers the velocity difference between the fluid exiting the blades and the fluid in the side channel. Badami & Mura gives the following approximation to estimate its value:

$$\sigma = \frac{2.6}{Z\left(1 - \left(\frac{r_1}{R_t}\right)^2\right) + 2.6} \tag{2.6}$$

Substituting equation (2.5) in equation (2.3):

$$\psi = 2\left(\frac{Q_m}{A_c U}\right)\left(\frac{R_t}{r_c}(1-\sigma) - \left(\frac{r_1}{r_c}\right)^2 \varphi\right) - K_p \varphi^2 \tag{2.7}$$

In order to estimate the value of the recirculation flowrate Q_m, the energy equation must be applied to the fluid in the vane grooves and in the side channel, with reference to a coordinate system moving with the impeller and the fluid respectively. By summing the obtained equations:

$$K_m \left(\frac{A_c}{A_2}\right)^2 \left(\frac{Q_m}{A_c U}\right)^2 + \left(\frac{r_1^2 - R_t^2}{R_t^2} + \left(\frac{U_{c_2}}{U}\right)^2 - \left(\frac{U_{c_1}}{U}\right)^2\right) = 0 \tag{2.8}$$

With the assumption that the fluid has a constant angular velocity in the side channel:

$$\frac{Q_m}{A_c U} = \frac{1}{\sqrt{K_m}} \frac{A_2}{A_c} \sqrt{\frac{R_t^2 - r_1^2}{R_t^2} - \frac{R_t^2 - r_1^2}{r_c^2}\varphi^2} \tag{2.9}$$

Where K_m is a loss coefficient that considers the energy losses due to restrictions and enlargements of the flow in the meridian plane and the losses due to the turbulent shear forces in the vanes, and A_2 is the outlet area of the blades.

This model supposes that there are no internal leakages in the pump. Badami & Mura [1] propose that the real flowrate coefficient φ_R is equal to the difference between the theoretical flowrate coefficient φ and the leakage coefficient φ_f:

$$\varphi_R = \varphi - \varphi_f \tag{2.10}$$

In their pump geometry, there are two main leakages: the leakage through the axial mechanical clearance between the impeller and the housing (φ_{f_1}) and the leakage through the stripper clearances (φ_{f_2}).

Using Bernoulli's equation and assuming the leakage induced by the drag of the impeller through the stripper can be correlated by a triangular drag velocity distribution in the clearance, the leakage flowrate coefficients can be determined:

$$\varphi_{f_1} = \frac{A_{f_1}}{A_c} \frac{1}{\sqrt{K_{f_1}}} \sqrt{\frac{\psi}{2}} \quad ; \quad \varphi_{f_2} = \frac{A_{f_2}}{A_c}\left(\sqrt{\frac{\psi}{Z_s K_{f_2}}} + \frac{1}{2}\frac{r_c}{R_t}\right) \tag{2.11}$$

Where A_{f_1} and A_{f_2} are the leakage areas and Z_s is the number of blades facing the stripper. In those equations, two new loss coefficients appear: K_{f_1} and K_{f_2}. Those coefficients consider the pressure drops in the different leakage areas.

Finally, the efficiency η of the regenerative pump is defined as the ratio between the hydraulic power P_h generated by the pump and the input mechanical power P_m. The

hydraulic and mechanical powers can be estimated using the flowrate and pressure coefficient of the pump:

$$P_h = \frac{1}{2}\rho A_c U^3 \varphi_R \psi \tag{2.12}$$

$$P_m = \frac{1}{2} A_c \rho U^3 \frac{r_c}{R_t}\left(\psi + K_p \varphi^2\right) \tag{2.13}$$

$$\eta = \frac{P_h}{P_m} = \frac{R_t}{r_c}\frac{\varphi_R \psi}{\psi + K_p \varphi^2} \tag{2.14}$$

To predict the hydraulic performances of a regenerative pump using this model, the coefficients K_m, K_p, k, K_{f_1} and K_{f_2} must be determined. In [1] those coefficients are considered as constants for a given geometry.

In this study, the effect of the leakages will be neglected ($K_{f_1} = K_{f_2} = 0$) and K_p and k will be determined using CFD simulations. The value of K_m will then be estimated from experimental data.

3. EXPERIMENTAL SETUP AND RESULTS

The previously described model will be applied to the following pump prototype (Figure 3.1).

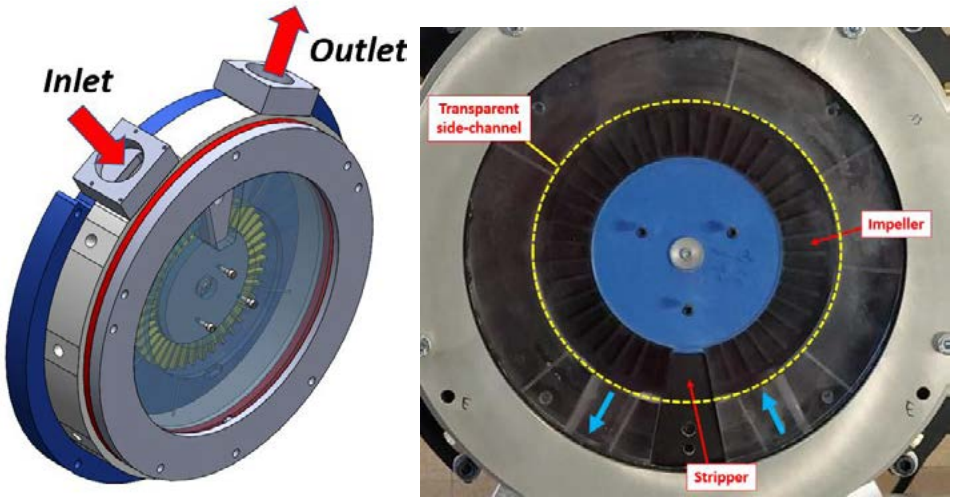

Figure 3.1. Regenerative pump prototype

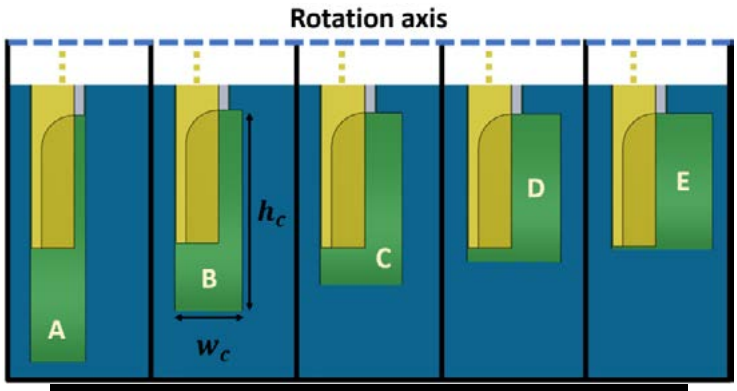

This prototype is a half regenerative pump (Figure 1.3). Unlike a full regenerative pump, in which the regenerative flow is on both side of the impeller, the half regenerative pump only features one regenerative flow in the side channel. This design simplifies the manufacturing and allows for focused investigation of regenerative flow behaviour while retaining the core operating principles of regenerative pumps. Theoretically, a half regenerative pump can

achieve the same pressure head as a full regenerative pump, but its flowrate is reduced by half due to the single-sided channel. However, this design introduces an axial clearance c_{a1} between the impeller and the housing (Figure 1.3), in which the fluid can flow. This creates internal leakages and viscous frictions that do not exist in the full pump configuration, impacting the performances of the pump.

Table 3.1. Constant geometrical parameters

$\boldsymbol{R_t}$	$\boldsymbol{82.5\ mm}$	$\boldsymbol{c_{a_{back}}}$	$\boldsymbol{0.7\ mm}$
$\boldsymbol{w_b}$	$8.5\ mm$	$c_{a_{front}}$	$0.25\ mm$
$\boldsymbol{h_b}$	$26.25\ mm$	$c_{a_{stripper}}$	$0.5\ mm$
$\boldsymbol{ep_{disc}}$	$2\ mm$	$\boldsymbol{c_{r_{stripper}}}$	$0.5\ mm$

Despite the constraints of the design, the channel geometry can be easily modified, and multiple pump configurations have been manufactured (Table 3.1 and Figure 3.2).

Configuration	w_c	h_c
A	$11\ mm$	$48.75\ mm$
B	$13.5\ mm$	$39.7\ mm$
C	$16\ mm$	$33.5\ mm$
D	$18.5\ mm$	$29\ mm$
E	$20\ mm$	$26.8\ mm$

Figure 3.2. Geometric configurations of the channel

To evaluate the performance of this half regenerative pump prototype, a dedicated hydraulic test bench was developed. This setup allows for the measurement of key hydraulic and mechanical parameters.

The test bench consists of a closed-loop circuit equipped with a variable speed electric motor driving the pump. A torquemeter equipped with an incremental encoder allows for the measurement of the input torque T_{exp} and rotational speed ω_{exp} of the impeller leading to the computation of the input mechanical power. The flowrate Q_{exp} is measured using an ultrasonic flowmeter installed downstream of the pump, while pressure sensors mounted upstream and downstream of the pump provide measurements of the pressure differential of the pump $\Delta P_{exp} = P_{outlet} - P_{inlet}$. A data acquisition system records all sensor outputs for post-processing and performance evaluation of the different pump configurations. The circuit also includes a fluid tank to minimize air entrainment as well as a regulation valve used to modify the flow' resistance and simulate different operating conditions (Figure 3.3). A temperature sensor and a barometer mounted on the fluid tank allows for the control of the fluid temperature and of the hydrostatic pressure inside of the hydraulic circuit. Pressure sensors mounted on the circumference of the pump also allows for the measurement of the pressure gradient inside of the pump but this experimental data will not be investigated in this paper.

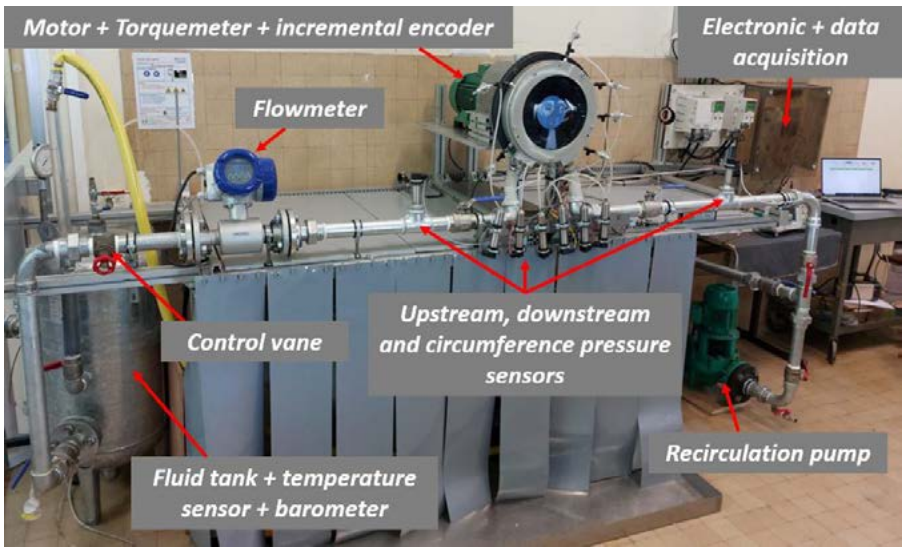

Figure 3.3. Hydraulic test bench

For each configuration, the pump rotational speed was maintained at a constant value, and the pressure drop of the hydraulic circuit was progressively increased by adjusting the control valve, enabling measurement of the pump flow/pressure and flow/efficiency characteristics.

Experimental results at 900 RPM (configurations A to D) are presented in Figure 3.4. Due to manufacturing issues encountered with configuration E, its performance could not be measured at 900 RPM; therefore, the results obtained at 600 RPM are reported instead.

φ_{exp} and ψ_{exp} have been calculated from experimental flowrate, pressure differential and rotational speed data using the formulas presented in eq.(1.1). The experimental efficiency was calculated from flowrate, pressure, torque and rotational speed measurements:

$$\eta_{exp} = \frac{Q_{exp}\Delta P_{exp}}{T_{exp}\omega_{exp}} \tag{3.1}$$

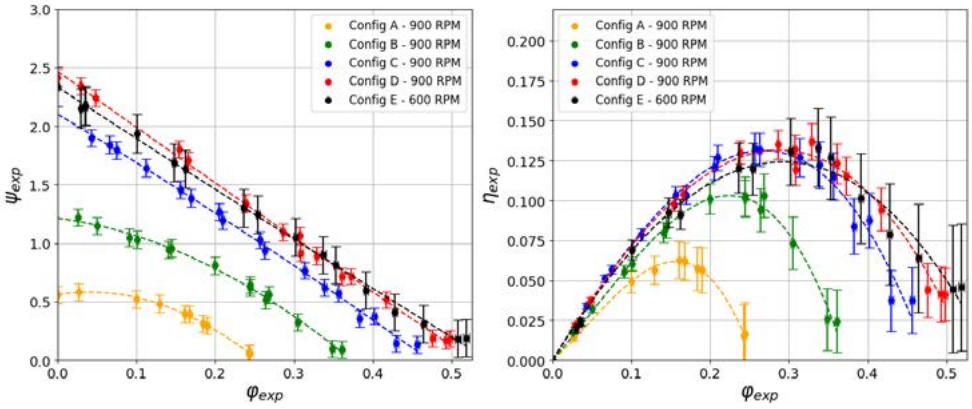

Figure 3.4. Experimental results

The study of the coefficient K_m will be conducted on configuration C at 900 RPM (blue curves on Figure 3.4).

4. ESTIMATION OF K_m

As mentioned in Chapter 2, leakage effects are neglected in this study. Using equations (2.3) and (2.9), an expression for the recirculation loss coefficient K_m can be derived:

$$K_m = \frac{4A_2^2(R_t^2 r_c^2 - R_t^2\varphi^2(R_t^2 - r_1^2) - r_1^2 r_c^2)(R_t r_c(\sigma - 1) - r_1^2\varphi)^2}{A_c^2 R_t^2 r_c^6\left(\psi + K_p\varphi^2\right)^2} \tag{4.1}$$

In this formulation, K_m is expressed in terms of known geometric parameters (R_t, r_c, A_2), dimensionless flowrate and pressure coefficient (φ, ψ) and unknown parameters σ, r_1 and K_p. The slip coefficient σ can be evaluated from eq. (2.6). The remaining two coefficients, K_p and k are determined via CFD simulations.

K_p represents the pressure drops in the pump's inlet, outlet and side channel. A simplified CFD simulation of these regions, excluding the impeller, enables the evaluation of the pressure drop generated by the pump. Experimental measurements were also performed using an impeller without blades and the recirculation pump installed on the test bench to produce the required flowrates (Figure 4.1).

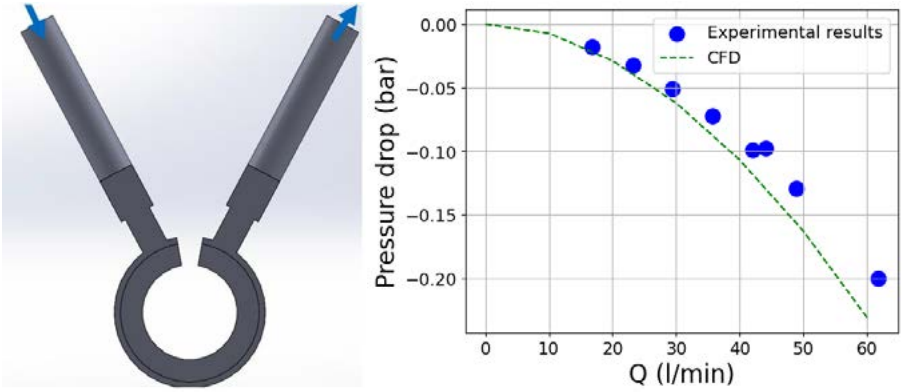

Figure 4.1. CFD geometry and comparison of experimental and CFD results

The experimental data and CFD predictions are in close agreement, with a minor deviation of approximately 25 mbar at high flowrates, attributable to leakage paths not included in the simulation. This agreement enables an accurate estimation of the pressure drop in complex channel geometries.

From the pressure drop curve estimated by CFD simulation, the value of K_p can then be determined:

$$K_p = \frac{2\Delta P_l}{\rho v^2} = \frac{2\Delta P_l}{\rho (Q/A_c)^2} \tag{4.2}$$

Where ΔP_l is the pressure drop at the flowrate Q and $v = \frac{Q}{A_c}$ is the fluid velocity in the side-channel. For configuration C, $K_p = 4.5$. Badami & Mura [2] reported a value of $K_p = 3.5$ for a regenerative air compressor with similar geometry, deriving the coefficient through conventional pressure-drop analysis.

The coefficient k is then evaluated from the velocity field in the side channel within a meridional plane. The radius r_1 is assumed to correspond to the center of the impeller inlet height. For configuration C, $k \approx 0.66$ (Figure 4.2) corresponding to the value used by Badami & Mura [2].

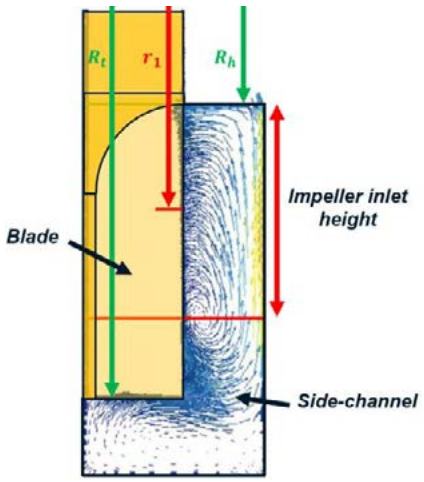

Figure 4.2. Flow in the meridional plane in configuration C at 900 RPM

With the values of K_p and k determined, K_m can be calculated from eq.(4.1) using the experimental φ and ψ data (Figure 4.3). In Badami's model [1], K_m is a constant loss coefficient. The mean value of the obtained K_m curve is then used. For configuration C, $K_m \approx 24.9$.

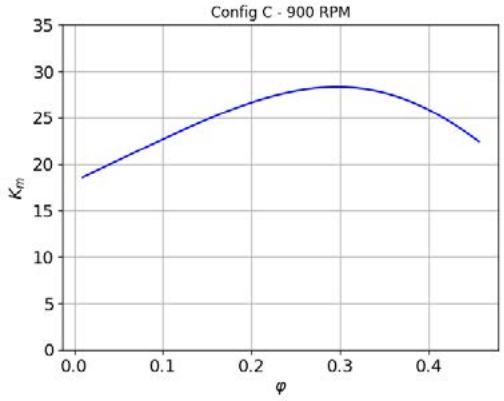

Figure 4.3. Calculated K_m for configuration C at 900 RPM

The obtained values of K_p, k and K_m enable prediction of pump performance through eqs. (2.3) and (2.14) (Figure 4.4).

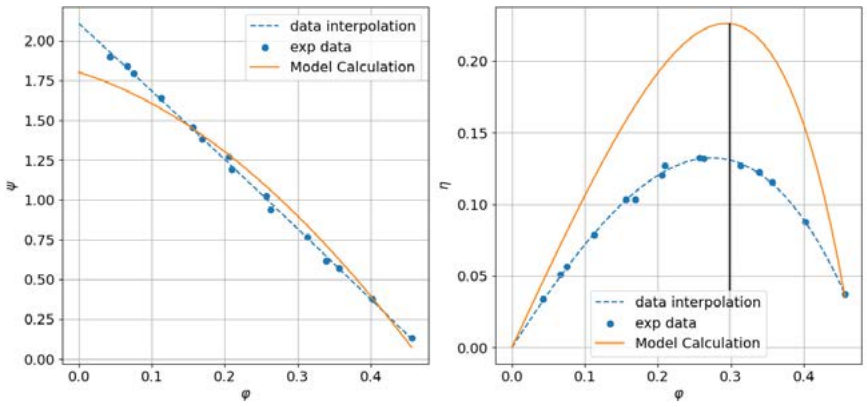

Figure 4.4. Computed pump performance and comparison to experimental data

Overall, the analytically derived $\psi = f(\varphi)$ curve (Figure 4.4) fit closely with experimental data. The predicted efficiency of the pump is overestimated because of neglected losses. However, the optimal flowrate of the pump is accurately captured.

Applying the same methodology to the remaining pump configurations demonstrates how channel geometry influences overall pump performance.

5. CHANNEL GEOMETRY INFLUENCE

In equation (2.3), the influence of the channel geometry is reflected in r_c, the mean channel radius of the pump, and in the loss coefficient K_p. Both parameters exhibit similar trends, decreasing from configuration A to configuration E (Figure 5.1).

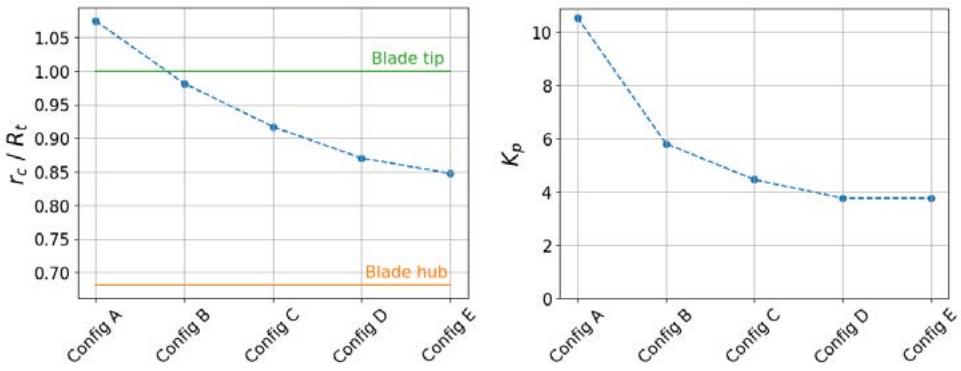

Figure 5.1. r_c and K_p values for each configuration

Variations in the channel geometry also affect the pump's efficiency curve. Figure 5.2 illustrates that configurations with smaller r_c exhibit higher maximum efficiency and a larger optimum flowrate, with an asymptotic trend observed around configuration D. The tendencies are consistent with both experimental and analytical results. A slight decrease in η_{max} is observed for configuration E, which can be attributed to the difference in pressure

resulting from the lower rotational speed, leading to a larger measurement error in the pressure sensors. This asymptotic behaviour around configuration D can also be seen in the variations of K_m (Figure 5.3).

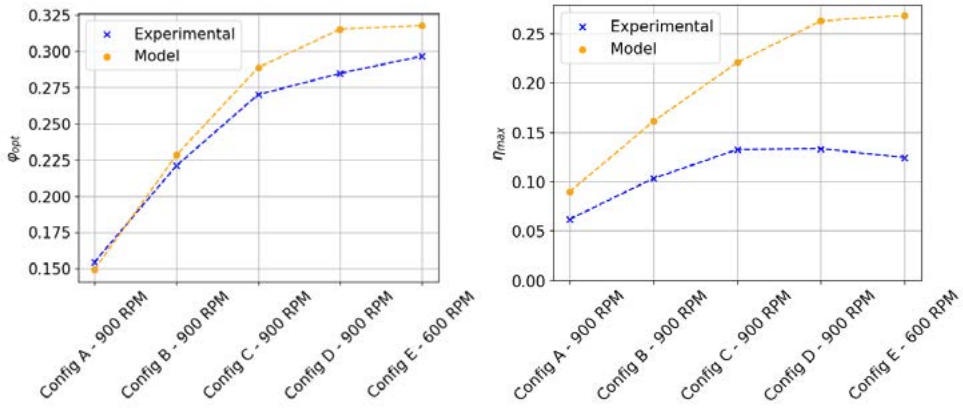

Figure 5.2. η_{max} and associated flowrate coefficient for each configuration

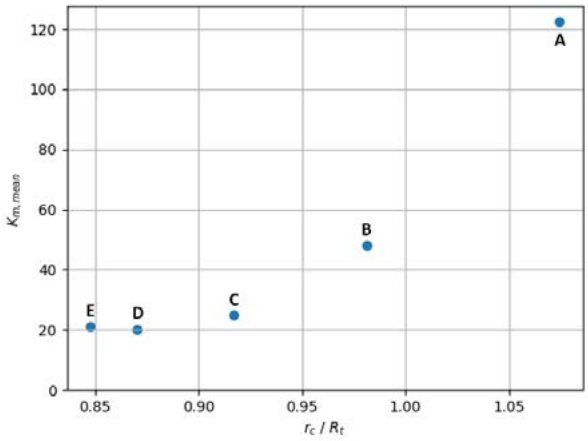

Figure 5.3. Mean K_m calculated for each configuration

6. CONCLUSION

This study provided further insight into the influence of side-channel geometry on the performance of regenerative pumps, with particular focus on the empirical coefficients of the model developed by Badami and Mura [1], based on the earlier work of Wilson et al. [6]. The loss coefficient K_p and the geometric coefficient k were estimated using CFD simulations, enabling the subsequent computation of the recirculation loss coefficient K_m. The model's efficiency predictions did not accurately reproduce the absolute efficiency

values due to neglected losses, but they provided a good estimation of the optimum flowrate coefficient when compared with experimental data.

In the present study, leakage effects were neglected and the coefficient k was assumed constant. Future work will address the role of mechanical clearances in the pump, aiming to refine the characterisation of their impact on internal flow dynamics and overall performance, while also examining the variability of k through CFD simulations.

Abstract.

Electrification in mobile hydraulics, particularly for material handling applications like electric forklifts, demands external gear pumps capable of reliable operation at very low speeds, high pressures, and elevated temperatures. The low-speed requirement arises from the low-flow needs of the hydraulic system. However, the operational speeds required by material handling applications often fall below the current minimum speed limit for external gear pumps (typically 500 rpm). This can lead to insufficient lubrication of tribological contacts, excessive wear of pump components (e.g.: bearings and gears), and significant volumetric losses. Bosch Rexroth has addressed these low-speed challenges in external gear pumps through the development of specialized low-speed characterization parameters and ongoing research into various pump optimization methodologies. This paper is a comprehensive compilation of low-speed operation requirements and challenges (e.g.: volumetric losses and wear), low-speed pump performance characterization parameters available with Bosch Rexroth, and ongoing research to address low-speed challenges (e.g.: surface coating technology). The paper introduces and explains two parameters to characterize the low-speed behaviour of external gear pumps: “zero delivery speed” and “hydrodynamic speed limit”. Zero delivery speed defines the minimum operating speed of the pump at which the theoretical flow equals volumetric losses. Hydrodynamic speed limit describes the operating speed of the pump corresponding to lubrication regime change from mixed film lubrication regime to hydrodynamic lubrication regime.

The research topics explored in this paper offer practical solutions to optimize external gear pumps for low-speed operation in mobile machinery. These studies directly address the wear on bearing and gear faces, and volumetric loss associated with low-speed operation of external gear pumps.

1. INTRODUCTION

Bosch Rexroth is one of the world's leading suppliers of drive and control technologies, significantly impacting the development in the industrial hydraulics sector. The company's core focus areas span mobile and industrial applications, factory automation, and digitization and software development, providing comprehensive solutions that integrate electric drives and valves, linear motion technologies, and hydraulics. Bosch Rexroth's extensive product portfolio encompasses hydraulic pumps, motors, valves, cylinders, and power units, catering to diverse industrial and mobile machinery requirements.

Hydraulic systems are integral part of mobile machinery deployed in agriculture, material handling, construction, and mining, to convert energy into fluid power and then into mechanical energy, enabling various actuators to produce force or motion. A typical hydraulic system comprises of a power source (e.g.: batteries), drive (e.g.: servo motors), pump, control elements (e.g.: valves), actuators (e.g.: cylinders, hydro motors), auxiliary components (e.g.: filters, accumulators), and a working medium (e.g.: hydraulic oil). A hydraulic system can either have a mechanical-hydraulic drive system where an internal combustion engine is used to drive the pump, or an electric-hydraulic drive system where an electric motor is used to drive the pump. Hydraulic systems are currently undergoing transformational change towards electrification where an electric-hydraulic drive system replaces the conventional mechanical-hydraulic drive system, which ensures improved energy utilization and reduced air and noise pollution. This is primarily driven by the electrification trends in non-road mobile machineries [1]. The material handling sector is in the forefront of electrification and has undergone much electrification in last decade, especially smaller forklifts, and the trend is continuing to bigger forklifts and reach trucks.

Applications such as lifting at very low speeds or idle machine operation require hydraulic systems capable of generating low flow rates while keeping the working pressure on the desired level. Electric-hydraulic drive systems, which utilize electric motors, can operate effectively at low speeds [2] compared to internal combustion engines. To manage low-flow criteria, traditional valve control systems are often implemented. These systems deploy additional valves to regulate flow, but this approach increases system complexity and cost. Furthermore, the energy losses associated with these valves significantly reduce the overall hydraulic system efficiency [3].

An alternative is a pump-controlled system that employs a pump capable of operating efficiently at low speeds, thereby eliminating the need for additional valves. External gear pumps (EGPs) are widely used in hydraulic systems due to their low cost, and simple and compact design. However, continuous operation of EGPs for electric-hydraulic drive systems under low-speed conditions implies significant challenges, including operating points with reduced volumetric efficiency and wear of components due to inadequate lubrication.

The objective of this paper is to:

1. Present the challenges and requirements from low-speed mobile machinery applications emerging due to electrification of hydraulic systems.
2. Evaluate the current capabilities of Rexroth EGPs under low-speed conditions to highlight the challenges.

3. Elaborate potential design optimizations to meet future market requirements in the electrified mobile machinery sector.

This paper compiles a set of operational requirements for EGPs operating at low speeds, specifically derived from mobile material handling applications. The work then investigates the low-speed performance of these pumps. To evaluate the minimum operational speed limit and to identify the lubrication regime corresponding to operating conditions, two parameters will be described– "zero delivery speed" and "hydrodynamic speed limit". Variations of these results with operating conditions (e.g.: speed, pressure, and temperature) are presented to illustrate the application of these parameters in low-speed performance analysis. Subsequently, the key challenges inherent in low-speed EGPs operation and their potential causes are identified. Finally, this paper consolidates relevant research addressing these challenges.

The paper concludes by synthesizing the findings and identifying directions for future research. By providing a comprehensive analysis of low-speed behaviour and presenting concrete optimization strategies, this paper aims to promote the broader adoption of EGPs in a wider range of electrification applications, thus paving the way for more efficient and reliable solutions.

2. EXTERNAL GEAR PUMPS AND LOW-SPEED OPERATION: STATUS QUO

The previous section introduced the integration of EGPs into electric-hydraulic drive systems. This section will delve deeper into EGPs, exploring the applications, the challenges, and the specific requirements for their operation under low-speed conditions.

2.1. External gear pumps

EGPs are positive rotary-displacement pumps. Meshing of drive and driven gears creates a low-pressure region at the suction side to which working fluid enters and is carried along with gear teeth and squeezed out at the outlet side. **Figure 1(b)** is the exploded view of an EGP with the major components highlighted. Two pairs of bearing and sleeve, housing, drive and driven gear, and covers constitute an EGP. EGPs stand out for their:

- Simple, robust and compact design.
- High volumetric efficiency and power density.
- Broad operational speed capabilities (500-6000 rotations per minute (rpm)) depending on pump size and pressure (0-280 bar).
- Low cost and maintenance.

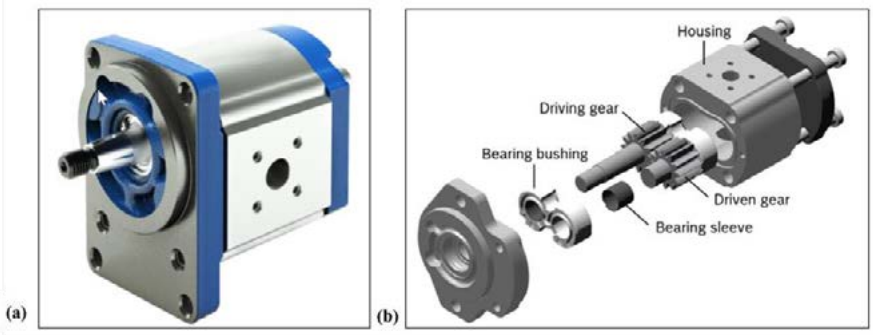

Figure 1: (a) Picture of a Rexroth external gear pump, (b) external gear pump components

Rexroth EGPs are widely used across diverse applications, particularly due to the low-noise operation achieved through their Silence and Silence Plus technologies, even under high-pressure conditions. While these pumps typically operate across a broad speed range, from 500-6000 rpm (for 1 cubic centimetre (ccm) pumps), many mobile and industrial applications specifically utilize pumps with displacements ranging from 7-28 ccm, where the operational speed range is often constrained to 500-4000 rpm. Anything below 500 rpm is treated as a low-speed requirement. The next section evaluates the general low-speed requirements from electrified mobile machinery applications.

2.2. Low-speed operation of external gear pumps: Application, Requirements, and Challenges

The demand for low-rotational-speed pumps is prominent in electrified material handling applications, which includes reach trucks, forklifts, scissor lifts, mobile cranes etc. **Figure 2** depicts a general speed-load diagram (or duty cycle) for EGPs in material handling application, where a significant portion of EGPs operation occurs at 100-300 rpm for short durations, even with intermittent pressures up to 280 bar. All these requirements exist within a demanding product lifecycle of 20000 operating hours for the pump. Apart from the mentioned conditions, it is well documented that the start-stop operations of the system pose significant threat to mechanical components like bearings [4]. EGPs have the capability to meet these requirements for short durations or limited load cycles, but continuous operation under low-speed conditions is to be investigated. The combination of low speed (below 500 rpm), high pressure (above 250 bar), and long and continuous operation (20000 operating hours) defines emerging low-speed requirements in the electric forklift market. These low speeds are crucial for tasks like exact positioning of loads, stacking, and automated movements, highlighting the need for highly precise movement and fine control of the forks. But most EGPs are not designed for continuous operation under such load collectives in the electrified forklift market; this is where active research is required.

Beyond material handling, the necessity for low rotational speed extends to applications like agriculture and construction demanding precise movements and control of actuators. Agricultural machinery requires precise planting and harvesting, where forward speed must be matched to implement function and ground conditions. Furthermore, road construction

equipment exemplifies this requirement, as paving and compacting demand consistent, low forward speeds for optimal material laydown and compaction density, effectively requiring machines to "crawl."

Figure 2 highlights the need for both low rotational speed operation and high rotational speed operation, under varying pressures, which are prevalent in material handling and agriculture applications that typically utilize fixed displacement pumps. Other pumps most used in mobile machinery applications include internal gear pumps and axial piston pumps. While internal gear pumps demonstrate comparable performance at lower speeds [5], EGPs surpass them in high-speed operation. Axial piston pumps, though capable, are generally costly and noisy to serve as a viable alternative to EGPs. Furthermore, axial piston pumps are more susceptible to oil contamination, posing an additional challenge compared to the more robust EGPs. Among the available options, EGPs emerge as the most suitable choice for the applications that require both low-speed and high-speed capabilities, specifically due to their cost effectiveness and simple construction.

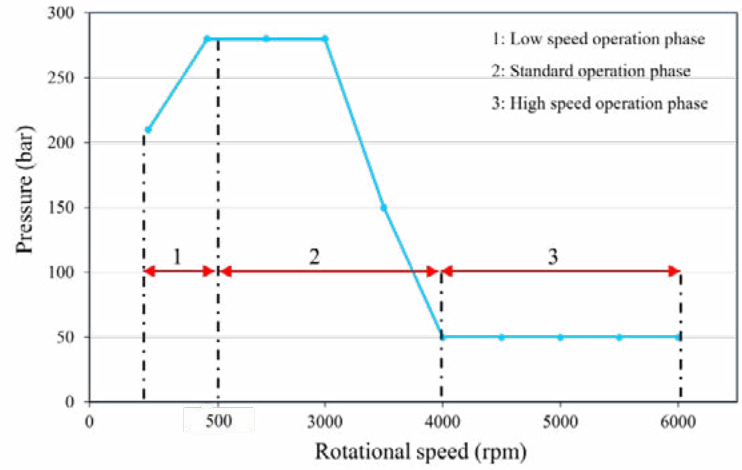

Figure 2: Example of a specific speed-load diagram for external gear pumps in material handling application

In short, EGPs have considerable potential to meet new requirements from mobile machinery application. Electrification of mobile machinery require pumps with both low-speed and high-speed capability. Pumps are expected to operate continuously under low-speed and high-pressure conditions. This brings new challenges and opportunities for external gear pump. This opens the possibility and requirement to study and optimize the low-speed behaviour of EGPs.

3. LOW-SPEED OPERATION: CHALLENGES

The preceding section focused on EGPs, and requirements for low-speed operation. The subsequent paragraphs will detail the specific challenges that arise during low-speed operation. Two major challenges are identified through literature review, field experience, and pump tests: volumetric losses inside the pump and wear of the pump components.

3.1. Volumetric losses

Volumetric losses describe the flow loss from the pump through internal leakage paths. Major internal leakage paths include the gap between housing and gear teeth tip, through gear flank contact region, between bearing face and gear face and between bearing contact faces. Internal leakage paths reduce the pump's net flow rate, thereby decreasing volumetric efficiency. Higher volumetric loss limits the minimum operating speed of the pump as the theoretical flow rate of the pump will equal the volumetric loss of the pump.

3.2. Wear of components

It is a fundamental principle that the flow rate from an EGPs is directly proportional to its operating speed. Consequently, at very low speeds, the resulting flow rate is significantly reduced. Low flow rate affects the lubrication and cooling of pump components. Apart from low flow rate, the hydrodynamic force generated by the rotation of the shaft is not sufficient to ensure a hydrodynamic lubrication regime between tribological contacts (explained in next section). During low-speed operation, the pump will be operating in mixed film lubrication regime which accelerates the wear of components. Along with lubrication, the pump working medium (oil) carries the chips generated due to the surface contacts inside the pump and prevents further wear or crack formation in pump components. Consequently, low flow rate leads to component wear, with bearings and gears being particularly susceptible. Abrasive and adhesive wear are a well-documented tribological phenomenon [6], which significantly diminishes the endurance life of these components and of the pump. Especially, continuous operation under low-speed conditions has been observed to cause partial removal of the polymer layer from polymer sleeves.

Apart from volumetric losses and wear, low flow rate leads to an elevated local pump temperature (i.e., the temperature of the working fluid inside the pump) as the cooling rate is directly proportional to flow rate. This elevated temperature further reduces the working fluid's viscosity or can cause permanent damage, such as oil degradation [7] thereby intensifying the lubrication deficiency. This creates a destructive cycle that continues until noticeable damage to the pump occurs**.**

In conclusion, most challenges observed during the low-speed operation of EGPs are due to volumetric losses, and wear of the components.

4. VOLUMETRIC LOSS: EVALUATION AND CHARACTERIZATION METHODOLOGY

The preceding section underscores challenges during low-speed operation and the need to investigate volumetric loss of the pump. Addressing these requirements requires testing capabilities and matured evaluation methodologies. The following section explains:

- Testing capability to measure and calculate flow rate and volumetric losses (Volumetric performance investigation test)
- Evaluation of low-speed performance (Volumetric loss characterization, zero delivery speed (hereafter ZDS))

Volumetric efficiency (η_{Vol}) describes the capability of the pump to deliver a flow rate close to its theoretical displacement, indicating the quantity of internal fluid leakage (Q_l in litre

per minute (lpm)). Volumetric efficiency is calculated from the theoretical flow rate (Q_{th}, in lpm) and real or measured flow rate (Q_{real}, in lpm). The measured flow rate is the flow rate generated by the EGPs during the operation. Theoretical flow rate is calculated from rotational speed (n, in rpm) and theoretical flow (V_{th}, in litre per revolution) as:

$$Q_{th} = n \times V_{th} \tag{4.1.1}$$

Volumetric efficiency (η_{Vol}) is calculated as:

$$\eta_{Vol} = \frac{Q_{real}}{Q_{th}} \times 100\ \% = \left(1 - \frac{Q_l}{Q_{th}}\right) \times\ 100\ \% \tag{4.1.2}$$

Volumetric losses reduce the real flow rate of an EGPs, leading to elevated temperatures and reducing the flow available for operating the working hydraulic components like hydraulic cylinders. These losses are approximately independent of rotational speed but highly dependent on operating pressure [8]. At low-speed operation, the real flow rate from the pump is inherently small and volumetric losses further diminish the performance of the pump. Therefore, accurately monitoring and characterizing a pump's volumetric losses is crucial for understanding its low-speed behaviour, necessitating mature testing and characterization methodologies.

4.1. Volumetric loss: Testing facility

Test benches capable for the measurement and recording of operating speed, operating pressure, flow rate, torque loss, and suction and outlet temperature are used to calculate results including volumetric efficiency, and volumetric losses. The same test benches are used to derive ZDS and hydrodynamic speed limit (hereafter HSL). The test bench includes a servo motor (e.g.: 45 kW for 16 ccm pump), a coupler to attach pump with motor, flow meter, rotational speed sensor, suction and outlet temperature sensor, pressure relief valve and an external leakage sensor. The test benches can test pumps from wide range of sizes (e.g.: 1 ccm to 45 ccm), wide range of pressure (e.g.: 0 to 300 bar) and temperature (e.g.: 100 °C). Testing is conducted on different batches and different number of pumps to ensure statistical confidence.

4.2. Volumetric loss characterization: Variation with pressure and temperature

Volumetric losses, flow rate, and volumetric efficiency are derived from the test bench data. **Figure 3(a-c)** presents the volumetric losses, flow rate and volumetric efficiency characteristics for different temperatures and pressures (P), keeping the operational speed constant. From **Figure 3(a)** it is observed that the maximum volumetric loss occurs in the medium pressure range. It is expected that volumetric loss of an EGPs will increase with increase in pressure, because of the higher-pressure gradient between suction and pressure side. However, the volumetric losses reduce from medium pressure to high pressure. This is primarily due to the process of "run-in", which every pump undergoes during initial operation. Run-in is the process of deepening the leakage path between gear teeth tip and housing wall during the initial operation of the pump in high pressure condition. Run-in occurs due to the bending and misalignment of gears (towards suction side) at high pressure operation. This causes excessive material removal from the suction side housing wall, and closing the leakage path for selected "run-in" pressure (usually 10% above the maximum operating pressure). For operation under lower pressures of the pump, volumetric efficiency will be reduced due to the enlarged leakage path. However, as the gear starts to bend or

misalign towards suction side due to higher pressure, the leakage path created by run in process is being closed and this phenomenon enhances the volumetric efficiency. The closing of above-mentioned leakage gap happens only for "Run-in" pressure. As a drawback, the flow and volumetric efficiency will be maximum only at run-in pressure compared to other pressure conditions. This is the reason for smaller volumetric efficiency and higher volumetric losses at mid-pressure range. The closure of run-in track due to high pressure is called passive radial gap compensation.

Figure 3(a) also shows the impact of temperature on volumetric losses. Comparing the results for 50 °C and 80 °C, a significant increase in volumetric loss is observed with increase in temperature. The maximum volumetric loss at 80 °C is more than twice that at 50 °C. As temperature increases, viscosity of oil decreases and reduction in viscosity leads to higher volumetric losses.

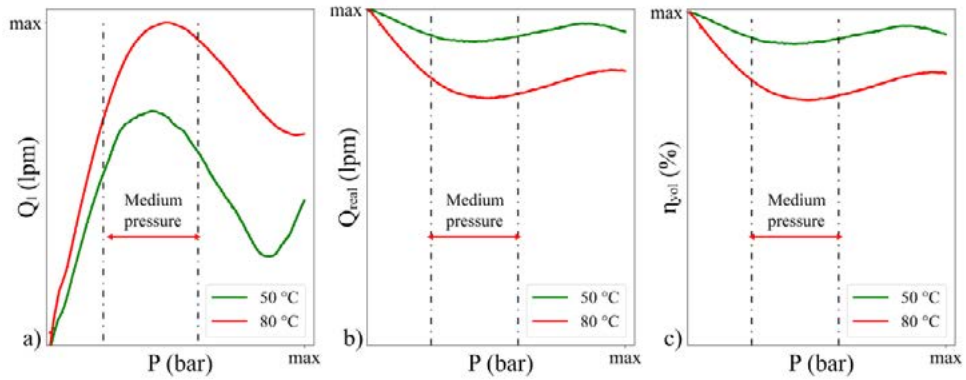

Figure 3: Variation of (a) volumetric flow loss, (b) flow rate, and (c) volumetric efficiency with pressure and temperature

Figure 3(b) and Figure 3(c) discusses the flow rate variation and volumetric efficiency variation with temperature and pressure. Flow rate and volumetric efficiency attains a minimum value at medium pressure range and maximum is observed during low- and high-pressure operation. With respect to temperature, a considerable drop observed at elevated temperature cases. The findings are aligned with volumetric loss findings as volumetric losses are maximum at medium pressure cases and minimum at low- and high-pressure cases, and volumetric loss increases with temperature. The observed results clearly indicate that medium pressure and high temperatures are the critical operating conditions for EGPs. These behaviours are valid for all modern external gear units using passive radial gap compensation over "run-in track".

4.3. Definition and calculation of zero delivery speed (ZDS)

Volumetric loss is important as it restricts the minimum operational speed of the pump. Understanding the minimum possible speed by the EGPs is required to define the operating boundary conditions. In this context, ZDS is the rotational speed at which the pump is operating without any measurable flow for a defined pressure and temperature. ZDS helps to identify the lower speed boundary for an EGP. Below ZDS, the volumetric losses from the pump equals flow from the pump and hence the pump is unable to produce any measurable flow at the outlet.

The calculation of ZDS for a given temperature and pressure, is derived from the flow rate - speed curve, for a fixed pressure and temperature condition as depicted in **Figure 4**. The speed (x-axis) corresponding to zero flow (y-axis) is calculated from the experimental data. The intercept point represents the state of no flow though the rotational speed of the pump is not zero.

ZDS is proportional to the flow capabilities of the pump. A pump with higher outlet flow (or with low volumetric losses) can provide flow at lower speeds. Flow rate and thereby ZDS is influenced by both operating temperature and pressure.

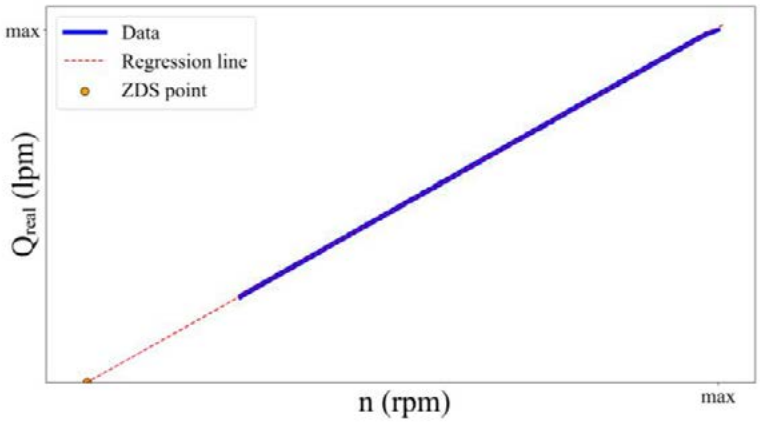

Figure 4: Calculation zero delivery speed from the flow versus speed curve

Figure 5 presents the ZDS variation with pressure for two temperature cases. As depicted in **Figure 5**, the variation of ZDS with pressure exhibits a parabolic profile, with its peak observed in the "medium pressure" or "centre pressure" range. This behaviour is consistent with the pump volumetric efficiency, flow rate, and volumetric loss characteristics, as shown in **Figure 3(a-c)**. The influence of temperature on ZDS is also presented in **Figure 5**. An increase in operating temperature leads to a reduction in flow rate, consequently elevating the ZDS. **Figure 5** conveys that at medium pressure and high temperature cases, pump should be run at higher speeds to have flow from the pump.

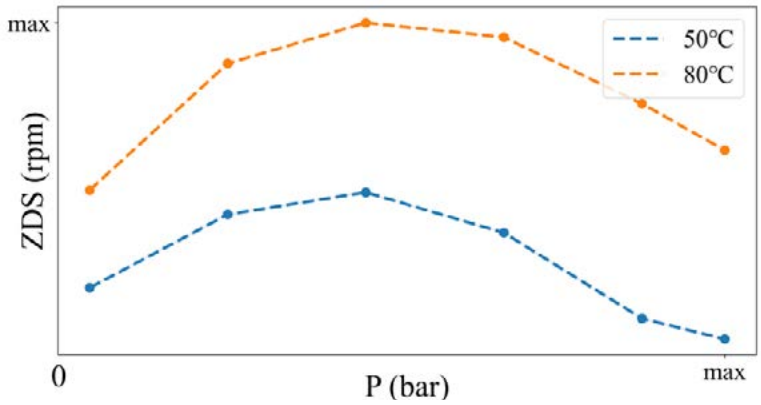

Figure 5: Variation of zero delivery speed with pressure and temperature

5. WEAR: EVALUATION AND CHARACTERIZATION METHODOLOGY

Apart from volumetric losses, wear is identified as a challenge during low-speed operation. The following section details about the characterization and evaluation methodology for wear.

Major tribological contacts of a pump include that between housing and gears, gears and bearings and between shaft and sleeve. During operation, the pump components and these tribological contacts are immersed in working oil which acts as the lubrication medium. Depending on the operating parameters like rotational speed, pressure, oil viscosity and temperature, a pump could be operating under boundary lubrication regime, mixed lubrication regime, or hydrodynamic lubrication regime. Hydrodynamic lubrication regime is characterized by a thick lubrication oil film between tribological contacts and ensures minimum contact wear during operation, while mixed film lubrication regime is characterized by thin film lubrication oil film, and metal to polymer contact between tribological contacts. Components operating under mixed film lubrication could encounter high wear and lubrication issues. The transition from mixed film lubrication to hydrodynamic lubrication is identified as the transition speed point, and adapted Stribeck curve is used to identify the transition point and lubrication regime [9]. Stribeck curve is usually deployed for bearing lubrication regime identification, but the concept is, under simplification and assumptions, applicable to pumps even though a pump consists of multiple tribological contacts including gear and bearings. The Stribeck curve for a pump discusses about the overall torque loss from the pump, which includes torque loss through all the tribological contact and viscos loss due to working oil. Transition speed from the Stribeck curve describes the minimum torque loss point for the pump, it doesn't mean all the components of the pump will be working in the hydrodynamic lubrication regime if the operating speed is above transition speed. At low-speed operating conditions, the pump speed could be below the transition speed point, and this will induce wear of the components and eventual failure of the pump. The load cycle capability of the pump for continuous operation under low-speed is restricted by the mixed film lubrication regime and the wear associated with the lubrication regime.

Above sections detailed about the importance of transition speed point and wear associated with mixed film lubrication regime. Extracting transition speed point from the Stribeck curve for the pump presents practical challenges. To address this, the paper is proposing a model that simplified the Stribeck curve into a function of torque loss and rotational speed by fixing operating pressure and temperature. The transition speed between mixed film lubrication regime and hydrodynamic lubrication regime is identified from this curve. This speed is defined as HSL. **Figure 6** represent a simplified Stribeck curve with lubrication regime and HSL illustrated.

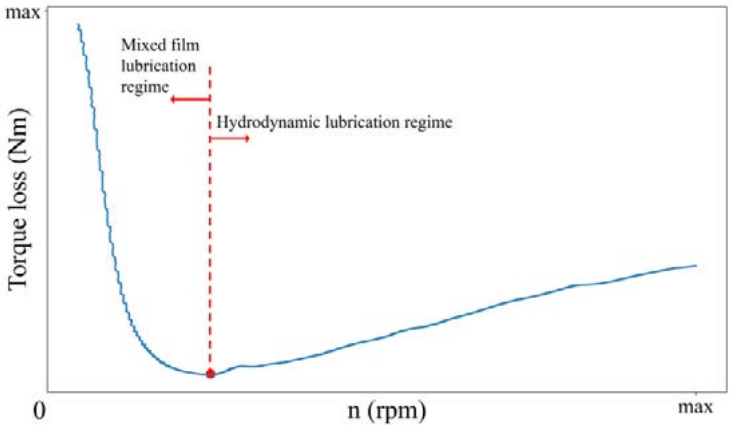

Figure 6: A simplified version of Stribeck curve with lubrication regime distinguished

5.1. Definition and calculation of hydrodynamic speed limit (HSL)

HSL is a parameter to determine the speed corresponding to minimum torque loss. Minimum torque loss directly correlates to minimum coefficient of friction (friction due to surface contact and viscosity of oil) and thereby to the speed at which the wear is minimum. Hypothetically pumps operating above the HSL could be under hydrodynamic lubrication regime and have better durability life in the long run. However further research is required to evaluate this hypothesis. It is possible that the pump components will be operating under different lubrication regimes even though the overall torque loss from the pump is corresponding to hydrodynamic lubrication. **Figure 7** shows a simplified Stribeck curve for EGPs. **Figure 7** illustrates HSL value for different pressure cases. **Figure 7** show a steep increase in torque loss value as operating speed falls below HSL. Continuous operation of pump under mixed lubrication regime will significantly affect the pump durability life, and for continuous operation, HSL is the minimum speed condition for the pump.

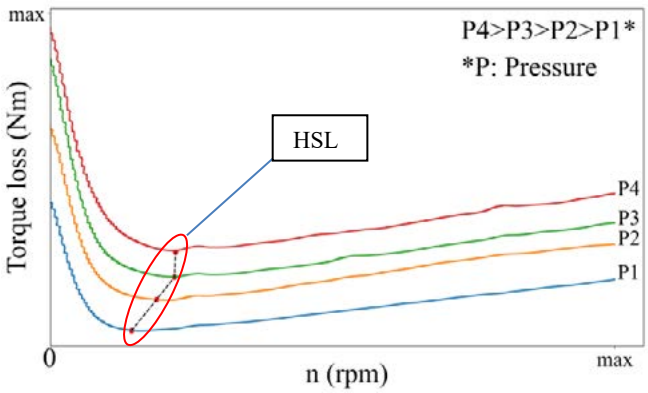

Figure 7: Torque loss versus speed curve for different pressures

HSL is a function of the operating pressure, temperature and viscosity of working medium. **Figure 8** presents the variation of HSL with pressure for a different temperature case. As the pressure increases, the hydrodynamic force required to generate an oil film between the

components also increases. The shaft rotation speed and hydrodynamic force generated are proportional. At higher pressure cases, higher hydrodynamic force is required to ensure hydrodynamic lubrication and operating speed is required to generate this force. Hence the HSL increases with pressure.

Figure 8 illustrates impact of temperature on HSL. An increase in operating temperature leads to a reduction in fluid viscosity, consequently reducing the generated hydrodynamic force and thus elevating the HSL required for hydrodynamic lubrication.

The last two sections described the various low-speed characterization parameters available including testing capabilities. It is observed that the ZDS and HSL ranges from 400 to 750 rpm (for 14 ccm external gear pump with passive radial gap compensation). However, the low-speed applications demand operational speed to be below 400 rpm. The decision if the pump is suitable for low-speed operation condition need to be evaluated carefully by considering the requirements and results from parameters like ZDS and HSL.

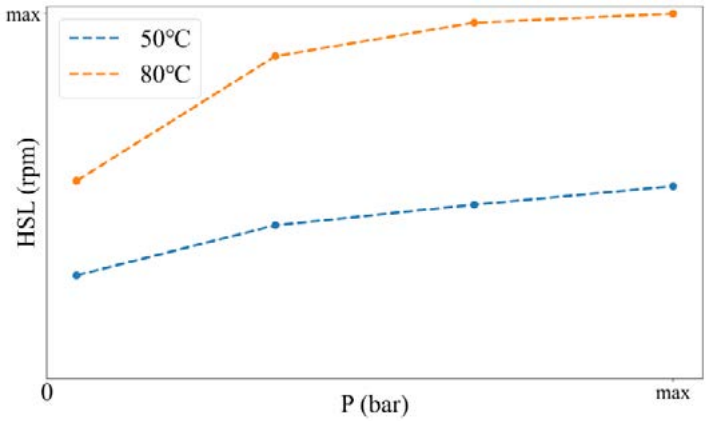

Figure 8: Variation of hydrodynamic speed limit with pressure and temperature

To study the wear performance and durability life of pump and components under low-speed operation, specific tests with focus on continuous operation of the pump and its components are developed. These tests are described in the pump durability testing section.

5.2. Wear measurement: Pump durability test

Pump durability tests are used to study the performance of the pump during and after continuous operation. These tests help to evaluate the wear on components, and variation in performance of the pump with continuous operation. Depending on the study requirements, a loading cycle is formulated for every test. This loading cycle will be executed for long periods of time (e.g.: 1000 hour) after which the pump will undergo through evaluation including performance, and tribological assessments. Tests are completed using a volumetric performance investigation test bench. Pressure, flow, external leakage and torque are continuously monitored and recorded for further analysis.

All the pumps that undergo durability test need to be investigated for their tribological parameters, including measurement of wear and microstructural analysis.

6. LOW-SPEED OPERATION: OPTIMIZATION MEASURES

Advanced research into the low-speed performance of EGPs is ongoing at scientific communities. These research addresses two critical issues: optimizing the pump to reduce volumetric losses, and enhance the wear robustness and reduce friction between components. The subsequent paragraphs detail some of the key research initiatives.

6.1. Pump optimization measures to reduce volumetric losses

High volumetric losses directly contribute to high ZDS for a pump. This limits the minimum operating speed for the pump and forces the pump to operate at higher rotational speeds. Following section compiles the research on this.

6.1.1. Precise bearing technology

Polytetrafluoroethylene (PTFE) based metal-polymer sleeves currently represent the state-of-the-art for radial bearings in EGPs. However, these metal-polymer sleeves exhibit large inner diameter tolerance fluctuation, making it challenging to achieve tight dimensional control. This difficulty is partly due to the inability to machine polymer sleeves post press-fitting into the bearing housing. Furthermore, recent research has highlighted the adverse environmental impacts associated with PTFE products.

Alternative solutions, such as bi-metal sleeves and Polyether Ether Ketone (PEEK) sleeves are actively evaluated. These offer the distinct advantage of allowing post-installation machining, enabling much tighter control over the inner diameter tolerances of the bearing. Achieving optimized clearance reduces the misalignment of gears [10];thereby mitigating stress on both the shaft and the sleeve, and also preventing creation of larger leakage paths between gear teeth tip and housing. Precise bearing technology can contribute to lowering the volumetric losses and thereby lowering the ZDS of the pump.

6.1.2. Radial gap compensation

Volumetric loss poses a significant challenge during low-speed pump operation, largely due to leakage across the radial gap between the housing and gear teeth tips. To mitigate this, novel designs actively reduce radial gap leakage. One promising approach involves incorporating a radial gap compensation element within the pump. This concept, state-of-the-art in internal gear pumps, dynamically adjusts the clearance between the gear teeth and the housing wall in response to operating pressure, thereby minimizing the leakage path [11]. **Figure 9** illustrates a proposed design featuring a radial gap compensation lid integrated into the pressure-side housing wall [12]. This lid is engineered to automatically adjust its position based on varying operating pressures. During high-pressure operation, the lid is pushed towards the gears, effectively reducing the clearance and thus dynamically controlling and minimizing volumetric loss through this pathway. Numerous iterations of this concept explore the optimal shape, position, and impact of the lid on internal leakage.

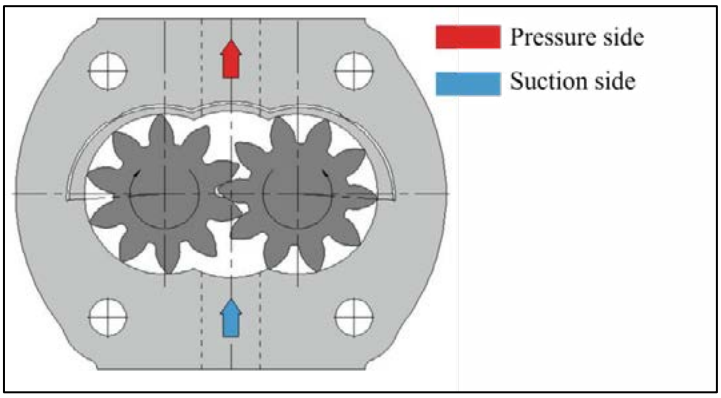

Figure 9: An example for radial gap compensation technology [12]

6.2. Enhancing the wear robustness and reduce friction between components

Enhanced wear robustness and reduced friction are crucial for improving both mechanical performance (e.g.: lower torque loss) and overall pump durability (e.g.: extended pump durability life). These improvements can be achieved through various methods, ranging from material property enhancements to advanced coating technologies. The subsequent section focuses on surface coatings that have demonstrated superior tribological properties – such as reduced wear, lower friction coefficients, and enhanced hardness – as documented in the literature.

6.2.1. Surface coatings for enhanced wear robustness of hydraulic components

Surface coatings are critical in tribology for reducing friction, mitigating wear, and enhancing the overall tribological performance of mechanical components [13]. For low-speed operation, wear on critical components like bearings and gears remains a significant challenge. Various coating materials, including Diamond-Like Carbon (DLC), Molybdenum Disulfide (MoS2), and Nickel-Molybdenum-Phosphide (Ni-Mo-P), are known to improve the tribological properties of coated parts [14] [15].

Specifically, applying DLC coatings to gears is documented to reduce friction at interfaces such as the gear-to-bearing contact and between the gear shaft and bearing sleeve. This friction reduction consequently minimizes torque loss and mitigates wear on these critical components. Moreover, reduced friction is expected to reduce the wear, enabling more prolonged and reliable operation under challenging low-speed conditions.

7. CONCLUSION

The electrification of mobile hydraulic applications, particularly in material handling, requires efficient electric-hydraulic systems capable of low-flow operation without traditional valving inefficiencies. This demands that EGPs operate effectively at low speeds, directly enhancing system efficiency and reducing costs. However, continuous operation (20000 operating hours) of these pumps at low speeds (< 500 rpm), high pressures (up to 280 bar), and elevated temperatures (80 °C) presents significant challenges, including volumetric losses and wear on bearings and gears.

This paper systematically addresses these requirements and challenges. The investigation utilized Bosch Rexroth's specific low-speed parameters: "zero delivery speed (ZDS)" and "hydrodynamic speed limit (HSL)". ZDS, a critical determinant of minimum pump operation, is significantly affected by temperature and pressure, increasing with temperature and following a non-linear (parabolic) curve with pressure. The HSL is crucial for minimizing torque loss and reducing component wear; operating below this limit drastically increases torque loss. Similar to ZDS, the HSL also rises with both temperature and pressure.

To overcome these low-speed challenges, the paper reviews and compiles practical, research-backed solutions. Specialized surface coatings are shown to directly mitigate wear, while advanced bearing technology and radial gap compensation offer promising approaches to minimize volumetric losses.

In conclusion, this work synthesizes the essential requirements and operational challenges of low-speed EGPs. It further highlights Bosch Rexroth's capabilities for their thorough investigation and identifies practical solutions for optimizing performance. Integrating these insights provides a clear path for EGPs to reliably and efficiently meet the stringent low-flow demands of electrified mobile hydraulic applications. This advancement will enable more sustainable and cost-effective electrified material handling systems.

Nandakumar P S received the bachelor's degree in Mechanical engineering from Vellore Institute of Technology in 2020, and the master's degree in Energy engineering and management from National Institute of Technology-Calicut in 2024. He is currently working as an Engineer at the Advanced engineering department of Bosch Rexroth. His research areas include hydraulic systems with a focus on external gear pumps and thermo-fluid interaction.

Vishnudas Ramaswamy received the bachelor's degree in Mechanical engineering from Amrita School of Engineering in 2010, the master's degree in Fluids Engineering from the National Institute of Technology Allahabad in 2012 , and the philosophy of doctorate degree in Fluid Mechanics from the Indian Institute of Technology Madras in 201, respectively. He is currently working at the Advanced Engineering Department of Bosch Rexroth India Pvt. Ltd. His research areas include fluid power systems, fluid mechanics, computational fluid dynamics, and multiphase flow.

Stefan Kock received his Mechanical Engineering degree from the Technical University of Dresden, Germany, and his Ph.D. from RWTH Aachen University, where his research focused on wind turbine drive trains and torque measurements. He is currently Team Leader for Advanced Engineering for External Gear Units at Bosch Rexroth. His research areas include drive train technology, mechatronic systems, fatigue assessment, finite element method (FEM), and fluid power drives.

Martin Laube received his Diploma degree as Dipl.-Ing. (univ.) in mechanical engineering from the Technical University of Munich (TUM) in 1996. He specialized during his studies in the field of Design and Development with a focus on machine elements, vehicle technology and fluid technology. He started his industrial career in 1996 as a development engineer for railway systems at Mannesmann Rexroth, Lohr a. Main. After holding various positions in sales and engineering for industrial applications at Mannesmann Rexroth and Bosch Rexroth (since 2001), he assumed the position of Engineering Director for Hydraulic Power Units, Manifolds and Systems at Bosch Rexroth AG in 2013. Since July 2024, he has been Vice President and Head of Product Area External Gear Units in the Business Unit Mobile Components at Bosch Rexroth AG.

Geometry-Aware Physics-Informed Neural Network: A Framework for Solving the Reynolds Equation with Starvation for Lubricated Contacts

Faras Brumand-Poor, Artem Konstantinov, Darren Lam Ming Hui, Eric Guntermann, Jakob Wirtz, Katharina Schmitz

RWTH Aachen University, Institute for Fluid Power Drives and Systems (ifas), faras.brumand@ifas.rwth-aachen.de

Abstract.

Machine learning has gained increasing attention in fluid power applications, particularly in condition monitoring and control. A promising development in this field is physics-informed machine learning (PIML), and specifically physics-informed neural networks (PINNs), which integrate governing physical laws directly into the training process. Unlike traditional networks, PINNs do not require data collection and can significantly accelerate computationally demanding simulations. This capability is valuable for studying lubricated contacts, such as seals in pneumatic valves, which operate pneumatic systems by controlling flow rate and pressure, and where accurate yet efficient modeling is essential. Seals are critical for maintaining pressure and preventing leakage; their malfunction can lead to costly failures, downtime, and environmental risks. However, seal behavior remains difficult to characterize due to the coupled hydrodynamic (HD) and elastodynamic (ED) effects within the sealing interface. Conventional elastohydrodynamic lubrication (EHL) simulations based on fluid-structure interaction models provide accurate insights. However, they are computationally expensive, limiting their usability for real-time or large-scale investigations. To address these challenges, this work extends a validated PINN framework for modelling lubrication behavior inside a pneumatic seal by introducing an unsupervised learning autoencoder (AE) to compress complex gap geometries into low-dimensional latent representations. The framework, consisting of a PINN, a loss balancing, and a hyperparameter tuning algorithm, has already been validated for modelling hydrodynamic lubrication simulations with transient phenomena and cavitation. The addition of the AE to the framework yields a geometry-aware PINN (GAPINN) capable of fast, accurate, and geometry-adaptive analysis of sealing systems, thereby enhancing the applicability of PIML in tribological research.

1. INTRODUCTION

Machine Learning has emerged as a promising class of numerous algorithms that can enhance different applications in fluid power, e.g., condition monitoring and control [1, 2].The field of physics-informed machine learning, with its novel class of data-free solvers, the so-called physics-informed neural networks, has shown great potential for accelerating distributed-parameter simulations with the integration of physical laws in the network and without the time-consuming collection of data [3–6]. Accelerating simulation, thus decreasing computational time, is especially relevant for investigating lubricated tribological contacts. One prominent example of such systems is a seal inside a housing and a counter surface, such as a pneumatic valve spool and a lubricant between the seal and the counter surface. Seals are usually less costly than other fluid power components, especially in pneumatic valves, but are crucial for the system. A non-functional seal might result in operational disruptions or a system failure, leading to expensive repairs, delayed production time, and possibly environmental hazards. Seals in fluid power systems are mainly responsible for maintaining operational pressure and preventing leakage. However, the operation of seals generates friction, causing a loss of overall efficiency, especially in pneumatic valves, which exhibit a substantial adverse effect due to increased friction on their dynamic behavior. Despite their significant role in fluid power components and systems, seal behavior is not completely understood due to the complex interactions of hydrodynamic and elastodynamic phenomena [7].

Elastohydrodynamic lubrication simulations or experiments are required to understand these tribological interfaces better. Experiments are rather time-consuming and costly due to the high measurement accuracy needed to obtain valuable information [8]. On the other hand, EHL simulations represent a different approach to obtaining a deeper understanding of these tribological systems by solving the Reynolds equation to compute the hydrodynamic pressure distribution and the deformation within the sealing interface. These EHL simulations primarily consist of a fluid-structure-interaction (FSI), which combines the hydrodynamic pressure buildup of the lubricant with a Finite Element Analysis (FEA) for the deformation. These FSI models provide accurate solutions but exhibit high computational costs [9, 10], which prevents real-time application or a detailed investigation of a significant number of operation points of a sealing system.

These limitations prevent optimal exploitation of sealings for fluid power systems and demand novel approaches for accurate and fast evaluation of different sealing system scenarios. PINNs represent a promising alternative to traditional EHL simulations since they incorporate the same underlying physical equations in the network training process and further solve the investigated scenario in a fraction of the time required by the EHL simulation [11]. Integrating physical laws also dismisses the necessity of data, which is not easily obtained for lubricated contacts, required for regular neural networks.

The first published work applying PINNs to the Reynolds equation was presented by Almqvist in 2021, demonstrating a fundamental implementation of PINNs for this equation [12]. More advanced approaches were later introduced by Zhao et al. and Li et al., who addressed the two-dimensional Reynolds equation for linear sliders and gas bearings, respectively [13, 14]. Rom was the first to develop a PINN capable of solving the stationary Reynolds equation in combination with the Jakobsson–Floberg–Olsson (JFO) cavitation model [15]. Building on this progress, Cheng et al. implemented a PINN framework that

solves the Reynolds equation using either the JFO or the Swift–Stieber (SS) cavitation model, incorporating three different multi-task learning strategies to balance the respective loss terms [16]. Recent work focused on the use of hard constraints to deal with the problem of cavitation [17, 18]. Further research was conducted on the application of hybrid PINNs, combining data-driven approaches and physical laws for the solution of the Reynolds equation [22, 23]. The prior work focused on stationary scenarios; Ramos investigated PINNs for solving the Reynolds equation with time-dependent height changes in journal bearings [25]. Rimon implemented a PINN to solve an elastohydrodynamic lubrication simulation using a simplified stationary one-dimensional Reynolds equation, without cavitation, and incorporating linear pressure-dependent sealing deformation based on the Lamé equation [27]. The mentioned studies focus either on stationary cavitation problems or dynamic problems without cavitation. Furthermore, most developed solutions do not focus on a PINN's ability to understand the investigated geometry. In the work of Rom, the eccentricity of the journal bearing was provided as an input to the PINN, thus adding some geometry-awareness to the PINN. To sum up, the current state of the art in PINNs for modelling hydrodynamic lubrication solves variants of the Reynolds equation; however, there has been little focus on implementing geometry-awareness in PINNs for such applications. The application of geometry-aware PIML has already been successfully used in deformation by implementing geometry-aware PINNs [32, 33] , or directly developing physics-informed graph neural networks (PIGNNs) [34-36].
In this work, a previously validated PINN framework (*ifas HD-Framework*) for seals [3-6] is used. The framework has been applied to solve the Reynolds equation, including transient cavitation modelling, surface roughness, and non-Newtonian lubricant, for interpolation and extrapolation tasks. Interpolation and extrapolation differ in whether the evaluated scenario was included during the training process. The framework has also been applied to solve deformation tasks [34]. The aim of the framework is to eventually model a complete EHL simulation with a PINN-based FSI structure. The hydrodynamic PINN in the framework requires geometric awareness to communicate with the deformation PINN; thus, the framework is extended with an unsupervised learning autoencoder that compresses the high-dimensional gap geometry of a pneumatic seal into a low-dimensional latent vector. This vector is passed to the PINN to create a geometry-aware PINN, which distinguishes itself from the prior framework by enabling the application to different, more complex, and more realistic sealing geometries.

2. HYDRODYNAMIC LUBRICATION – THE REYNOLDS EQUATION WITH CAVITATION MODELING

Elastohydrodynamic lubrication simulations are essential for analyzing wear, friction, and leakage in lubricated mechanical interfaces. These simulations investigate the dynamic interactions between lubricants and contacting surfaces, focusing on the computational modeling of surface deformations and the resulting hydrodynamic pressure within the contact area. They have proved to be pivotal for the design and optimization of tribological contacts across various industrial applications. The DDS (Dynamic Sealing Simulation) model is an advanced simulation framework that has been validated against experimental data under different operating conditions [6]. This model enlightens the complex interactions between a seal and its mating surface, emphasizing the lubricating film that separates them and significantly influences seal behavior. It employs the finite-element software ABAQUS

to simulate seal deformation under various operating conditions accurately, integrating the Reynolds equation through custom user subroutines to calculate hydrodynamic phenomena. This research encompasses the solution of the Reynolds equation as well as the simplification of the model by excluding surface deformation, contact mechanics, and friction. The objective is to study lubrication aspects without the added complexity of deformations. Given its rigorous consistency with experimental results, an accordingly simplified variant of the DDS model will serve as a benchmark for validating the solution of the Reynolds equation in this work.

The Reynolds equation (2.1), as integrated into the DDS model, is based on Osborne Reynolds' original formulation from 1886 and extended by the Jakobsson-Floberg-Olsson cavitation model. It is described as follows [5]:

$$\underbrace{\frac{v}{2}\frac{\partial}{\partial x}((1-\theta)(R_q\Phi^{\tau}+h))}_{Couette\ flow} - \underbrace{\frac{1}{12\eta}\frac{\partial}{\partial x}(\Phi^{p}h^{3}\frac{\partial p}{\partial x})}_{Poiseuille\ flow} + \underbrace{\frac{\partial}{\partial t}((1-\theta)h)}_{Transient\ term} = 0 \tag{2.1}$$

This extension introduces the cavitation fraction concept, represented by the variable θ [8]. The value of θ traditionally denotes the local volume fraction of the gas phase, ranging from zero (no cavitation) to one (complete cavitation). In this work, since a pneumatic system is examined, the cavity fraction is utilized to model the starved film height of the lubricant in the investigated gap, where 0 represents a filled gap and 1 represents an empty gap. The Reynolds equation describes the hydrodynamic pressure p and the cavity fraction (starved lubricant) θ in thin liquid films, accounting for the dynamic viscosity η , the relative velocity v between the contact surfaces, and the gap height h. The variables of time t and position x are also essential to its formulation. Additionally, the model incorporates the shear and pressure flow factors Φ^{τ} and Φ^{p} according to the work of Patir and Cheng [19, 20] allowing for the consideration of surface topography effects on lubrication. Said flow factors are finally complemented by the root mean square roughness R_q, culminating in a partial differential equation that assumes a crucial role in the analysis of lubricated contacts with incompressible fluids.

The Fischer-Burmeister equation (2.2), as employed by Woloszynski et al. [21], establishes the relationship between the p and θ:

$$p + \theta - \sqrt{p^2 + \theta^2} = 0 \tag{2.2}$$

The value of θ provides insight into the occurrence of a starved lubricant within the tribological contact, with the pressure dropping to zero (cf. (2.2)). The JFO cavitation model and its implementation make minimal assumptions about the physical mechanisms leading to a starved lubricant (cavitation), resulting in a non-zero cavity fraction. This allows the model to track lubricant distribution in tribological contacts with limited lubricant supply, such as grease-lubricated sealing contacts in pneumatic spool valves. In these cases, a non-zero cavity fraction indicates partial filling of the sealing gap. Both the Reynolds and the Fischer-Burmeister Equations are structured to equate to zero, establishing the groundwork for the computation of physics-based losses for neural networks, as will be demonstrated during this paper.

3. MATERIALS AND METHODS

3.1. *Hydrodynamic Lubrication and the Potential of Physics-Informed Neural Networks*

As introduced in Chapter 2, one essential mathematical tool for simulating the pressure distribution in lubricated contacts is the Reynolds equation. Numerical techniques like finite volumes, finite elements, or finite differences are usually used to solve tribological issues in situations like the Reynolds equation, where an analytical solution is not available. However, using numerical approaches frequently necessitates a significant amount of computing power and has proven to be very time-intensive. The solution may lie in the realms of PIML, which has recently shown considerable promise in tribology, facilitating notable advancements [10, 24].

To improve the depiction of phenomena like wear, lubrication, and friction, PIML, more specifically PINNs, incorporates models with physical principles to direct the learning process, in contrast to typical machine learning techniques that only use data-driven methodologies [10, 26]. PINNs employ a neural network for predictive purposes but are trained with applicable laws of physics by including residual terms derived from PDEs in the loss function [28]. Therefore, these models frequently produce results that are more accurate and reliable than those obtained using only data-driven approaches and are used in a variety of tribological applications, ranging from the anticipation of wear or damage to the assessment of lubrication conditions on hydrodynamic surfaces.

Like conventional neural networks, PINNs process inputs like position x, time t, and further case-dependent parameters. The network's output is produced after these input values are processed by the network's hidden layers that comprise a predefined number of neurons. Each neuron carries out a series of mathematical operations that culminate in a complex function, which is then characterized as the network's output.

Once the network has produced an output, the training commences, involving the computation of various supervised and unsupervised losses that are then utilized in the enhancement of neuron parameters, namely the weight and bias.

Figure 3.1 illustrates an exemplary PINN. The network depicted is a hybrid PINN consisting of three physics-informed and one data-driven components. The available data is employed to accelerate the convergence of the governing equations, thereby facilitating the attainment of a more accurate solution.

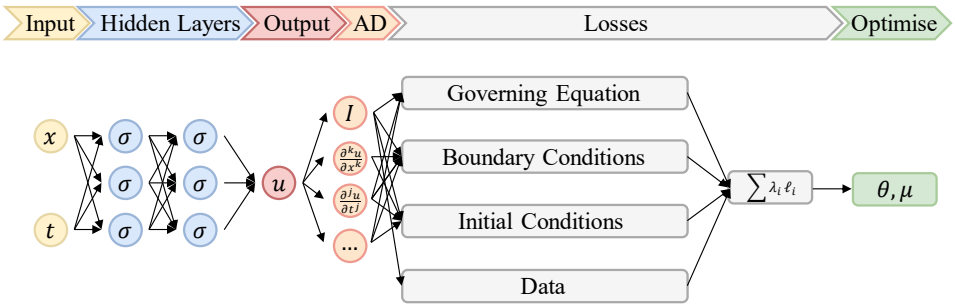

Figure 3.1: Schematic illustration of a PINN [3]

The residual loss (or Governing Equations-Loss, as depicted in Figure 3.1) coincides with the residuals of the governing physical equations, making this an unsupervised loss since there is no direct comparison to a reference value [29]. The evaluation of the loss is conducted at designated spatial and temporal locations, referred to as collocation points, by inserting the PINN's outputs at said points into the governing physical equations and determining the residuals. At this point, it becomes apparent why equations (2.1) and (2.2) must equate to zero (as mentioned in Chapter 2), because the residual between the PINN's output and the governing equations at specific collocation points can only be computed if the right side equals zero.

In addition to the residual losses, PINNs also rely on losses associated with boundary and initial conditions. The objective of said losses is to guarantee that the prescribed boundary and initial conditions for the partial differential equation are satisfied. The presence of a direct value comparison in this loss computation makes these two losses subject to supervisory control. The data loss term corresponds to the classical data-driven loss. Following the determination of the individual losses, the loss terms are then each multiplied by a weight factor and added together. Subsequently, the network parameters $\vec{\theta}$ are optimized so that the weighted loss sum is minimized.

3.2. The ifas HD-Framework

Having established the fundamental principles of hydrodynamic lubrication and the use of PINNs in this realm, the following section will present the structure of the ifas HD-Framework. For a more detailed description also regarding the parameter of the framework and the whole training process the reader is advised to refer to this work [3]. The ifas HD-Framework comprises three main pillars that are all implemented in the Python programming language: the HD-PINN, the Bayesian Optimizer from the Keras Tuner Library [30] and the Adaptive Moment Estimation Optimizer from the Keras Library [31].

The training in this framework begins by employing the Bayesian Optimizer to find the optimal hyperparameters (HP) for the HD-PINN. These include all the parameters that are necessary for the initial construction of the PINN. After that, the PINN computes the initial pressure and cavity fraction distribution for the given input and initializes the loss functions. The iterative body of the training process involves adapting the network parameters $\vec{\theta}$ by the Adam Optimizer based on the loss functions and a consequential recalculation of the pressure and cavitation distribution by the PINN. Once the desired number of epochs has been achieved, the training has completed, and the PINN's losses are transferred back to the Bayesian Optimizer to complete the final optimization of the hyperparameters for that training.

Contrary to previous studies, the HD-PINN in this work consists of a PINN that is preceded by an autoencoder. Figure 3.2 illustrates the novel hydrodynamic framework with the AE, which processes the sealing and counter surface's high-dimensional height profile, provided by the finite-element software ABAQUS, through a Python interface with the encoder to a low-dimensional latent vector consisting of n_{latent} height parameters. To validate the compression, the decoder reconstructs the latent space into a high-dimensional height profile, which is then compared to the original profile. Subsequently, the latent vector

$$\vec{h}_{latent} := \left[h_1, h_2, \dots, h_{n_{latent}}\right] \tag{3.1}$$

is passed to the hydrodynamic PINN in an input vector $\vec{\mathcal{P}}$

$$\vec{\mathcal{P}} := \left[\vec{x}, t, p_l, p_r, \theta_l, \theta_r, \rho, \eta, R_q, \Phi^\tau, \Phi^p, v, h_{lubricant}, \vec{h}_{latent}\right] \text{ with} \tag{3.2}$$

$$\vec{x} := [x_1, x_2, \dots, x_{200}] \tag{3.3}$$

which is then presented to each neuron of the first hidden layer.

Within each of the $n_{neurons}$ neurons in the n_{layers} hidden layers of the PINN, the respective inputs of a single neuron are multiplied by a weight w, summed up, and finally offset with the bias b of the current neuron.

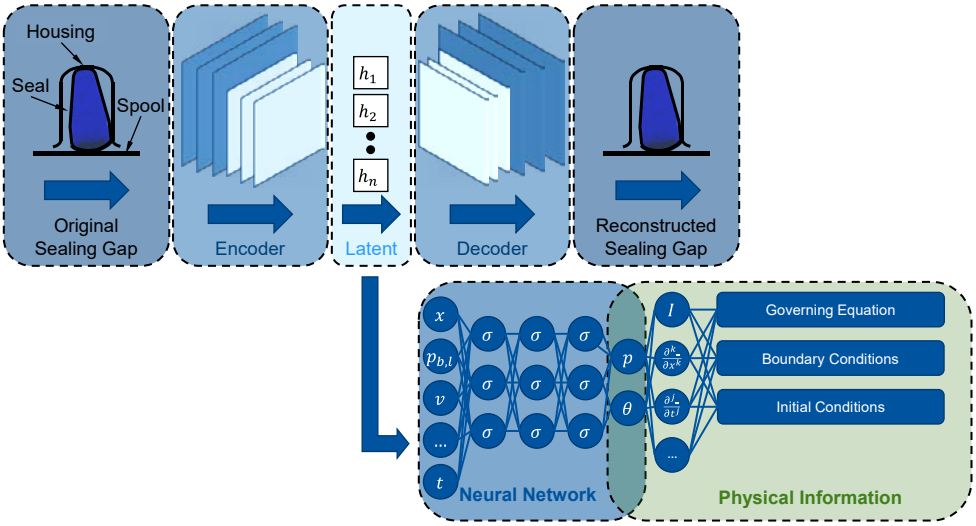

Figure 3.2: The ifas HD-GAPINN

The result will then serve as the input of the neuron's activation function f whose evaluation is then characterized as the neuron's output σ. These individual outputs are required for the solution of the governing equations, namely the Reynolds and Fischer-Burmeister equations, as well as the boundary and initial conditions. In this work, the layer size $n_{neurons}$ will stay constant across all n_{layers}. Additionally, all neurons in one layer will host the same activation function f, thus a different activation function can only be achieved in a different layer. Eventually, the PINN computes the pressure p and the cavity fraction θ, depending on the network parameters $\vec{\Theta}$:

Once the PINN has produced its output, various losses are calculated to ensure its accuracy. These losses include a residual loss for both the Reynolds- and Fisher-Burmeister equation (domain Ω), a boundary condition loss (domain Γ) and an initial condition loss (domain Υ). Partial derivations that may occur in the complex differential equations during loss computation ($\frac{\partial^k u}{\partial x^k}, \frac{\partial^j u}{\partial t^j}, \dots$), are usually determined by employing automatic differentiation (AD), which efficiently computes gradients of any order with machine accuracy by applying differential rules such as the chain and product rule. However, in all its efficiency, the computation of partial derivatives with AD relies on the prerequisite of a continuous function. It thus introduces a limitation into loss calculations, as it does not adequately

account for inputs of a discrete nature. When aiming for a high degree of realism in the underlying simulation, the processing of discrete inputs becomes indispensable because realistic geometries are captured through discrete measurements into a height profile. Thus, to address this limitation, this work will use the finite-difference method (FDM), more specifically, the central finite-difference scheme, for the computation of partial derivatives.

4. RESULTS

Having outlined the methodology used to achieve the research objectives of this work in the previous section, this section presents the obtained results. The results of this study encompass a variation of two geometries ("*Slight Seal Contact*" and "*Seal Geometry with Kinks*") across two different scenarios, namely both with and without the consideration of cavitation modelling. In each test case ("*Slight Seal Contact*", "*Seal Geometry with Kinks*"), the autoencoder was trained with latent-space sizes of 8, 16, and 32, leading to height latent vectors of the exact dimensions that were consequently provided to the PINN.

4.1. Slight Seal Contact without Cavitation Modelling

This first presented test case is characterized by a slightly stressed seal with a force exerted on the housing and prolonged onto the seal. Since cavitation is not taken into consideration, the loss calculation for this test case solely revolves around the residual and pressure boundary condition loss $\mathcal{L}_{\Omega_{Residual}}$ and $\mathcal{L}_{\Gamma_p}$. This specific test case is relevant for assessing the accuracy of the PINN's geometry-aware loss computation, which relies on finite difference schemes to approximate the derivatives of the height profile. Figure 4.1 shows the results of the AE with different latent size (8, 16, 32), the results of the PINN and the relative error of the PINN ($p_{PINN} - p_{DDS}/p_{DDS}$). For each latent size, the reconstruction of the height and the pressure computation of the PINN yield good results. In Figure 4.1 (left column), the PINN configured with an 8-dimensional latent space shows a maximum absolute percentage pressure error of 1.4%. By expanding the latent representation to 16 dimensions, the peak absolute percentage discrepancy decreases to 1.2%, indicating a slight improvement in accuracy. Further increase of the latent size to 32 yields a maximum absolute percentage error of around 1.5%, thus worse than the smaller latent sizes. An increase in the latent size does not necessarily result in a better performance of the PINN. The latent size primarily affects the performance of the compression and reconstruction of the AE. Since all three variants show a good match between the original and reconstructed height profiles, the use of a smaller latent size allows for the possibility of using a smaller network size, as the layer sizes should be proportional to the number of inputs. Thus, the size of the latent space should be selected rather smaller and can be checked by the reconstruction accuracy of the AE. The increase in latent size does not necessarily translate into better physical fidelity and may, in fact, introduce unnecessary complexity that hinders generalization. Overparameterization can lead to overfitting or suboptimal convergence, especially when the problem geometry does not warrant such a high-capacity representation.

In summary, this test case demonstrates that increasing the latent dimension from 8 to 16 improves the quality of the predicted pressure field by enabling the PINN to better resolve small variations in geometry. However, further increase to 32 dimensions offers no clear advantage and slightly worsens performance, emphasizing the importance of balancing representational power with the complexity of the underlying physical domain.

Nevertheless, each investigated latent size shows good results in combination with the PINN.

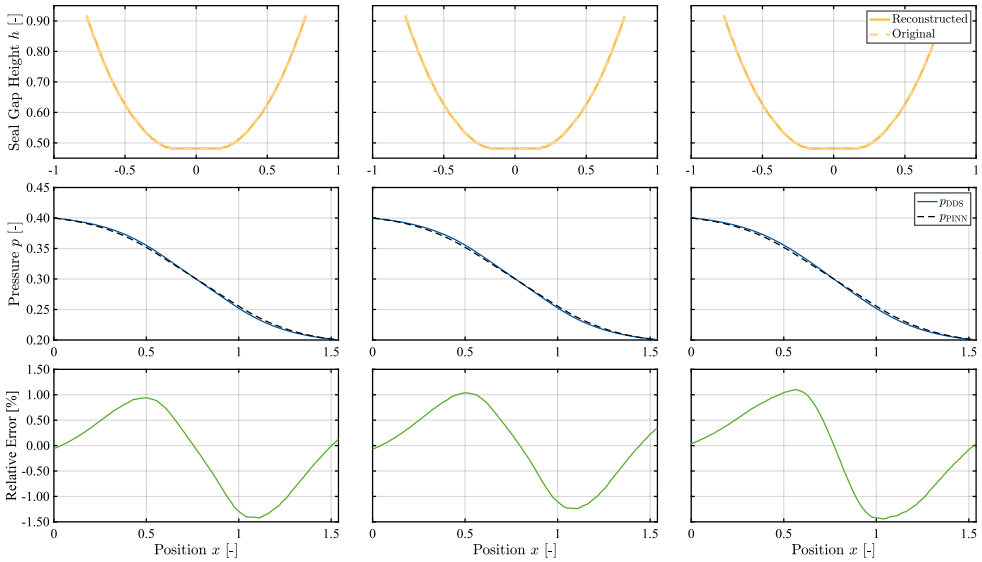

Figure 4.1: Pressure Distribution for Geometry "*Slight Seal Contact*"

4.2. Seal Geometry with Kinks without Cavitation Modelling

This second investigated test case is characterized by a seal that is pressed against a diagonal slider and thus contains kinks and steep gradients. Analogously to the test case "*Slight Seal Contact*" without the consideration of starved film height, the loss calculation for this test case revolves around the residual and pressure boundary condition loss $\mathcal{L}_{\Omega_{Residual}}$ and $\mathcal{L}_{\Gamma_p}$.

This test case was designed to evaluate the PINN's capabilities in handling high height gradients, which is particularly relevant for this geometry-aware PINN because its loss computation relies on a finite-difference scheme for the derivatives of the height profile. Finite-difference schemes, being numerical, introduce an error into the computation that can severely alter the result if said computation proves to be vulnerable to error propagation. This is especially the case when error-prone intermediate results experience a potentiation. According to Equation (2.1), such a potentiation of the height profile in combination with its x-derivative is introduced in the Reynolds equation and thus also in the computation of the Reynolds loss term (scaled with the factor three, cf. x-derivation of h^3 in Reynolds equation (2.1)).

The results shown in Figure 4.2 demonstrate a slightly worse approximation of the pressure distribution for lower latent space sizes than the previous test cases; the maximum absolute percentage error reaches up to 2% for latent space sizes of 8 and 16. For the 32-LS case, however, the PINN manages to obtain excellent results, leaving the maximum absolute percentage deviation from the ifas DDS-reference below 0.7%.

Clearly, the PINN profited from a higher resolution of the challenging height profile. This may be attributed to a better performance of the finite-difference Method for higher latent space sizes, resulting in a more accurate loss computation and thus a more effective training.

Nevertheless, the performance in all three test cases is sufficient for a precise modelling of the hydrodynamic pressure.

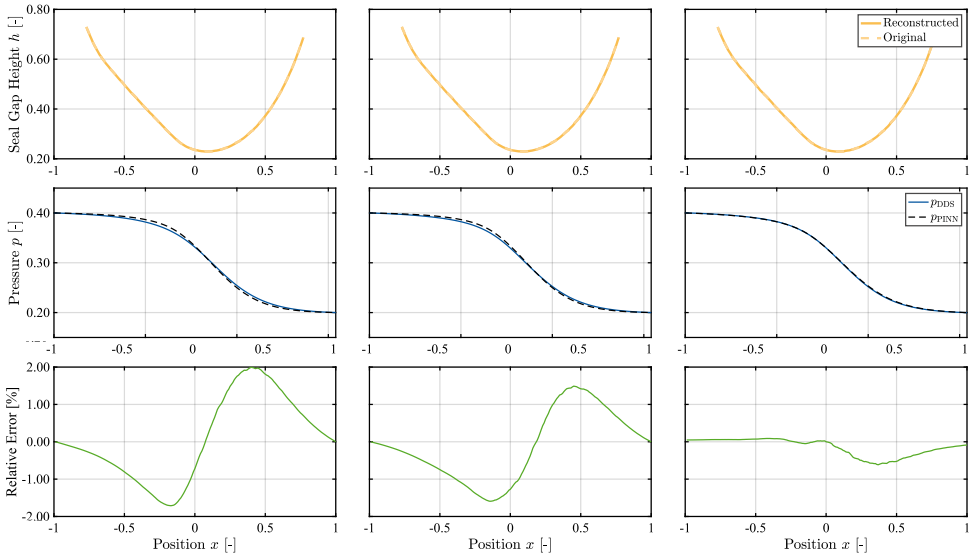

Figure 4.2: Pressure Distribution for Geometry "*Seal Geometry with Kinks*"

4.3. Slight Seal Contact with Cavitation Modeling

The following section extends the first test case by including the starved film height, which increases the complexity of the PINN's training. In contrast to the previous test cases, the PINN's training now incorporates all losses described in Section 3.2. In addition, a Filtered Absolute Error metric is used to compare the results between the PINN and the DDS for the cavity fraction and pressure. This accounts for differences in numerical precision between the two methods. For instance, in regions where cavitation should ideally be zero, the DDS may yield values on the order of 10^{-20}, while the PINN may only approximate this with values around 10^{-5}. The usage of a relative error in these areas would not adequately illustrate the accuracy of the PINN. By using the "Rolling Mean" filter, the mentioned outliers from the absolute error $|(p,\theta)_{PINN} - (p,\theta)_{DDS}|$ are eliminated.

In this test case, shown in Figure 4.3, the PINN does not perfectly reproduce the pressure and cavitation peaks. However, for the 16-LS and 32-LS cases, the pressure peaks are well captured, with absolute errors of less than 0.05. The sharp cavitation peak remains a challenge across all latent space sizes, with maximum absolute errors ranging between 0.01 to 0.15. It becomes apparent that the inclusion of cavitation significantly increases the complexity of the problem, making it more challenging for the PINN to correctly identify the regions of maximum pressure and cavitation. Nonetheless, the performance of the PINN could potentially be improved through extended Bayesian Optimization training, allowing for the discovery of more optimal hyperparameters and a better global minimum.

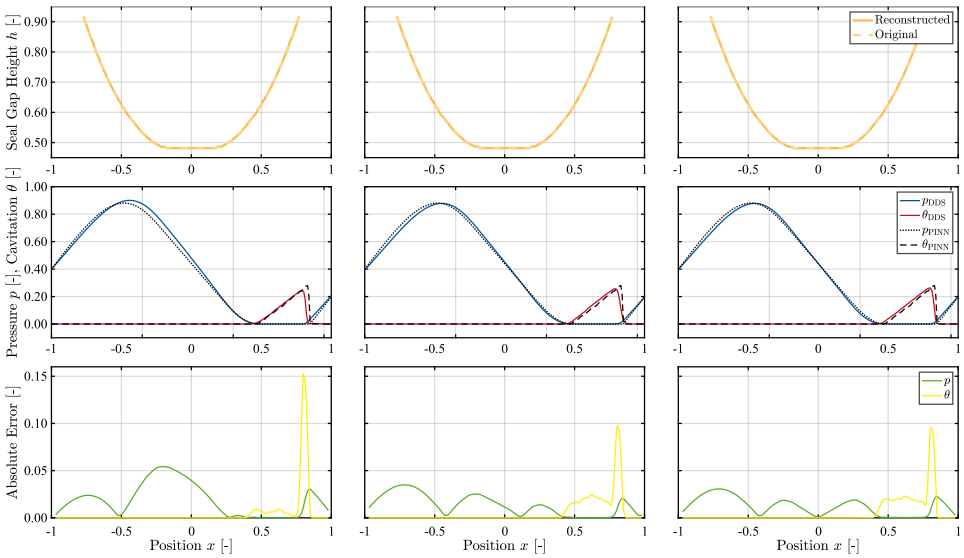

Figure 4.3: Pressure and Cavitation Distribution for Geometry "*Slight Seal Contact*"

It is worth noting that the application of soft-constraints is not expected to improve the overall results. This is because soft-constraints primarily assist in the transition regions between pressure and cavitation, rather than directly enhancing the PINN's ability to identify the locations of maximum pressure and cavitation. Therefore, they do not offer a complete solution for addressing the PINN's limitations in capturing these critical features. Nevertheless, all three setups display good agreement between the PINN and the numerical solver, especially when considering the speedup from four milliseconds to one to two seconds (Intel I9 13th-generation processor, 128 GB RAM DDR5, and Nvidia RXT 4090) in terms of computation time for PINN and DDS. Table 4.1 summarizes the results of the different test case by displaying the mean absolute error (MAE) and the root mean squared error (RMSE) and underline the high accuracy for each test case and each latent size.

Case	**Latent**	**MAE p**	**MAE θ**	**RMSE p**	**RMSE θ**
1	32	0.0050	-	0.0060	-
1	16	0.0024	-	0.0029	-
1	8	0.0027	-	0.0033	-
2	32	0.0020	-	0.0018	-
2	16	0.0027	-	0.0020	-
2	8	0.0028	-	0.0021	-
3	32	0.0118	0.0056	0.0151	0.0205
3	16	0.0134	0.0057	0.0172	0.0193
3	8	0.0185	0.0057	0.0254	0.0279

Table 4.1: Mean absolute error and root mean squared error for each test case

To sum up, the results show that the extension of the AE enables the PINN to obtain geometry-awareness and solve each test case with high accuracy for all three latent sizes. Since all latent sizes displays sufficient accuracy, the usage of a smaller latent size is promising since it would less increase the input size of the PINN and thus keep the whole framework as lightweight as possible.

5. CONCLUSION

This work focused on the conception, implementation, and testing of a geometry-aware physics-informed neural network, comprising the HD-PINN from the ifas HD-Framework and an extension that enables it to process more complex and realistic geometries. The extension included the finite-element software ABAQUS for the seal model, a Python interface that extracted height profiles from ABAQUS, and an autoencoder that enabled the compression of those height profiles to make the input processable for the PINN. The PINN's capabilities in the pressure and cavitation prediction for lubricated sealing gaps in pneumatic valves were then assessed in three test scenarios. All pressure and cavitation distributions produced by the PINN were then systematically compared to those generated by the ifas DDS for the identical test scenarios.

This work represents the next step in implementing a PINN-based fluid-structure interaction for elastohydrodynamic lubrication simulations. The novel framework extends the current state-of-the-art of PINNs in hydrodynamic lubrication by adding geometry-awareness and enables the coupling with the deformation part of the elastohydrodynamic simulation. Furthermore, the findings show that the PINN can process a latent representation of a high-dimensional variable, which is a promising result, since the PINN for the deformation also needs to process the high-dimensional load, described by the hydrodynamic pressure vector, coupled in the fluid-structure-interaction. To sum up, the findings underline the potential of PINNs to model elastohydrodynamic behavior in lubricated contacts in pneumatic seals, and the next steps are to implement an AE for the deformation PINN and, eventually, couple all components in a fluid-structure-interaction.

Abstract

Engineering drawings and 3D (3-Dimensional) models store vital information that is essential for any industrial product life cycle – right from designing and manufacturing to order placement and inventory management. Accurate retrieval of the information requires intensive manual efforts and is prone to human bias and error. In this paper, we present two novel methods to extract information from 3D models and 2D engineering drawings. This information is contained in the models and drawings with different file formats such as portable document format (PDF) and computer aided design (CAD) models. This makes it difficult to integrate the drawing data into the company's data management system. Hence, we have used optical character recognition (OCR) to gather dimensions and specifications from the drawings and models of different file formats. The information is also present in different fonts and locations across the drawing or models. Although these documents contain a lot of relevant data, they also include unnecessary information. The fine tuning of character recognition models is done in the context of mechanical drawings, which improves the quality of data reading. Additional quality checking parameters such as nearest character matching and template matching of required text areas are also integrated to avoid a trade-off between speed and accuracy. The accuracy of the correctly read tokens using a combination of above-mentioned OCR strategies gives an accuracy of approximately 93%, while the detections with low confidence are automatically filtered out. This leads to the error proof output of the data in a format that is expected by the end user. An OCR based strategy for information extraction in this manner significantly reduces manual efforts and the same methodology is widely scalable across different types of drawings and models.

1. INTRODUCTION

Hydraulic drawings contain critical information that is used from the design and development stage to manufacturing and ordering. In this era of digitalization, it is an

All Open Access articles are peer-reviewed, distributed under the Creative Commons Attribution-Non Commercial 4.0 International

organizational prerogative to arrange, clean, label, and store data for inferences and insights. However, this requires tremendous human effort, and the repetitive manual entry is prone to errors. The drawings and documents have accumulated over the years through internal innovative developments and external mergers. The format of the data is varied, and the numbers are huge. The drawings contain information about different child parts, dimensions, specifications, and material details. Drawings / any relevant fluid power circuitry are stored as three-dimensional (3D) models or two-dimensional (2D) images. Moreover, some of the drawings are scanned and stored in document formats like PDF as discussed in Jameison et. al. [1]. The scanned documents are noisy and extraction of useful information from such documents is challenging. Despite many advances in OCR-based document analysis, significant challenges remain in industrial engineering contexts. A large portion of legacy mechanical drawings exists as old, noisy PDF files, many of which are scanned images containing faded print, and handwritten annotations. Such documents have low contrast, background noise, and inconsistent text orientation, making text extraction difficult for standard OCR systems. The current methods reviewed in the literature cannot be directly applied to accurately extract structured engineering information from these documents, highlighting the need for a robust, domain-specific OCR framework.

The interpretation of 3D model textual data on a large scale without metadata is a hugely time-consuming task. OCR has not been used in the popularly available literature to interpret area, mass and other data for 3D models with high accuracy, this is something that we have attempted for the first time in our use case. The paper presents two OCR-based frameworks to extract engineering information from existing 2D drawings and 3D CAD models. For 2D drawings, we convert pages to images, split them into quadrants, run OCR, and match the text against internal databases to identify materials and surface finishes. For 3D models, we have automated Creo View Lite to open files, capture the “Summary” window, apply OCR, and parse values relevant to the model’s design. OCR in our use case has been finetuned to handle text, numeric and specials symbols data as high accuracy is a requirement for our case. The goal is to reduce manual work and errors in feeding data into company systems.

Information extraction from 2D Drawings: Mechanical drawings often contain critical information that must be accurately identified for further analysis in manufacturing industries. They have critical specifications, dimensions, and material details that directly influence design and production quality. Traditionally, these drawings have been manually interpreted by engineers. However, a vast number of legacy drawings exists only as PDFs or scanned images, making automated extraction of textual information tricky.

Based on literature, very recent research introduces eDOCr2 [2], a hybrid framework that combines traditional OCR, image processing, and Vision-Language (VL) models to extract structured and semantic information from mechanical engineering drawings (EDs). To improve semantic understanding and reasoning, eDOCr2 integrates Vision Language models (Qwen2-VL-7B and GPT-4o) after segmentation to verify, filter, or retrieve information [3]. Some literature proposes an OCR-based system using Tesseract OCR [4] to extract text from general digital images through detection, segmentation, and binarization. It separates the text from the background and then detects the text. Although these techniques extract text by applying different methods like text localization, binarization, etc., the method operates on entire drawings and does not explicitly consider sub-region OCR to boost recognition performance. Unlike standard documents, mechanical drawings contain multi-scale annotations, symbols, non-standard fonts. Optical character recognition (OCR)

systems trained on printed or handwritten text often underperform on these noisy, skewed, and symbol-heavy images. Consequently, there is a need for robust and domain-specific extraction pipelines that can bridge the gap between raw images and structured databases.

In this work, we propose a quadrant-based OCR technique for mechanical PDF drawings. The approach converts each drawing page into an image, divides it into four quadrants, applies OCR independently, and then maps extracted text to a structured excel database. Dividing image into more than four quadrants can result into system processing overhead, which will take long time for processing. The resulting information is stored in Excel along with the drawing names, creating a structured dataset. This workflow is lightweight and adaptable, provides improved accuracy by localizing OCR to smaller image regions.

Information extraction from 3D models: 3D models across Danfoss and other multinational corporations dealing in mechanical models and assemblies require the area, mass, volume and other data of the parts to be saved across different product lifecycle management software such as SAP, Siemens Teamcenter, etc. The manual entry of a large number and variety of components consumes longer man hours and is a non-value-added activity. Additionally, the handling of different types of files such as step (STP), part (PRT) and assembly (ASM) may employ different software tools and strategies to ensure the correct file is used and its subcomponents are all loaded properly. Repeating this monotonous process leads to human error, especially since area, volume and other values are required to be in single point precision and a single wrong entry may affect the system data in the long run. The quality control of such processes additionally needs to be performed manually, which again may contain human bias and discrepancies.

Hence, there is the requirement of an automation system that can process many files with high accuracy, extract relevant information from the same and return the digitized version of the results. All of this should be done in a fraction of the time required to repeat the same manually. Different software packages were that were popularly available were compared for analysis [5]. Most software either did not contain metadata for viewing or displayed incorrect values. To address this lacuna, a non-parametric method was needed. Thus, CREO View and Python based OCR dependent logic was developed to access and digitize area, volume, mass, and envelope information for STP, PRT and ASM type mechanical model files. This can return accurate information without any human intervention and segregate healthy and unhealthy files on its own, thus producing additional insights.

The main contributions made in this paper can be listed as following: (1) Automated information extraction from old, noisy, and sometimes scanned mechanical drawings in PDF format, (2) proposed a quadrant-based OCR technology to improve the accuracy of text extraction of existing methods, (3) applying OCR to 3D model snapshots, overcoming challenges of graphical overlays and extracting engineering-specific dimensions and annotations, (4) proposed a model viewer based software for 3D model data extraction, (5) combining two OCR engines to achieve optimally best results for small fonts and numeric data of 3D models.

2. INFORMATION EXTRACTION FROM OLD, NOISY DOCUMENTS AND IMAGES

Any leading manufacturing industry player always strives to make their products environment friendly and sustainable. So, the materials that are used to make mechanical products play a pivotal role. Mechanical CAD drawings contain the data of dimensions and tolerances along with critical information regarding which materials are to be used, and surface finishes required for each component in product manufacturing. Accurate identification and evaluation of constituent materials and finishing ensure Danfoss products are aligned with current sustainability goals. We developed a robust OCR approach to identify material specifications and surface finishes. We have used Tesseract OCR as it is open source and all the computation happens locally, which helps to maintain the confidentiality of data.

The proposed solution is implemented in four major steps:

i. Image segmentation and optical character recognition
ii. PDF to Image conversion
iii. Text consolidation
iv. Pattern matching and classification

2.1. Image Segmentation and Optical Character Recognition

The first step involves opening a PDF document with the help of a default PDF viewer of the operating system. The system attempts to identify and activate the system's default PDF viewer window. Now the system's screen dimensions are calculated to identify the best capture regions. The screenshot capture process implements a quadrant-wise approach for capturing the screenshots of PDF content. Now based on the document's width and height, which is extracted from PDF metadata, it calculates the optimal zoom level. This is done to maintain the resolution of the text present in the PDF. The viewport manipulation works in the clockwise direction starting from the top-left quadrant. Now the system applies to the calculated zoom level and captures the screenshot. Following this, it captures the screenshots of all the quadrants ending at the top-right corner. The captured screenshots are then saved with the detailed name of the file followed by the quadrant name for further analysis as seen in Fig. 1.

As an initial step, OCR is applied separately to each quadrant image. Each image maintains its resolution loaded using image processing libraries that provide image format support and image manipulation techniques. Based on the image quality, different methods are used like denoising and contrast enhancements to improve text definition. The images are converted into high contrast black and white images which are optimal for OCR. The Tesseract OCR engine is configured with required parameters for technical document processing, along with including language models appropriate for engineering terminology and character recognition settings. In this process, accuracy is preferred over speed. The extracted text from each screenshot is stored in a temporary text file, which is further used to post-process the data to extract the relevant information.

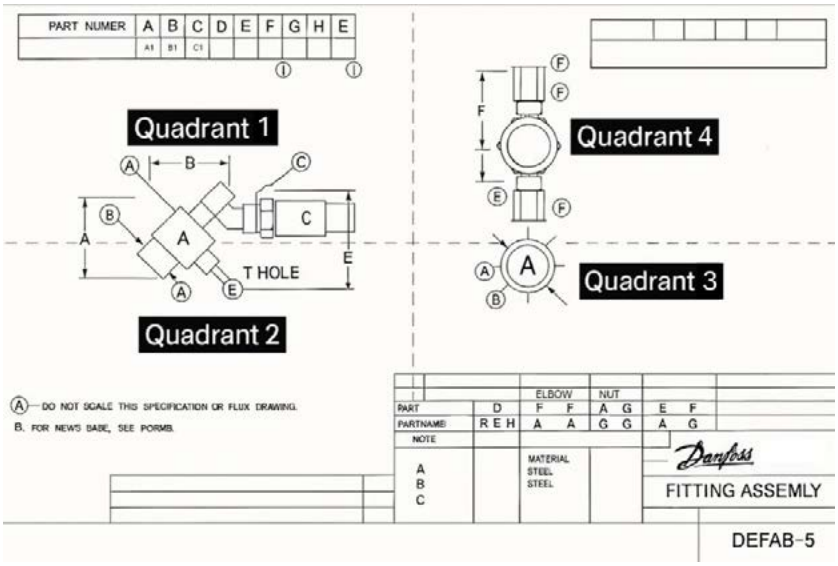

Fig. 1. Representative Dummy Drawing with quadrant references

2.2. PDF to Image Conversion

This step includes direct conversion of PDFs into images. This process makes use of specialized PDF-to-image conversion libraries that interpret the PDF format and generate bitmap representations of the document. The conversion process converts all pages within each PDF document, creating joint photographic experts' group (JPEG) images at a resolution suitable for OCR analysis. The output images are organized in such a way that it maintains the directory hierarchy which has clear association between image name and original source PDF name. Now all JPEG images are converted to portable network graphic (PNG) image format. PNG is a lossless format that preserves image quality throughout the process [6].

Now the image cropping phase is implemented, which applies strategic segmentation to full-page images, focusing on relevant content that is present in the PDF. By leveraging domain specific knowledge, we targeted the selection of regions where most critical information lies. The regions include a title block, material specifications, and annotations block. The cropping method begins by analyzing the dimensions of the full-page image to set proportional dimensions for the interested regions. The primary extraction focuses on the upper half of the document, which commonly contains detailed specification table and material information. After that, it extracts focused regions like the bottom-right area of the document, which typically has title blocks and primary material specifications in mechanical drawings.

Now each cropped image is given a descriptive name as "original filename + region-identifier" and saved as seen in Fig. 2 in the regions highlighted by quadrants 3 and 4. This

segmentation approach allows for region specific OCR, which not only reduces computational overhead but also improves the detection accuracy.

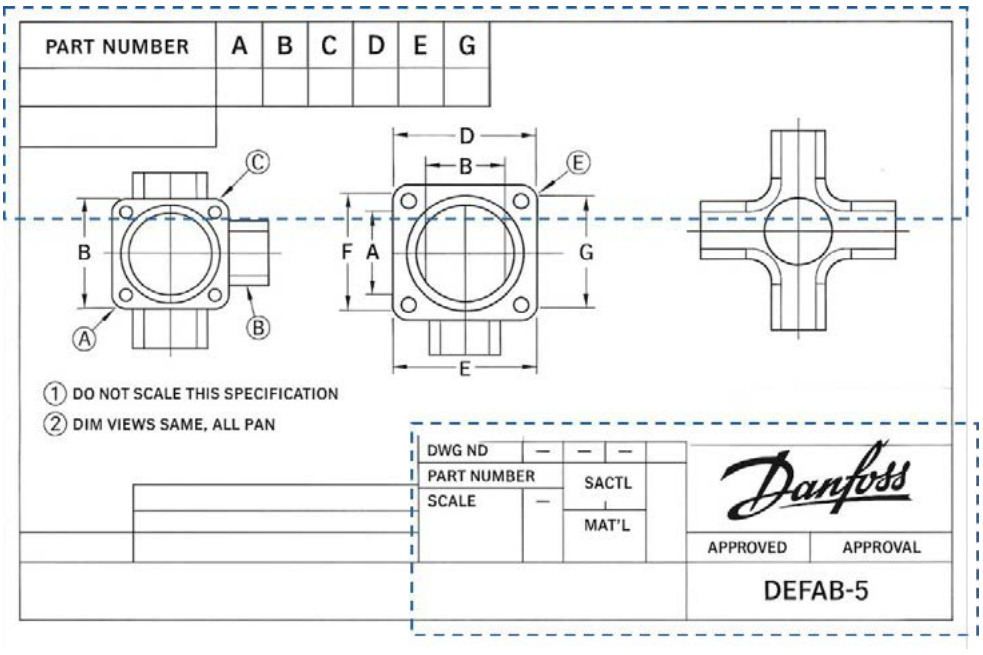

Fig. 2. Representative Dummy Image of Drawing with Identified Region

2.3. Text Consolidation

Text consolidation phase includes concatenation of different text extraction outputs in analyzable collection of text data. This process begins with collecting text data from three different methods:

i. Native PDF text extraction using PyPDF2 library of Python.
ii. From quadrant-based screenshot OCR results from the first step.
iii. Direct image conversion OCR results from the second step.

Each text data source provides unique characteristics. Native PDF text extraction usually provides high accuracy for digitally created documents, preserving exact characters. The screenshot-based OCR results are important, as it extracts text from specific information in dense regions of the drawings. The integration process concatenates these different text sources while maintaining source identification markers that make analysis of data easier.

The consolidated text undergoes initial cleaning process that removes whitespace patterns, normalizing line break characters. Additionally, the code generates an uppercase variant of the text to reduce case insensitive pattern matching operations. This duplicate representation ensures that material specifications written in various case combinations can be identified.

After consolidating and removing inconsistencies from the text, now comes character level error correction phase. This step is specifically performed to handle common misidentifications. This process applies domain-specific correction rules, that account for the visual similarities between certain characters, in the context of industrial specifications.

The most fundamental confusion is between letters and numbers that are visually the same. The letter 'O' is replaced by number '0' in context where numeric value is expected. Lowercase 'l' characters are converted into numeric '1' when there are alphanumeric specification codes. Also, some technical specification needs corrections for misidentification such as 'AIST' replaced by 'AISI' to correct common misreading of 'American Iron and Steel Institute' abbreviation. Apart from this character level correction, this solution also takes care of spacing irregularities, hyphens, dashes, and punctuation marks that commonly occur in technical document processing. Although rule-based standardization resolves many character-level ambiguities, it does not fully capture contextual intent. Future mitigation strategies should integrate contextual AI models and pattern-based validation to disambiguate visually similar characters using semantic cues and domain knowledge, thereby improving accuracy in technical document interpretation.

2.4. Pattern Matching and Classification

2.4.1 Material Name Recognition

The material recognition process implements a database-driven approach to correctly identify the materials. This process begins with accessing the material column from the predefined database of excel format. Material names are normalized to lowercase format to avoid case-insensitive matching. The matching algorithm works on exact string matching within collected text from different phases. For each material name in the database, the code searches for its presence in the collection of data.

Some domain specific logic rules are implemented to handle ambiguous material terminology that may appear to be the same. For example, when the material name 'anneal' is found, the algorithm applies additional check to ensure that 'annealing' is not present in the same document, as these terms represent different material specifications and should not be conflicted. Valid matches are stored into result set along with its document name. The identified materials are stored in the form of comma-separated values.

2.4.2 Material Specification

Material specification is one of the most complex aspects of pattern matching. It requires a valid pattern recognition capability to identify and validate the material specification codes commonly used in industrial applications. This process identifies various material specification codes like AISI steel standards, W-codes, and generic specifications.

The American Iron and Steel Institute (AISI) specification identification starts with pattern matching, which will first identify the characteristics format of 'AISI' prefix followed by numeric codes ranging from three to four digits. Each AISI code undergoes the verification of material specification codes against the database, ensuring that only valid AISI designations are stored in the results.

W-codes are processed based on the pattern matching which begins with letter ‘W’ followed of alphanumeric characters. The W-code processing algorithm implements a comprehensive character correction system that addresses common misreads. The character correction process replaces frequently confused characters with the most likely intended value in the context of material specification codes. The letters 'o' and 'O' are standardized to '0', because the material specification does not contain letter ‘o’ or ‘O’. The W-code validation process includes length verification to ensure that processed codes are of five-character format.

2.4.3 Surface Finish

Surface finish recognition focuses on identifying surface treatment and finishing specifications. The surface finish defines the final appearance, texture, and protective characteristics of materials. This process begins with text normalization performed to address the common OCR misinterpretation of finish specifications.

These include the replacement of 'ES _' with 'ES', and the systematic replacement of punctuation marks that are frequently misread during OCR processing. Exclamation marks are converted to '1' when they appear in specification contexts, addressing a common OCR confusion pattern. For each finish specification in the database, the system applies string normalization and searches within the processed OCR text using both exact matching and the character-substituted variants.

Special case handling addresses industry-specific terminology. For instance, when the term 'protective' is identified within the document text, the system automatically adds 'protective oil' to the finish specifications, recognizing this as a standard industry term. This attention to terminological precision reflects the critical importance of accurate finish specification in manufacturing and compliance contexts.

All extracted information related to material names, material specifications, and surface finish details is stored in a structured Excel-based database. The process begins by uploading a folder containing the required PDF mechanical drawings, after which the automated extraction workflow is initiated. Each PDF drawing is processed sequentially, and the extracted results are systematically stored in the Excel database. The structured database maintains key attributes for every processed drawing, including the PDF drawing name, material name, material specifications, and associated surface finish information. This organized representation of extracted data enables efficient retrieval and analysis. As a result, the proposed system significantly supports product engineers in making faster and more informed design and material-related decisions, while reducing the need for manual interpretation of engineering drawings.

3. INFORMATION EXTRACTION FROM 3D MODELS

The 3D model parts of any hydraulic or relevant industry are primarily of 3 types – STEP, PRT, and ASM. These files may be generated by different software and contain different metadata and compositions. The STP files are normally generated through the Autodesk platform software and are widely usable across different cross platform 3D model handlers. However, being a proprietary data format, use with other software requires export and conversion into another suitable format. The PRT and ASM file types are more common

and can be generated using a wider variety of software, such as PTC Creo Parametric and Siemens NX.

In terms of complexity, the STP files are easiest to handle as they contain suppressed parts and hence can be directly visible and accessed. In most cases, these types of files contain metadata as well, as they are built using a standardized method and hence require some information related to area and material to be already present in the model. The PRT files are the second easiest type of file to handle as they contain all required sub parts arranged under the parent part. However, the issue occurs when the subparts have failures during building or are damaged as part of the migrations from one platform to another. This can occur either if the model was not downloaded or imported incorrectly, or if the model itself has errors while building. The ASM files are the most difficult to handle as directly opening the ASM alone provides no information other than envelope; it requires the individual PRTs inside it to be handled as separate files. Also, in case of nested ASMs it should be ensured that the incorrect PRT is not chosen as seen in Fig. 3. Additionally, any damaged or broken ASMs should be automatically filtered out and not allowed to proceed with data extraction.

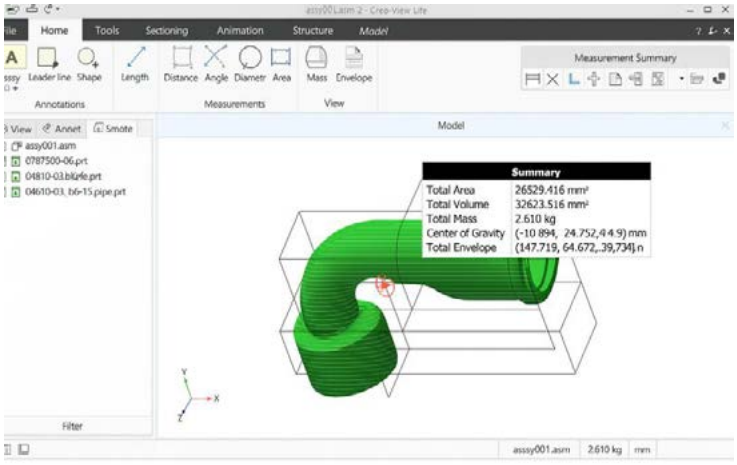

Fig. 3. Representative dummy structure of assemblies and Summary window

3.1. Software to view 3D model data

To get the area, volume, and other descriptive information about the 3D models, a software is required where one can access and open every type of file and additionally, give indicators of damaged cases without any false positives. Generic options such as Creo Parametric 3.5.0, SolidWorks and Autodesk Inventor were explored and referred to through literature. Creo Parametric allows easy access to PRT and ASM files; however, it requires manually intensive conversions to open STP files. Additionally, it offers viewing of metadata parameters, provided that the built file has metadata. For SolidWorks, the file formats are not always handled properly and give a lot of launching errors. For the Autodesk Inventor,

it is good for viewing and accessing STP files, but for PRT and ASM files it does not contain a lot of the information needed for data entry, like volume, mass, and more [7].

The reason that these software do not work with optimal efficiency is because they are predominantly parametric software, i.e., they work best with models which already have predefined settings and parameters as a part of their design. However, since most models made in a corporate environment are a result of the interaction of multiple software and their versions, the parametric measures often are hidden or removed with user interaction. Hence, there was a requirement for software that could not damage the entities of the model itself but just give the information in a collected way.

For this purpose, the most optimal software to be found was Creo View Lite 8.1. This software comes as a part of the PTC suite of software and is a viewer that can open STP, PRT and ASM type files. Additionally, it can indicate which subparts of these models are damaged using warning marks and it can indicate "broken" assemblies in red as well as observed in Fig. 4. The Creo View window has an interesting feature known as the Summary feature under the markups section, that shows information about the model regarding the Area, Volume, Mass, Centre of Gravity and Envelope. This information is highly accurate and useful to us as it contains data about all the parameters that can be needed as part of the SAP data entry. However, this tool does not save the results of the summary anywhere directly. Hence, an approach was required to save the summary data in some format for use later.

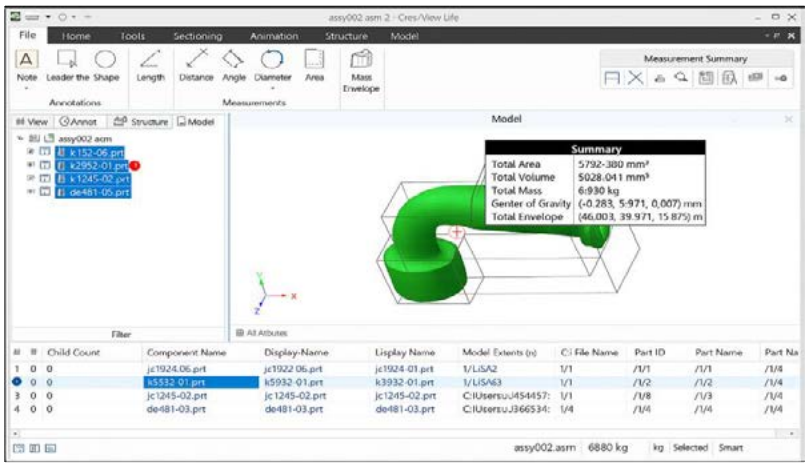

Fig. 4. Representative locations of Summary window with broken parts marked in red

3.2. Using Metadata Extraction

An initial attempt to extract the data was done using Creo Parametric's metadata extraction. This involved linking Creo Parametric with a Creoson API server that could intermittently ping the software in the background to access metadata on its own. However, this process observed multiple limitations. The metadata is only present for around 10% of total files (30,000 STP and 20,000 ASM files that we processed), which amounts to a very less

percentage. Also, the API can only handle up to 15 fields at once instance, requiring the instances to be stopped and restarted after every 15 files.

The metadata was affected by certain software defined settings which might not be correct for every model. For example, the automatic material assigned for a lot of the models was stainless steel; however, this was the wrong material and hence manipulated the mass value from the actual value.

Owing to all these issues, the OCR-based approach was chosen as the best method to extract the Summary information from the Creo View lite software's summary window.

3.3. The Process - Extracting files

The first step involves choosing the correct file for information extraction. The arrangement of the files is in a nested folder–inside-folder arrangement. The correct file is the one that is inside the folder starting with the keyword "MD" and contains the latest revision. At times, the file may be of a different name than the one inside the folder, hence a smart adaptive logic is needed to find the naming inside which is closest to the given part name. For this purpose, match-by-similar name logic was used, and this was verified with the domain experts to ensure the correct file was being loaded.

The file loads up and opens in Creo View. The first thing to do is to tick the checkbox next to the filename, which makes the file visible.
This is where the OCR process starts.

3.4. Optical Character Recognition Techniques for Different Texts

Optical character recognition finds different ways of working in different use cases. For the clicking of the checkbox at the first box, an approximate coordinate region is given to the system within which it looks for the text entry. In Creo View, the checkbox is at the upper left quadrant region of the window, so the OCR is made to act in that region initially only. The text is of the font Calibri, with a font size of approximately 12-14 pixels. As per Park and Shin [8], for such conditions, Tesseract OCR or EasyOCR provide the best results. For recognizing small Calibri text in paragraph form, Tesseract OCR generally offers better accuracy than EasyOCR due to its optimized handling of clean, printed fonts and structured layouts. Multiple methods of OCR were also compared, such as TrOCR (Transformer OCR, used by Microsoft Tools) [9], and Mistral OCR [10]. A comparison was done between all the different possibilities using a variety of parameters.

Feature	**Tesseract (v4/5)**	**EasyOCR**	**TrOCR (Base/Large)**	**Mistral OCR (LLM)**
Architecture	LSTM + Statistical	CRNN (Deep Learning)	Vision Transformer	Large Language Model
Best For	Scanned Docs, High Res	Noisy/Scene Text	Handwritten/Curved	Semantic Understanding

Inference Speed	Extremely Fast (<0.2s)	Fast (~0.5s - 1s)	Slow (~3s - 8s)	Slowest (API/GPU heavy)
Model Size	~20 MB	~80 MB	~1.5 GB+	~4 GB+ (or API call)

While EasyOCR is faster and easier to set up, it tends to struggle with small font sizes and produces more errors in such cases where there are multiple words close to each other. Tesseract, though slower, benefits from extensive customization options and consistently delivers more precise results for small, well-formatted text like Calibri. This is due to the differences in the way they target individual frames, as seen in Fig. 5.

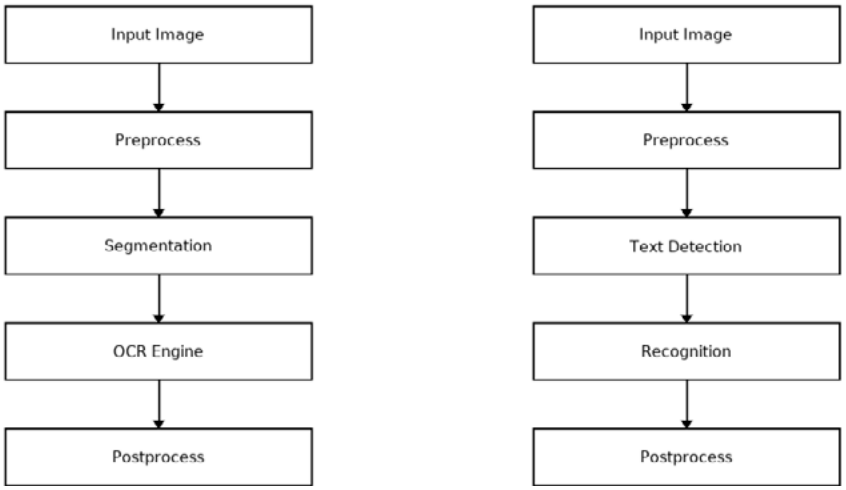

Fig. 5. Comparison of Tesseract OCR and EasyOCR in terms of working

Thus, a combination of EasyOCR and Tesseract OCR is used. First, Tesseract OCR detects smaller text like names of file and subparts, and EasyOCR detects the bigger text like markup subtab and summary option.

Tesseract OCR includes a set of configurable modes known as page segmentation modes (PSMs), which are essential for tailoring how the engine interprets the layout of text in an image. These modes are particularly useful when dealing with different types of documents or image structures, such as full pages, single lines, or isolated words. For example, PSM 3 is the default mode and works well for general documents with multiple blocks of text, while PSM 11 is ideal for images containing a single, uniform block of texts such as a cropped paragraph in Calibri font. These modes help Tesseract decide whether to look for multiple columns, lines, or just a single word, which directly impacts the accuracy of OCR results. Selecting the right PSM is crucial, especially when working with structured fonts like Calibri, as it allows the engine to better understand the spatial arrangement of characters and lines, reducing recognition errors and improving overall performance [11].

For ASM files, the OCR can find files which have broken PRTs as present in it as well. Often, the name of the PRT may contain a drop-down triangle next to it, indicating the presence of 1 or more nested ASMs. In such nests, the name of the PRT and the ASM may be the same, hence a 50 to 100-pixel margin to the bottom of the last entry needs to be reread for confidence. The broken ASM is found by applying a red mask over the images of the summary. If a red region is identified in the region of the ASM, it means it is a broken file.

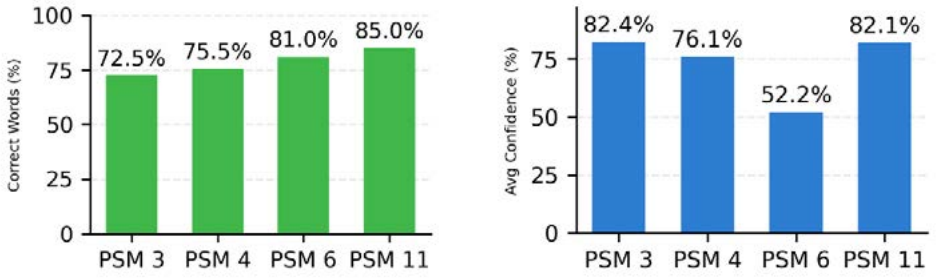
3.5. OCR for Data Extraction from Snapshots

To extract the data, pattern matching is performed to get entries of area, volume, and other information from the summary snap. Generally, the data follows a fixed structure of ~ symbol followed by the value followed by 3 decimal points. However, it may also contain exponential marks like +/- e^0, which need to be interpreted as scientific symbols. This is done using Tesseract OCR, which finds good application in this case as it works for mathematical text.

Additionally, the text might be present in multiple regions like top right, middle, bottom right, etc. Hence, a fallback logic is added starting in anticlockwise order across the image to read if not found in any region. For the envelope, it may contain data such as “Enve”, “ENVELOP” and other formats, hence all possible combinations of case and letter mappings are considered. Once the data is extracted for each file it is automatically added to an excel. This principle can also be extended to cases involving fluid power drawings specifically – involving complex wiring and/or component symbols. The relevant character / symbol matching in this case simply changes but follows the similar generic principles of searching by character in multiple locations of a document as fall back, or mapping the mis detected characters to their nearest matches based on historical interpretation of that character based on testing with a sample dataset.

4. RESULTS AND DISCUSSION

The entire pipeline of the OCR process for both 2D PDF drawings and snapshots of 3D models involves the need of a dedicated system with stable to high configuration settings. A PC with a high configuration of not less than 32GB RAM and a GPU was used to perform the OCR for the drawings and to capture the snapshots for the 3D model information extraction. The pipeline follows the mass download of all required files onto the dedicated system, followed by the identification of the relevant files to be processed using a naming convention as specified by a product engineering team.



In case of the PDF files, they are converted into images (as discussed in Section 2) and processed. Overall, each file takes around 20-30 seconds to be processed from end to end. The proposed system for text extraction from PDF drawings was tested on a collection of PDFs mechanical drawings. This solution was tested on a sample of 30 engineering drawings in PDF format. Material information was successfully extracted from 90% of the drawings with 79% accuracy. For material finish information, data was extracted from 83% of the drawings with 72% accuracy. By implementing the proposed solution, manual effort can be reduced by approximately 76%, resulting in significant time savings and improved efficiency in processing engineering drawings. Unsuccessful extraction of information from PDF was due to low-quality and unreadable drawings. The database matching step helped

filter out irrelevant or misrecognized text, ensuring high-quality results. The final structured output in excel format enabled engineers to take decisions related to the material specifications.

As per the observations and discussed Section 3.4, for the 3D models text extraction, EasyOCR performs better in individual character cases, but Tesseract OCR performs better in cases of repeated words. For example, for occurrences like “Volume: 12345.67”, EasyOCR is better at interpreting the relevant data; however, when it comes to compound words such as “Total Volume”, Tesseract OCR performs better. Hence, EasyOCR is first used to quickly extract text from the snapshot for an initial overview and to give a general idea about locations of words. Then, Tesseract OCR with different PSM settings is applied to the same file for more detailed results.

To accurately detect word combinations like ‘Area’, ‘Total Area’, and ‘Volume’, analysis of different PSM modes of Tesseract was done. Fig. 6(a) shows that higher PSM values generally result in more correctly detected words for a given file. However, as seen in Fig. 6(a) when comparing based on confidence of the individual PSM modes independently, it was observed that PSM 3 and PSM 11 gave good results in terms of detection confidence. The only case that seemed to act poorly in this case was the PSM 6, with a confidence of around 52%. This did not correlate with the accuracy-based findings in Fig. 6(a). This meant that no PSM configuration alone would give accurate and confident results.

Thus, the best approach was using the average result of all the different modes. When tested on a sample batch of 100 files, it was observed that this method gave balanced results. The logic was finetuned and scaled by mentioning the exact possible combinations of words that could be seen in the screen capture and estimating fallback regions across the image to determine which region contained the numeric information. For example, the image could contain the information in either the middle region or the upper right region of snapshot, and hence the code was arranged to look at those regions in order of possibility and determine the final reading from only one.

(a) Accuracy of detecting correct words for different modes

(b) Corresponding confidence score for each mode in detecting the words

Fig. 6. Performance of Tesseract OCR page segmentation for accuracy of detecting correct words and corresponding confidence score for different modes

Once the information was extracted, it was seen that the extracted text and numeric values for the different classes like area, volume etc., have some amount of overlap due to their occurrences appearing very close to each other and the OCR not being able to understand which unit at the end of the numeric value belongs to which class. For example, as seen in Fig. 7, some of the values of Area are interpreted as Volume and some values of Volume are often interpreted as Envelope. The cases with more than 2 overlaps are highlighted in green. However, they are filtered out on the basis of the error handling strategies which involves extracting the values at least twice in one iteration to check if the value extracted belongs to that class actually or not. Coupled with code to declare some preset formats of the text (E.g., volume values start with ~, integral value of the number will always be followed by 3 decimal points, etc), it highly improves the accuracy of text extraction from the snapshots irrespective of the location of the text.

Fig. 7. Confusion Matrix indicating the accuracy of detection of words as per category

The logic was finalized on a batch of 10,000 ASM files, of which only 4700 were healthy unbroken files whose information we could enter into the system. Out of a total of 23,500 words/phrases (4,700 healthy file entries * 5 columns), 21,900 were detected correctly. This was verified using an automation script checking generic conditions (incomplete words, white spaces, etc) and manual quality checking. The same method when scaled to all ~50,00 files led to an overall accuracy of 93.1% for the text interpretation logic, which was in-line with the accuracy seen on the batch of 10,000 files. While the paper shows samples of dummy parts, the logic has been tested on actual industrial partner parts across multiple divisions and types.

5. CONCLUSIONS

This system demonstrates a practical approach for extracting textual information from mechanical drawings using OCR-based techniques. The methodology of converting PDFs into images, segmenting them into four quadrants, and applying OCR provides significant improvements in recognition accuracy. By matching extracted results with a database, the system ensures that only relevant and valid information is retained. This helps in reducing errors commonly associated with OCR in technical drawings. The data extraction from 3D models offers an opportunity to expedite a process that would otherwise require extensive manual intervention with high chances of error. Additionally, a large database of readily available dimension and weight possibilities might also help in creating models for interpolation or estimation in cases of those models wherein a stable build is not present. In the field of fluid power and its related disciplines, the adoption of methods that minimize repetitive manual tasks and automate data collection offers significant advantages. By streamlining these processes, organizations can not only improve the efficiency of data management but also enhance their ability to estimate and identify optimal design solutions for future projects. Automation reduces human error, accelerates workflows, and ensures that valuable engineering data is captured consistently and accurately.

Importantly, the scope of this approach is not confined solely to technical drawings within the fluid domain. The same strategy can be extended to a wide range of fluid power documentation, including power circuitry diagrams, hydraulic schematics, pneumatic layouts, and design review charts. Because the methodology does not rely on project-specific retraining or exhibit bias toward a particular type of drawing, it remains flexible and broadly applicable across different design contexts.

This universality means that engineers and designers can apply automated data handling techniques to diverse aspects of fluid power systems without the need for specialized customization.

6. FUTURE SCOPE

The strategy discussed is highly scalable and can be replicated with minor fine tuning for different types of drawings and models across industries. OCR-powered vision systems observe and automate conversion systems for electronics components as well, providing detailed information of components at each process step and saving thousands of engineering hours. The collected information can be implemented in generative AI to generate drawings and models of a given configuration on its own. To integrate additional fluid power circuitry and documentation, a modification would be needed to understand symbolic text instead of regular numeric text. With a combination of OCR powered text matching and location-based template matching, the symbols and nearby text can be found in a similar manner. Additionally, conversion of the relevant drawing circuitry into a suitable image or PDF format will also be viable to simplify the complexity of working with different file types.

7. ACKNOWLEDGEMENTS

The authors gratefully acknowledge the support from the different Danfoss divisions, whose 3D models and drawings were instrumental in validating this solution. The domain expertise

and technical guidance provided by the different divisions were invaluable to the successful validation of this work. The authors thank Satish T., Shilpi S., Ketan M., Bernie B., Hemant S. and Prajakta K. We would also appreciate support from Jeff H., Rahul V., Prashant J. and leadership of Danfoss India Innovation Centre (DIIC). The authors highly appreciate Dr.-Ing. Robert Rahmfeld for his unwavering help and support.

Abstract.

Axial piston units (APUs) are key components of hydrostatic drivetrains, where End-of-Line (EoL) testing ensures product quality by detecting manufacturing or assembly defects before delivery. Vibroacoustic (VA) measurements offer potential for fault detection in roller bearings, but their robustness is challenged by process variations, particularly fluctuating fluid temperatures that influence hydraulic pulsations and lubrication behavior. This study investigates these effects in a replicated EoL scenario, comparing two conditional anomaly detection (AD) approaches from the field of machine learning (ML): a residual based method and a feature augmentation strategy that incorporates fluid temperature into the feature space of a One Class Support Vector Machine (OCSVM), against a baseline using only VA features. The results demonstrate that, while temperature-induced effects are less pronounced than natural serial variability, their impact on VA behavior remains detectable. Importantly, residual-based AD yields improved fault detection performance compared to both the baseline and feature-augmented approaches, provided that sufficient data is available. These findings underline the relevance of accounting for temperature effects in data-driven EoL testing and highlight the potential of ML-based methods to enhance the robustness of VA-guided quality assurance in APUs.

1. Introduction

Axial piston units (APUs) are the central elements of high–power-density hydrostatic drivetrains and hydraulic work drives [1]. Their wide application spectrum is driven by key advantages, including robustness, high pressure capability, precise controllability, and compatibility with electrified drivetrain topologies such as hybrid and fully electric vehicles [1, 2]. These features establish APUs as indispensable components in both established and emerging mobile-hydraulic systems. As the operational heart of such systems, APU condition is decisive for sustained performance and service life; deviations typically show up as elevated noise, reduced efficiency, lowered power delivery, or accelerated wear [3]. Ensuring consistently outstanding acoustic and performance characteristics therefore requires

All Open Access articles are peer-reviewed, distributed under the Creative Commons Attribution-Non Commercial 4.0 International

rigorous quality assurance throughout production. In parallel, enhancing the reliability of fluid power systems remains a central research priority [4], addressing both optimized materials and components as well as advanced data analysis methods.

1.1. Motivation for End-of-Line Quality Assurance

While advances in materials and design remain essential, verifying every manufactured unit is crucial to ensure consistently high quality. This final check, known as End of Line (EoL) testing [5], functions as a 100 % inspection gate that confirms acoustic and performance compliance, assembly conformity, and contractual tolerances before delivery. Unlike development tests that explore robustness and failure mechanisms under defined conditions, EoL testing verifies that each product instance meets the validated design and enables targeted rework or sorting when deviations occur [5]. Such measures are particularly relevant during ramp up of new product families, after specification updates, or following supplier changes for critical parts like roller bearings, where process variability is elevated and customer confidence must be secured. Comparable situations often arise in mobile working machines, where new variants are introduced under tight schedules and reliability and acoustic performance expectations are especially high [6]. In addition, EoL results can be linked with Statistical Process Control (SPC) [7] to track hydraulic or performance indicators over time and detect systematic process trends.

Beyond these conventional checks, vibroacoustic (VA) measurement has become a key element of EoL testing, complementing functional and hydraulic evaluations with information on dynamic behavior. VA metrics support quality assurance on two levels: directly, by quantifying noise emissions or tonal content relevant for perceived quality and compliance, and indirectly, by providing sensitivity to internal rotating components [8, 9]. In this way, VA data can reveal anomalies in gears, roller bearings, or tribological interfaces such as the slipper swashplate or valve plate–cylinder block contact [10]. Roller bearings are particularly critical, as they operate under substantial radial and axial loads and respond sensitively to even small deviations in geometry, lubrication, or assembly. Such deviations leave characteristic VA signatures that influence smoothness, efficiency, and wear. By capturing these effects, tailored VA-based verification at EoL not only secures acoustic requirements but also highlights subtle deviations in component behavior. Consequently, fault detection in roller bearings using VA and advanced signal processing has become the subject of several research studies [11, 12].

1.2. Problem Statement and Contribution

The implementation of a robust VA EoL test, however, is challenging, especially in the context of manufacturing hydraulic components, which often involves a complex and diverse product portfolio. Robustness is compromised by two main factors: first, frequent batch- and test-stand-related variations in VA behavior causing abrupt data shifts and drifts [5, 13], and second, the high sensitivity of VA measurements to environmental influences, which can be significant in an industrial setting. Direct disturbances like structure-borne noise from adjacent machinery affect VA measurements [14]. However, a more natural source of variation within the hydraulic system is the fluctuating fluid temperature, which this study focuses on. In analogy to the fluid type [14], it can have a major influence on the VA behavior of APUs since it directly affects the fluid viscosity, which in turn has a known effect on hydraulic pulsations [15]. Furthermore, the fluid also lubricates the roller bearings, and it is known

that their VA behavior is influenced by the lubricant's properties and the fluid temperature, consequently [16]. While this effect may be negligible for healthy bearings compared to the dominant hydraulic pulsations, it is no longer trivial in the case of faulty bearings. For the detection of defective roller bearings at the EoL test stand, it is therefore important to investigate the sensitivity of VA measurements to bearing faults relative to the natural process variation, to which the fluctuating fluid temperature is a major contributor.

However, characterizing such complex system behavior and detecting faults in the rotary group of an APU with conventional SPC methods is not trivial, as these methods are typically designed for monitoring single, univariate process parameters (e.g., via control charts). The high-dimensional and non-stationary nature of raw VA signals makes them poorly suited for such an approach. This challenge motivates the use of machine learning (ML) and deep learning, which has become a growing research area for handling complex data patterns, aligning with both Industry 4.0 initiatives and advanced trends in condition monitoring and fault detection of rotating machinery [17, 18]. This data-driven approach, as supported by the trends in [4], enables new possibilities for ensuring quality and reliability at the EoL stage, where the application of ML techniques offers substantial potential [19].

Based on these aspects, our previous work [20] focused on the implementation of an ML-based pipeline for detecting faulty roller bearings using VA sensors. Different sensor applications, load points, and signal processing techniques were investigated, thereby addressing research gaps related to EoL testing of highly varied products [5], and particularly APUs. To the best of our knowledge, only Gaugel et al. [6] have previously addressed the EoL testing of APUs, though their work focused on optimizing test cycle objectives rather than explicitly modeling environmental influences and considering VA signals. While they mention varying fluid temperatures as a relevant factor, it was not systematically investigated. In contrast, this work asks whether and how ML-based anomaly detection (AD) can be made robust against fluctuating fluid temperatures in a realistic EoL scenario. Thus, the objective is to evaluate different strategies for conditional AD under these varying conditions. This forms the foundation of our study. Accordingly, the contribution of this paper comprises the following aspects:

- Analysis of the influence of fluctuating fluid temperatures on the VA behavior of APUs based on a new dataset from a laboratory EoL testing scenario with manipulated roller bearings
- Evaluation of the robustness of ML-based AD for faulty roller bearings against these temperature variations, using the framework from our previous work [20]
- Comparison of approaches for conditional AD to compensate fluid temperature effects using a One-Class Support Vector Machine (OCSVM).

Compared with [20], the present study fixes load conditions, employs a single sensor, and evaluates an AD approach based on the same overall framework.

2. METHODOLOGY

It is is necessary to provide a more detailed explanation of the individual techniques and methods within the applied framework. For the subsequent analyses and experiments, it is further important to describe the dataset used, even though it originates from the same experimental test campaign as the dataset employed in the investigations presented in [20].

Hence, an in-depth description of the test campaign is omitted, and only the most relevant information as well as the differences between the data used here and those of the previous study are provided. To assess the robustness of fault detection, we additionally apply a consistent evaluation scheme for AD, which is likewise explained in the following.

2.1. Experimental Test Campaign Dataset

An experimental test campaign on a laboratory test rig was conducted to reproduce a realistic EoL scenario. This was necessary because obtaining meaningful data from real EoL tests is difficult, requiring large numbers of faulty units and varied test conditions. The essential setup of the test rig and the sensor arrangement is shown in Figure 1. However, for the present study only the triaxial accelerometer mounted on the test rig is considered. According to [20], measurements in the y-direction provide reproducible results and represent a solid basis for robust VA fault detection. Accordingly, only data from this measurement axis are analysed. This sensor remained installed throughout the entire campaign, whereas the test specimen, i.e., the APU under investigation, was replaced for each test in order to reproduce a realistic EoL scenario. Bent axis type units of the same specification were used, of which seven were available. Nevertheless, by exchanging the rotary groups to imitate serial dispersion due to assembly tolerances, 30 different rotary group-housing combinations could be realized, all of which underwent the same automated test procedure. In a second phase of the campaign, 14 faulty tapered roller bearings were mounted on new rotary groups and installed into the APUs. These were primarily the large tapered roller bearings in the O arrangement that support the rotary group, which were abrasively manipulated at the outer ring as well as at the rolling elements. This procedure resulted in a broad spectrum of fault intensities and localizations, leading to correspondingly different anomalous VA behaviors.

The standardized test procedure consists of traversing a full factorial set of operating points defined by rotational speed, swash plate angle with respect to displacement, and pressure, with the APU operating in pump mode. Preceding this procedure, however, is a 15-minute run-in phase at a stationary load point specified in Table 1, which, on the one hand, enables comparable conditions within the operating map. On the other hand, this phase more realistically reflects an actual EoL scenario, since the test rig is restarted for each experiment. In particular, the fluid temperatures at the beginning of each test vary, leading to significant differences depending on whether the test rig is started for the first time at the beginning of a day or whether tests are conducted in quick succession with preassembled rotating group-housing combinations. An overview of the distribution of temperatures, measured at the leakage oil drain (see Figure 1 in the hydraulic circuit), is provided in Figure 2. During the 15-minute run-in phase, one interval per minute was recorded at 10 Hz over a duration of 5 seconds, from which the mean value was calculated. Although temperature control within the operating map ensures reasonably stable fluid temperatures, this is not possible during the run-in phase due to self-heating caused by the load valve, resulting in the fluid warm up behavior shown. A notable effect of increased warm up due to the faults cannot be observed.

Table 1: Operating point during the run-in phase

Rotational speed	Displacement	High-pressure	Low-pressure
1000 rpm	Maximum	70 bar	30 bar

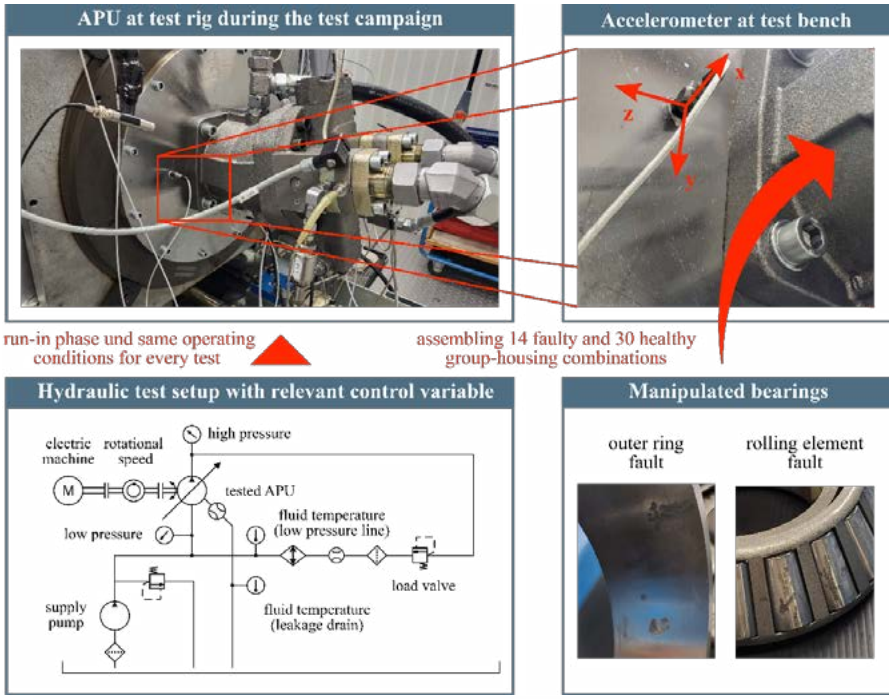

Figure 2: Setup for the experimental test campaign imitating a real EoL sce-

In this study, we explicitly use the VA measurements that were recorded simultaneously with the case drain temperature during the run-in phase, here with a sampling rate of 20 kHz. Since interval measurements during the run-in phase were not available for every test, the dataset is limited to 39 measurements from 25 healthy and 14 faulty units. In total, this results in 39 × 15 time series of length 100000 samples each, together with the corresponding fluid temperatures, which were already averaged and are included as scalar values.

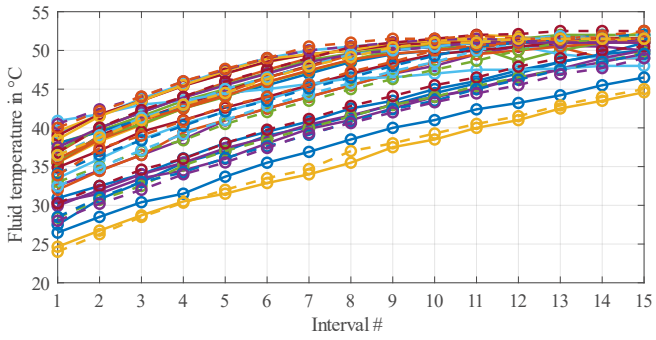

Figure 1: Trends of the fluid temperatures at the leakage drain during the run-in phase, with each color-line-style combination representing

2.2. Vibroacoustic Feature Extraction

For robust fault detection, we must construct informative features that effectively characterize VA behavior while being independent of external disturbances. This reflects

conventional approaches in ML, whereas current research also considers deep learning based methods that do not rely on predefined features. Instead, these features are learned directly by the model, which, however, requires large amounts of data. As such data cannot be assumed in this scenario, we follow previous work on (VA) fault detection and quality monitoring by relying on predefined features, which also enhances interpretability and robustness. In this regard, it is worth noting studies such as [21], which show that the performance of such conventional ML approaches can be competitive with more recent deep learning methods when it comes to detecting roller bearing faults based on VA behavior.

Signal processing plays a decisive role in this context, as it can enhance the fault-related information contained in the data. As demonstrated in our previous work [20], a fundamental step is to transform the time-domain signal into the frequency domain, for instance using a Fast Fourier Transform (FFT). This makes the periodic impulse sequences caused by defect overrollings more visible in the data. Moreover, envelope analysis of the analytic signal—combined with an empirically chosen band-pass filter—yielded almost perfect results in [20], thereby confirming the recommendation of Randall et al. [22] that the character becomes even more evident in the envelope spectrum. Nevertheless, the choice of an appropriate frequency band remains a general challenge and requires substantial domain knowledge, which is not always available in practical applications [11]. For this reason, the present study focuses exclusively on the raw spectrum-based approach. This choice is deliberate to isolate temperature effects on the fundamental signal characteristics and to create a baseline method that does not depend on domain-specific knowledge**.**

For the subsequent feature extraction, only the raw spectrum is utilized. Following the band definitions in Table 2, the spectrum is divided into several frequency regions. For each band, the mean value and the kurtosis are calculated. The mean reflects the overall energy distribution within a frequency band and is sensitive to shifts in load or operating conditions, while the kurtosis quantifies the impulsiveness of the signal content and is well established as an indicator for localized bearing faults. To clearly distinguish both types of features, the mean values corresponding to the frequency bands are referenced as F1, F3, F5, F7, and F9, whereas the kurtosis values are denoted as F2, F4, F6, F8, and F10. This feature set provides complementary information: the mean captures gradual changes in spectral energy, while the kurtosis highlights the presence of impulsive fault signatures. In this way, temperature-induced effects on the spectral characteristics can be systematically captured without relying on application-specific band selection as required in envelope analysis.

Table 2: Frequency bands used for the calculation of the features

Frequency Band	**1**	**2**	**3**	**4**	**5**
Range [Hz]	0 - 120	120 - 360	360 - 840	840 - 1800	1800 - 3200

2.3. Conditional Anomaly Detection using One-Class Support Vector Machine

In the context of AD, we employ a ML model that interprets healthy units as a single class; hence the AD task can be regarded as one class classification. Because only healthy units are used for training and no mapping to multiple labels is performed, while faulty units are reserved solely for evaluation, the approach may also be described as semi-supervised AD. As the base model in this work, we use an OCSVM, which adapts the standard SVM for binary classification to the one class setting and, with a radial basis function kernel,

effectively generates a closed decision region around the input data. The basic operation is as follows: the OCSVM learns a decision function that accepts regions of feature space populated by the training data (healthy units) and rejects regions that deviate from this distribution. A small fraction of training samples may be allowed outside the decision region through a hyperparameter, which controls the trade-off between sensitivity and robustness. For further details regarding the method and its implementation in MATLAB R2022b [23], refer to our previous study [20] and to [24]. Specifically, a radial basis function kernel was used. The kernel scale was selected using a subsampling-based heuristic procedure [23].

Train-test-partitioning is applied accordingly to Figure 3, with the test portion used for evaluation as described below. To prevent data leakage from the test set, the standardization parameters (mean and standard deviation) were computed exclusively from the training data. These parameters were then applied to standardize both the training and the corresponding test data. In addition to the VA features, the model is extended in a second approach by including the mean fluid temperature for each interval. This variant is referred to as temperature-augmented AD (TAD), in contrast to the standard AD approach using only the VA features (SAD). The rationale is that including temperature should allow the model to represent shifts in the data driven by temperature and to learn possible correlations between temperature and the VA features. In this sense the approach can be seen as conditional AD: temperature does not define the nominal behaviour itself but provides context under which a more robust fault detection is to be achieved. Note that alternatives exist: Wißbrock et al. [25], for example, apply conditional isolation forest variants to incorporate specifications and test run conditions, while other studies propose splitting the dataset by test rigs [26].

An alternative or complementary approach to conditional AD involves the use of linear mixed-effects (LME) models. Each VA feature y_{ij} related to an i-th unit or test and its j-th interval can be expressed as

$$y_{ij} = \beta_0 + \beta_1 T_{ij} + \beta_2 n_{ij} + u_i + \epsilon_{ij} \qquad (2.1)$$

where β_0 is the global intercept, β_1 and β_2 are fixed effects representing the systematic influence of fluid temperature T_{ij} and test interval $n_{ij} \in [0; 15]_{\mathbb{N}}$, u_i is the random effect capturing serial dispersion, e. g. unit-to-unit variability, and ϵ_{ij} is the error representing unexplained variation. The residuals r_{ij}, i.e., the deviation of each observation from its expected value given temperature, interval, and unit, can then be computed as

$$r_{ij} = y_{ij} - \left(\beta_0 + \beta_1 T_{ij} + \beta_2 n_{ij}\right) = u_i + \epsilon_{ij} \qquad (2.2)$$

based on the estimated coefficients β_0, β_1 and β_2. These coefficients were estimated for each feature separately using the fitlme function, which implements linear LME models based on maximum likelihood estimation [27]. The residuals r_{ij} serve as compensated features for subsequent AD (see Figure 3). By training an OCSVM on these residuals (i.e. residual-based AD or RAD), the model can learn to detect anomalies relative to the expected behavior under the given operating conditions, thereby reducing false predictions due to temperature shifts.

2.4. *Evaluation Approach*

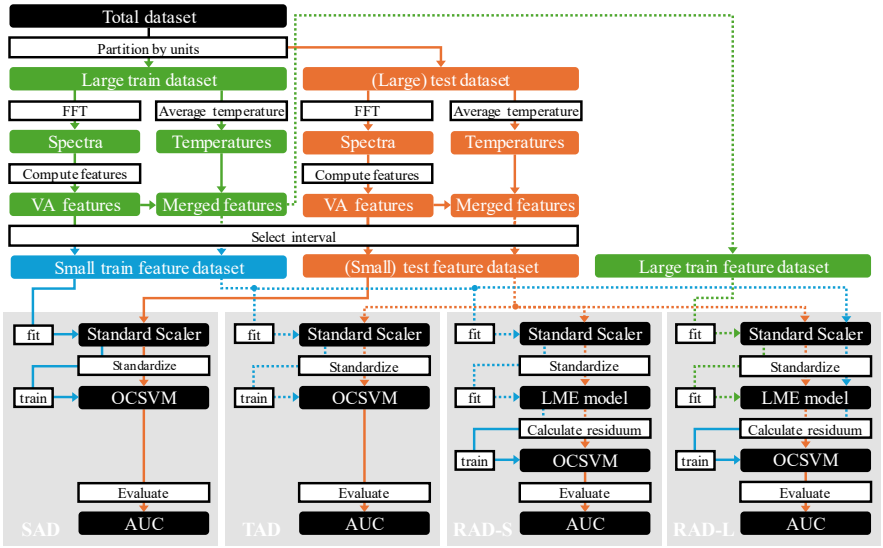

Figure 3: Pipeline for training and evaluating different anomaly detection models. The process includes feature extraction from raw data, data partitioning, and model-specific training and evaluation steps.

The evaluation of the models and of the overall is based solely on the test data, which include a subset of the healthy instances (disjoint from training data instances) and all the faulty instances. Given the limited dataset, five different train-test-splits are generated with respect to the healthy data, in order to obtain statistically more robust statements regarding model performance. The exact partitioning of the datasets depends on the experiments and will be described in detail later. In general, however, training and test data are kept disjoint not only at the instance level but also at the unit level. If multiple intervals from the same unit are considered, they must not be distributed across training and test data within the same split. Furthermore, it should be emphasized that train-test-partitioning applies to the entire pipeline, and consequently, the LME model, i.e. the coefficients β_0, β_1 and β_2, must be estimated exclusively based on training data.

For evaluation, an appropriate metric is employed, which is computed for each of the four splits and then averaged arithmetically. Specifically, the Area Under the Receiver Operating Characteristic (ROC) Curve is used (AUC). The ROC curve characterizes the relationship between the true positive rate (TPR)—i.e., the proportion of correctly identified faulty units—and the false positive rate (FPR)—i.e., the proportion of healthy units incorrectly flagged as faulty. Thus, the AUC is defined as

$$AUC = \int_0^1 TPR(FPR)\partial FPR, \tag{2.3}$$

with

$$TPR = \frac{TP}{TP + FN}, FPR = \frac{FP}{FP + TN} \tag{2.4}$$

where TP and FP denote the number of true positive or false positive instances, respectively, and FN and TN the number of false negative and true negative instances. Since this relationship inherently depends on the threshold applied to the anomaly scores, integrating over the ROC curve to compute the AUC provides a single threshold-independent value that serves as a robust performance indicator for each model.

3. EXPERIMENTS

Based on the described method for extracting VA features, the following section first presents an analysis of the data from the underlying experimental test campaign with respect to fluid temperature effects, while also accounting for potential time-dependent influences such as run-in, in accordance with the LME model framework. Specifically, an analysis of variance (ANOVA) is performed on the model to quantify the significance and relative strength of both temperature and interval effects across the features and principal components. Subsequently, the results of three distinct experiments are presented and discussed in terms of the robustness of fault detection using the conditional AD approach.

3.1. Analysis of Fluid Temperature Effects in Vibroacoustic Data

For the evaluation of temperature effects, we initially consider only the 25 healthy units in order to exclude fault-related VA anomalies and isolate the inherent variability of the process, without the need to perform train-test-partitioning. To gain a general understanding of the variation within the experimental test campaign, it is useful to apply dimensionality reduction techniques to interpret the ten VA features, derived from the raw spectrum, with respect to temperature effects. For this purpose, principal component analysis (PCA) is employed, which identifies orthogonal principal components (PCs) in descending order of explained variance, spanning the low-dimensional PC space, with the proportion of variance illustrated in Figure 4, alongside the factor loadings represented by arrows in the biplot, which indicate the contribution of each feature to the linear combination of the respective PCs. In particular, the second PC exhibits a correlation with rising temperature whereas isolating other time-dependent effects based on this representation is not feasible. It is, however, evident that the second PC is largely determined by features F1 and F2. Regarding the Pearson correlation shown in Table 3 for both the first two PCs and the individual features, high correlations with fluid temperature can be seen in general for F3 and the second PC, whereas the first principal components appear to reflect other, more random sources of variability, which account for a larger portion of the overall variance in this context.

Table 3: Pearson correlation coefficients of each feature with respect to the fluid temperature

PC1	PC2	F1	F2	F3	F4	F5	F6	F7	F8	F9	F10
-0.02	0.39	0.29	0.04	0.47	0.27	0.09	0.03	-0.25	0.12	0.19	0.06

In order to quantitatively assess the extent to which the temperature effect contributes relative to random serial dispersion, while simultaneously separating this effect from other potential time-dependent influences, the aforementioned ANOVA is employed to the mixed-effects model according to (2.3) from the features as well to the first two PCs. According to the p-values summarized in Table 4, a statistically significant effect of temperature is evident for most features as well as for the first two PCs. By contrast, the residual time-related effect

does not reach significance in any case and can therefore be considered irrelevant in the context of this study.

Table 4: P-values from ANOVA indicating the significance of effects (values below 0.05)

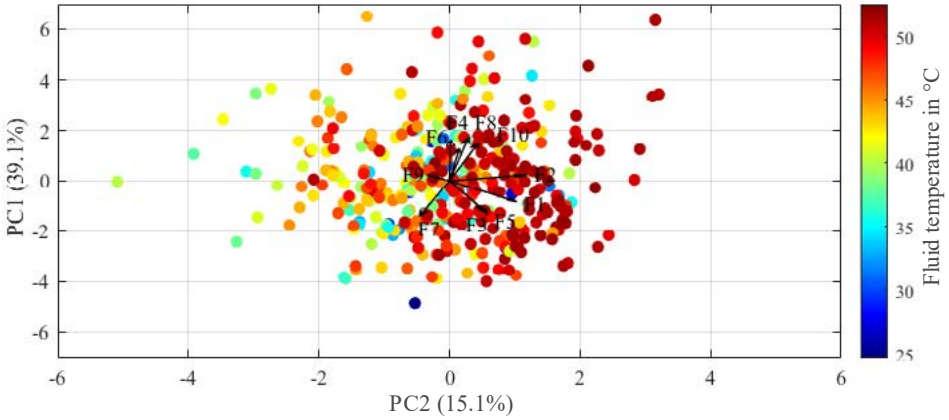

Figure 4: Low-dimensional PC spaces resulting from the PCA of the healthy instances across all intervals, including factor loadings and explained variance

Effect	PC1	PC2	F1	F2	F3	F4	F5	F6	F7	F8	F9	F10
Temp.	0.00	0.00	0.00	0.49	0.00	0.00	0.09	0.57	0.00	0.02	0.00	0.22
Time	0.33	0.65	0.92	0.64	0.75	0.66	0.73	0.55	0.48	0.62	0.75	0.73

3.2. Fault Detection Results

In this study, two different experiments are conducted to assess the effect of varying fluid temperatures on fault detection and to evaluate the resulting implications for the comparison of the employed conditional AD methods. In the first experiment, training and testing are performed for each interval in isolation. In the second experiment, scenarios are compared with either similar or strongly differing temperature distributions across the training and test sets. In both cases, all intervals are available for selection. The five data splits, as described in Chapter 2.4, are maintained consistently regarding the units in both training and test sets.

In the context of RAD, two approaches for constructing the LME model are considered within the experiments (see Figure 3). In the first approach, i.e. RAD-S, only the data used for training the OCSVM according to the respective split are included (20 instances per split, e.g. one instance per unit for training). In the second approach, i.e. RAD-L, all intervals of the units within the train portion are used, providing a larger basis for characterizing the temperature effect (20 × 15 instances per split, e.g. all instances of one unit for training).

3.2.1. Experiment 1 – Interval-wise Comparison

As shown in Figure 2, the spread of fluid temperatures decreases over the course of the run-in period, suggesting that the VA behavior in later intervals would similarly exhibit reduced variability based on prior observations. However, when considering the AUC values in Figure 5, no clear trend is apparent, implying that here the influence of temperature and other run-in effects is not pronounced. While the second interval tends to show slightly lower

AUC values, overall, the AUC remains relatively stable across intervals when averaged over the splits. In most cases, the fifth split is particularly critical and occasionally yields AUC values below 0.8 when the residual-based AD is applied using the LME model with the larger dataset. For the other splits, however, and on average, the AUC values are considerably higher than those obtained with the smaller dataset or with the standard OCSVM (with or without temperature as an additional feature). Moreover, the larger-dataset LME model exhibits less overall variability, consistently achieving mean AUC values between 0.958 and 0.989, and does not show the negative outlier observed in the second interval.

In analogy to the trends in Figure 5, the exemplary ROC curves averaged over the splits in

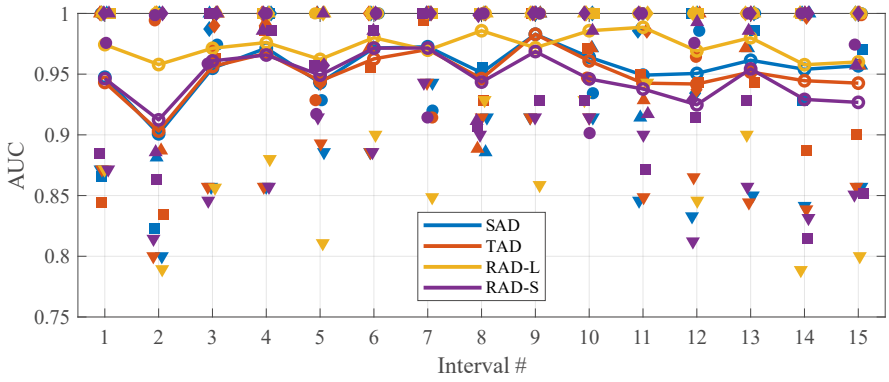

Figure 5: Mean AUC values for all intervals averaged over the splits, with individual AUCs of the splits additionally shown as scatter points with different markers

Figure 6 do not differ strongly from interval to interval. Nevertheless, it can be observed that RAD-L achieves higher true positive rates at the same false positive rate (FPR). For practical EoL testing, performance at a low FPR is crucial, as this minimizes pseudo faults that would lead to unnecessary rework. Notably, at an FPR of 5%, the RAD-L method maintains a true positive rate (TPR) over 90%, a clear advantage over the other methods. Notably, for the last interval, the ROC curve of RAD-S is lower, resulting in a reduced AUC (see also Figure 5). This can be attributed to the narrower temperature spread in this interval, as shown in Figure 2, which limits the LME model for the residuals to a small temperature range.

3.2.2. Experiment 2 – Similar vs Mixed Temperature Level

The previous experiment eliminated non-temperature-related time effects by using a constant interval. However, this approach also limited the variance in the considered temperature levels. To more clearly assess the influence of fluid temperature on fault detection performance, we now compare scenarios with very constant temperature levels to those with highly varying temperatures. In the first case, a temperature level is chosen according to Figure 2 that is traversed by every unit during the run-in; consequently, for each unit, the interval closest to 42 °C is selected. In the second case, all instances—that is, data from all units, runs, and intervals—are pooled, and for each unit a random interval is selected, ensuring that the full spectrum of fluid temperatures observed during the run-in phase is represented in the dataset. To ensure statistical reliability, ten repetitions with different randomly selected intervals per unit are performed for this latter scenario.

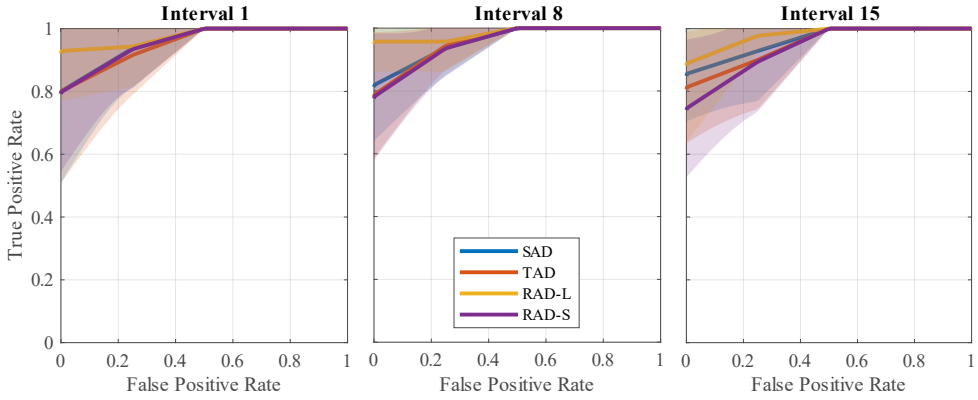

Figure 6: ROC curves averaged over the splits, with the shaded area representing the standard deviation and exemplary curves for three of the 15 intervals shown

The results of this experiment regarding the fault detection performance, measured in terms of AUC, are summarized in Table 5. In line with the expectations about general process variability due to temperature effects, it becomes evident that fault detection works better under comparable temperature levels than when the wide range of temperatures occurring during the run-in phase is taken into account. Importantly, further time-dependent effects cannot be concluded from this experiment, since, as shown by the temperature distributions in Figure 2, different intervals may correspond to the same fluid temperature level of approximately 42 °C across different units. Thus, for the case of comparable temperatures, nearly perfect results can be achieved: with TAD, every split yields an AUC of 1.0, while SAD and RAD-L also reach perfect performance in all but split 5. In contrast, for the mixed-temperature scenario, RAD-L achieves the highest AUC in each split, outperforming the other methods. Consistent with the findings of Experiment 1, split 5 is again the most problematic, likely due to the specific units contained in this subset. Across both scenarios, however, RAD-S consistently underperforms, reaching an average AUC of 0.946 in the mixed-temperature case and 0.892 in the constant-temperature case. Indeed, as shown in Figure 7, this is mainly related to a lower TPR at a FPR of 0, indicating that some faulty units do not exhibit anomalous patterns in the features when using RAD-S, leading to an overlap in the anomaly scores. At this point, the RAD-L–based method, in contrast, achieves a relatively high TPR for mixed temperature levels.

3.3. Discussion and Limitations

The experimental results indicate that fluid temperature during the run-in phase has a measurable effect on the VA behavior of APUs. Feature F9, in the highest frequency band, is particularly relevant for distinguishing healthy from faulty units, as suggested by the choice of the bandpass filter in the envelope-based analysis in [20]. However, the impact of temperature is limited: Table 4 shows significant effects, but correlations in Table 3 and the first principal component (see Figure 4) suggest only minor contributions compared to inherent production scatter. Similarly, experiment 2 or Table 5 shows that fault detection is only slightly affected by mixed fluid temperature levels, and temporal effects across intervals in Experiment 1 (see Figure 5) are minimal.

Table 5: AUC for similar and mixed fluid temperature levels with respect to different splits as well as the average. Since in the case of mixed levels repetitions regarding the mixing of the intervals are performed, the standard deviation is additionally report.

Levels	Method	Average	Split 1	Split 2	Split 3	Split 4	Split 5
Similar	SAD	0.974 ± 0.052	**1.000**	**1.000**	**1.000**	**1.000**	0.871
	TAD	**1.000** ± 0.000	**1.000**	**1.000**	**1.000**	**1.000**	**1.000**

	RAD-S	0.892 ± 0.069	0.883 ± 0.006	0.886 ± 0.000	0.986 ± 0.000	0.929 ± 0.000	0.779 ± 0.015

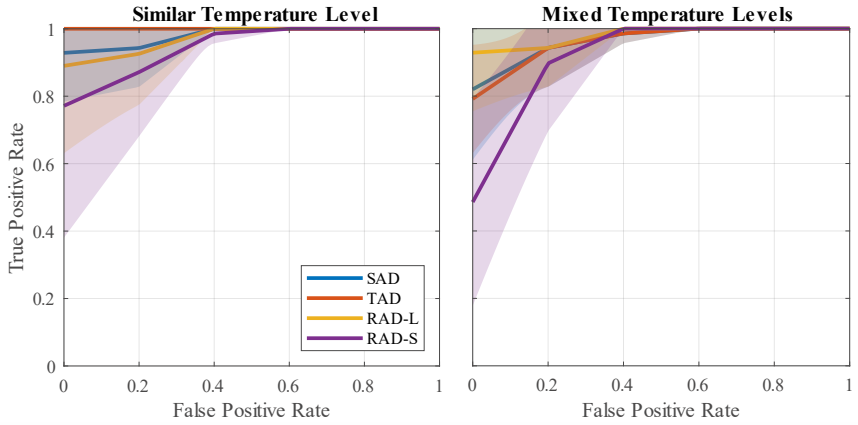

Figure 7: ROC curves averaged over the splits (and repetitions), with the shaded area representing the standard deviation and curves for similar and mixed temperature levels

Adding temperature as an explicit feature in the OCSVM provides little additional benefit. Performance does not deteriorate, and in the constant-temperature scenarios in experiment 2, results occasionally improve, likely coincidentally, since the feature is effectively constant. Limited variance and the implicit encoding of monotonic temperature effects in the VA features reduce the value of including temperature alone. In contrast, residual-based preprocessing or RAD clearly improves fault detection. By modeling monotonic temperature effects using a linear residual model, the method reduces systematic shifts before

OCSVM evaluation. Robustness requires a sufficiently large dataset: The limited data from a single interval makes the RAD-S approach prone to unstable coefficients in (2.2). The resulting model risks underfitting, as it cannot reliably separate systematic temperature trends from the dominant production scatter. In contrast, RAD-L, with all intervals included, provides a simple and interpretable data-driven correction. While this reduces the risk of underfitting, the general challenge with small industrial datasets remains a potential for overfitting the AD model itself, a risk that was mitigated here by using a simple OCSVM.

Nevertheless, several limitations must be considered for industrial EoL testing. Variability in APU specifications, tolerances, and supplier components may cause distributional shifts in features that neither OCSVM nor residual models can fully accommodate. Operational conditions such as pressure, rotational speed, swash angle, and initial oil temperature are more variable in production than in the laboratory. While temperature was explored as a conditioning variable, real EoL scenarios involve multiple interacting factors, limiting the predictive power of a single conditioning feature. Finally, the limited number of faulty units constrains statistical generalization, particularly for residual-based models requiring sufficient coverage to estimate systematic effects accurately.

4. Conclusion and Outlook

This study investigated the detection of APUs with faulty roller bearings in a laboratory-based EoL testing scenario, focusing on VA measurements and the influence of fluid temperature variations. Across two experimental setups, semi-supervised ML methods were employed for AD, comparing a conventional OCSVM approach with temperature-augmented and residual-based strategies for conditional AD. While temperature-induced variations were relatively small compared to the inherent production scatter, residual-based preprocessing proved effective in compensating for monotonic temperature effects, leading to improved fault detection performance and more stable AUC values compared to standard OCSVM or temperature-augmented OCSVM. Importantly, this approach not only enhances robustness against systematic disturbances but also increases interpretability, as the linear residual model clearly quantifies the temperature contribution to the VA features. These results highlight that even in the presence of moderate environmental variations, a semi-supervised residual-based pipeline can reliably identify faulty units within the scope of this study, demonstrating its potential relevance for real industrial EoL testing, where multiple sources of variability must be accounted for.

Future research should address the study's limitations by investigating additional sources of variability, such as background noise or the diversity of product variants, which may induce substantial data shifts. In the latter case, alternative conditional AD approaches could be explored, for instance methods capable of compensating for variations in categorical variables such as component suppliers or APU specifications. Regarding the VA behavior itself, non-linear modeling techniques may also be promising, provided that sufficiently large datasets are available. More generally, systematic, in-line data collection under realistic production conditions—including comprehensive sensing of potential disturbance factors—would enable more robust, data-driven fault detection and provide a foundation for extending these methods to industrial EoL testing.

BIOGRAPHIES

Maximilian Romeser received his B.Eng. in Automotive Engineering from Ulm Technical University of Applied Sciences in 2021 and his M.Sc. in Automotive Engineering from the University of Stuttgart in 2023. Since 2023, he has been pursuing a Ph.D. at Ulm Technical University of Applied Sciences in cooperation with Bosch Rexroth AG. His research focuses on data-driven methods for industrial serial testing of axial piston units.

Reinhold von Schwerin received his Ph.D. in Computational Science from Heidelberg University and is now a professor for Data Science, Machine Learning and Artificial Intelligence at Ulm Technical University of Applied Sciences. Furthermore, he serves on the board of Directors of DASU - Transferzentrum für Digitalisierung, Analytics & Data Science Ulm which strives to strengthen the ties between academia and industry in the fields of Data Science, ML and AI.

Case Study on Independent Metering Hydraulics for Energy-Efficient Battery-Electric Telescopic Loaders

Fabian Kreutmayr, Lucas Cayé, Markus Imlauer

HAWE Hydraulik SE, {f.kreutmayr, l.caye, m.imlauer}@hawe.de

Abstract.

This paper discusses the topic of energy-efficient hydraulics on battery-electric telescopic loaders. For this, two hydraulic systems are compared. The first one is a standard setup that can be found in classical machines that are driven by a combustion engine. The second one is a proposal using a decentralized independent metering approach. Through a comprehensive case study, the energy efficiency of both systems is evaluated. Thereby, it is shown that modern hydraulic setups can generate a great benefit for electrically driven machines by extending battery load cycles or reducing the required energy capacity to be installed, respectively.

Keywords. Mobile machines, energy efficiency, independent metering, battery-electric telescopic loaders, electrification.

1. INTRODUCTION

The transition from diesel-hydraulic to fully battery-electric mobile working machines is a process that is fundamentally reshaping the system-level energy architecture of such equipment. In this new paradigm, it is imperative that every kilowatt-hour drawn by the hydraulic circuit be meticulously balanced against a series of stringent constraints on battery capacity, including weight, installation space, upfront cost, and charging intervals. Consequently, the hydraulic subsystem, which was previously regarded as a passive energy consumer, has evolved into a pivotal mechanism for attaining an uninterrupted, eight-hour operating window within a designated energy budget [1].

Conventional hydraulic architectures – including open-center and load-sensing systems – are predicated on centralized valve blocks and extensive pressure lines. These designs introduce inherent inefficiencies, including high stand-by losses, throttling across metering orifices, and dynamic mismatches between pump output and actuator demand [2]. These inefficiencies are becoming increasingly unacceptable in battery-electric platforms, where energy is a scarce and costly resource. This comes from the fact that additional battery packs

All Open Access articles are peer-reviewed, distributed under the Creative Commons Attribution-Non Commercial 4.0 International

are adding both weight and cost to machines, which is undesirable from an economic point of view.

In order to address these limitations, this case study explores a decentralized independent-metering (IM) architecture, in which compact, seated valve cartridges are mounted directly onto each hydraulic actuator [3]. This physical reconfiguration of components eliminates the necessity for external load-holding and counterbalance valves. Additionally, it offers more direct control, thereby reducing pressure losses. Notably, this system facilitates native support for gravity-assisted lowering, a feature that is crucial for the system's functionality. When paired with a variable-speed electric motor-pump unit (MPU), the IM concept provides access to advanced supervisory functionalities, including electronic flow sharing, adaptive pressure control, and load-aware energy scheduling.

In this work, a full-scale experimental evaluation is conducted using battery-electric telescopic loader. The machine is tested in two configurations: (i) a baseline layout in an open-center system setting, and (ii) the reengineered IM-based hydraulic circuit. Both systems are assessed on the exact same machine using repeatable, standardized loading cycles that are representative of typical material handling tasks in logistics, construction, or agricultural environments.

In summary, the study establishes a foundation for the advancement of intelligent energy-efficient hydraulics by demonstrating its potential as a component-level enhancement and a fundamental enabler for the cost-efficient, space-conscious, and operationally viable electrification of next-generation mobile machinery. This work aims to demonstrate the transformative potential of rethinking hydraulic systems from a first-principles energy-efficiency perspective, tightly integrated with modern electric powertrain technologies.

1.1. Literature Review

Recent shifts toward higher energy efficiency in the mobile machinery market are driven by regulatory requirements and ongoing electrification. However, research on more energy-efficient hydraulic circuits has been active for many years. A brief literature review highlights some significant work in this area.

Opgenoorth et al. [4] present an advancement of the STEAM hydraulic system originally developed at IFAS, RWTH Aachen. Their work introduces a multi-pressure hydraulic architecture applied to an excavator platform, featuring three pressure lines that are dynamically regulated via electric motors. The system employs two separate electric drives – one powering a conventional pump and the other driving a pump-motor unit. These pressure sources, in combination with the tank pressure, are selectively routed to the actuators through a configurable valve network. A central focus of the study is the design of a supervisory controller responsible for optimal state selection, determining both the active pressure lines and their respective pressure levels based on actuator demand. In a simulated 90° dig-and-dump cycle, the proposed system demonstrates a 29% increase in efficiency of hydraulic System compared to a conventional reference model, underscoring the potential of multi-pressure architectures and reduction of throttle losses for energy-optimized mobile hydraulics.

A novel independent metering valve configuration for excavator boom control, integrating three electrohydraulic 2/2-way proportional poppet valves with a 4/3-way directional control valve is proposed by Nguyen et al. [5]. The control strategy combines pump speed modulation with valve actuation, wherein the inlet valve is fully opened to minimize throttling losses, while the outlet valve is regulated based on a predefined flow rate and position feedback. The architecture supports multiple operating modes, including regenerative functions such as low-side regeneration retraction, in which the boom is retracted solely by gravitational force without active pump contribution. This functionality is enabled by an additional short-circuit valve integrated into the system. Experimental evaluations demonstrate energy savings of up to 22% in power retraction mode and 6.5% in high-side regeneration mode compared to a conventional reference system. Moreover, the configuration achieves improved position accuracy while reducing overall system complexity.

Hansen et al. [6] present a system design aimed at reducing energy consumption in mobile hydraulic applications. Their approach is implemented on a JCB telescopic handler and utilizes a separate-meter-in/separate-meter-out valve configuration embedded within a load-sensing (LS) hydraulic system. The conductive subsystem is realized using two 3/2-way proportional valves, each governed by distinct PI controllers. The study focuses on the development of a control strategy that enables precise modulation of flow paths and pressure levels to match actuator demands. Comparative analysis against a conventional pressure-compensated proportional valve setup reveals significant energy-saving potential. For the evaluated duty cycle, the proposed configuration achieves a reduction in energy consumption exceeding 30%, demonstrating the effectiveness of the control-oriented valve architecture in enhancing hydraulic efficiency.

1.2. Main Contribution and Outline

Although there is a wealth of literature on the advantages and disadvantages of modern IM systems, this work focuses on a standardized comparison with a conventional hydraulic circuit on a real-world telescopic loader. The main efforts are:

- The Definition of a standardized test procedure for both the conventional system and the IM system.
- The equipment of a battery electric telescopic loader with a conventional hydraulic circuit and a modern decentralized IM system.
- A comprehensive testing phase followed by a thorough analysis of the results.

The structure of the work is as follows: First, the telescopic loader and the hydraulic circuits are introduced. Next, the experimental setup and the type and number of experiments are presented. Next, the results are presented and interpreted. The work concludes with a summary and a recommendation for future research.

Figure 1: Image of the telescopic loader used in this work.

2. SYSTEM

In this section, the hydraulic system used in the telescopic loader is introduced. An image of the overall machine can be seen in Figure 1. We start with an explanation of the machine's conventional configuration, which serves as the basis of our study. Afterwards, an introduction of the adapted IM system is given.

Maximum load	3200 kg
Maximum lifting height	7 m
Battery capacity	63 kWh
Peak power overall	120 kW
Peak hydraulic power	60 kW
Volume flow	20 – 100 l/min
Maximum pressure	240 bar
Pump rotational speed	500 – 2200 rpm
Motor rotational speed	0 – 6600 rpm

Table 1: Technical data of the telescopic loader used in this work.

2.1. Technical Data

The telescopic loader that is used for this case study has a maximum load capacity of 3200 kg and a maximum lifting height of 7 m. Moreover, it is equipped with a fixed-displacement axial piston pump that delivers flows from 20 to 100 l/min with a rotational speed from 500 to 2200 rpm. The rotational speed of the motor that is driving the pump ranges from 0 to 6600 rpm, i.e. there is a gear with a ratio of 3 in between the two components. The maximum pressure is 240 bar.

The drivetrain of the machine is fully electrified, i.e. it contains no combustion engine. For this, eight battery packs with a total capacity of 63 kWh are installed. It is assumed that the machine lasts an average working day of 8 hours with only one loading cycle. The system can provide a peak power of 120 kW, from which the hydraulic system accounts for 60 kW. Table 1 provides an overview of those key points.

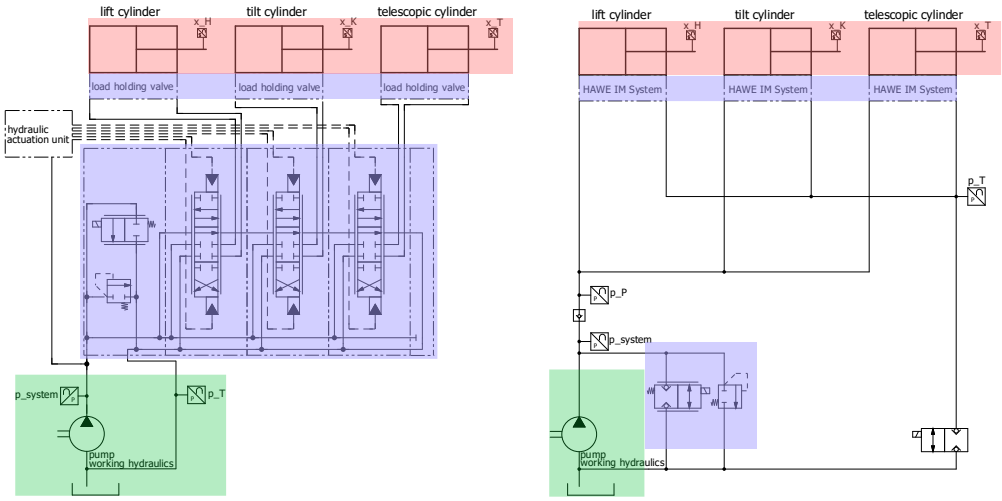

Figure 2: Excerpt of the hydraulic circuits used in this case study. On the left-hand side, the conventional configuration is shown. On the right-hand side, the IM system is shown. The colors indicate the different parts of the system, i.e. actuator, control valves, and pump.

2.2. Conventional Configuration

In conventional mobile machinery – particularly within the lower-cost segment – open-center valves in constant-flow hydraulic systems are commonly employed. This comes from the easy-to-use and cost-effective nature of such system. The reference machine used in this study is likewise equipped with such a baseline hydraulic architecture. This constant-flow system, characterized by a fixed volume flow, serves as the benchmark for evaluating alternative hydraulic system topologies.

On the energy generation side, the baseline system utilizes an axial piston pump with fixed displacement. This can be seen in the green marked sections of the hydraulic circuits depicted in Figure 2. In the electrified machine, which is used in this work, this pump is driven by an electric motor, which also powers additional consumers mounted on the same

shaft. The electric motor can be operated at discrete rotational speeds, which can be set by the driver and are regulated by the machine's control unit.

On the actuator side, the telescopic loader features three individually controlled consumers: a lift cylinder, a telescopic cylinder, and a tilt cylinder as depicted in Figure 2. These are responsible for manipulating the kinematic chain.

So, this investigation focuses on quantifying the impact on the hydraulic systems' impact on the overall energy balance of the machine, using working cycles that include the three cylinders. On the left-hand side of Figure 2 the conventional hydraulic configuration for the cylinders, which are marked in red, is shown. Hereby, the conductive section, which is marked by blue color, is realized as an open-center valve system. The valves of each cylinder are implemented as 6/3-way proportional spool valves with hydraulic actuation. An additional component of the conductive path is formed by load-holding valves, which are positioned between the spool valves and the actuators. Those are necessary to prevent free falling loads in case of a hydraulic hose failure.

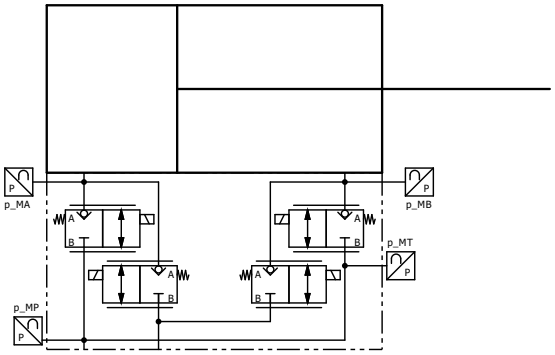

Figure 3: Detailed view on the used IM system. The valve and sensor configuration is the same for all the three equipped cylinders.

2.3. Independent Metering Configuration

As mentioned previously, the second configuration relies on a decentralized independent metering approach. In the selected system design, actuator control is achieved via four 2/2-way proportional seated valves, as shown in Figure 3. This configuration is applied to all three cylinders shown on the right-hand side of Figure 2.

Each valve of the IM system governs a single flow direction, necessitating the simultaneous and interdependent operation of multiple valves. To achieve this, all the seated valves are electronically actuated by a controller applying a PWM signal on the valves' coils. Direction and openness of the valves is controlled by the machine's operator via a joystick. To extend a cylinder, the inflow valve on the A-side and the outflow valve on the B-side are opened, while the retract direction requires to actuate the inflow valve on the B-side and the outflow valve on the A-side, respectively. While the design and tuning of the low-level control strategy is out of scope for this work, interested readers are advised to review e.g. [7, 8, 9].

To emulate a constant-flow system in conjunction with the IM valve architecture, an additional flow-controlled 2/2-way proportional seated valve is employed parallel to the

pump. This configuration ensures that the desired flow is delivered from the pump to the actuated function at any time.

It is to note that there are no load-holding valves used in the IM configuration. This comes from the fact that the valve blocks are directly mounted to the cylinders. This decentralized approach enables the seated-valves to additionally fulfill the load-holding functionality. Moreover, it is to note that additional shock-valves are used to protect the cylinders, and no specific pressure compensator is used. To ensure readability, those are not drawn in the right circuit of Figure 2.

3. EXPERIMENTAL SETTING

To enable a consistent and comparable evaluation of the hydraulic systems implemented on the telescopic loader, a standardized test cycle is defined. This cycle is designed to facilitate a comprehensive assessment of both the machine's hydraulic subsystem and its overall energy consumption. The evaluation is conducted using the machine depicted in Figure 1 with the hydraulic circuits from Figure 2 installed. In the following section, the load cycle and evaluation metrics are introduced.

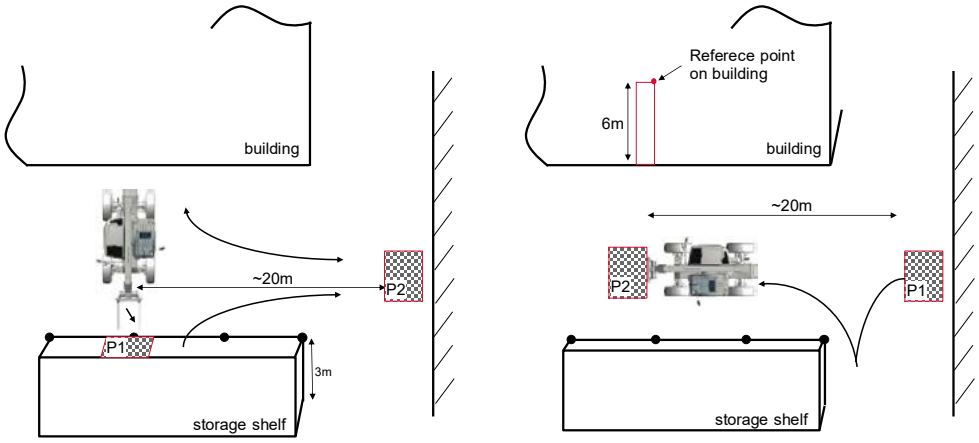

Figure 4: Illustration of the reference cycles used for the benchmark tests. The left image shows the "Pick and Go" task. The right image shows the lifting task.

3.1. Load cycles

Telescopic handlers exhibit highly variable load profiles during operation, depending on their specific application domain in e.g. construction or agriculture. Related machines, such as wheel loaders, are typically evaluated using so-called "Pick and Go" tasks, which are represented by a standardized Y-cycle [10, 11].

Since the aim of this study is to test both hydraulic systems using a representative working scenario, two adapted Y-cycles are used to reflect the operational characteristics of the machine. This includes a simple "Pick and Go" task and a lifting task in which the telescopic functionality is used.

3.1.1. Pick and Go

The “Pick and Go” test cycle involves a defined load being moved in a stacking and transport operation. An illustration of this is shown in the left part of Figure 4. Starting from Position 1 (P1), located at a vertical height of 3 m above ground level, the telescopic loader picks up the load. In the second step, the load is transferred to Position 2 (P2), which is located at ground level, covering a horizontal distance of 20 m. This operation represents a downward transfer from elevation level 1 to level 2.

In the third phase of the cycle, the telescopic loader drives backward in an unloaded state. In steps 4 and 5, the load is picked up again at P2 and transported back to P1, followed by a return to the starting position.

3.1.2. Lifting

To take the far-reaching telescopic functionality into consideration, a second load cycle is introduced. Thereby, the load is transferred to a position that is elevated to 6 m above ground level. This extended reach scenario is meant to represent typical use cases in e.g. construction and logistics where elevated placement of materials is required

In the first step of the cycle, the telescopic handler picks up the load at P1, which lies at ground level. This is followed by a transport manoeuvre that includes a 180-degree rotation of the machine. In the third step, the load is elevated to the height level of the target position P2. The horizontal distance between both points P1 and P2 is 20 m. Upon reaching the target position, the load is lowered back to ground level in step 4. In step 5, the telescopic handler traverses the transport path back to P1. Finally, in step 6, the load is placed back at the initial location. An illustration of this can be seen in the right part of Figure 4.

	Conventional System	**IM System**
#1	800 kg | 23 l/min | Pick & Go	800 kg | 23 l/min | Pick & Go
#2	800 kg | 40 l/min | Pick & Go	800 kg | 40 l/min | Pick & Go
#3	800 kg | 100 l/min | Pick & Go	800 kg | 100 l/min | Pick & Go
#4	1500 kg | 23 l/min | Pick & Go	1500 kg | 23 l/min | Pick & Go
#5	1500 kg | 40 l/min | Pick & Go	1500 kg | 40 l/min | Pick & Go
#6	1500 kg | 100 l/min | Pick & Go	1500 kg | 100 l/min | Pick & Go
#7	800 kg | 23 l/min | Lifting	800 kg | 23 l/min | Lifting
#8	800 kg | 40 l/min | Lifting	800 kg | 40 l/min | Lifting
#9	800 kg | 100 l/min | Lifting	800 kg | 100 l/min | Lifting
#10	1500 kg | 23 l/min | Lifting	1500 kg | 23 l/min | Lifting
#11	1500 kg | 40 l/min | Lifting	1500 kg | 40 l/min | Lifting
#12	1500 kg | 100 l/min | Lifting	1500 kg | 100 l/min | Lifting

Table 2: List of all experiments conducted for this work.

3.2. Load and Pump Conditions

Both test cycles are conducted under two distinct load conditions. In the first scenario, a transport weight of 800 kg is selected. This corresponds to 25% of the machine's nominal lifting capacity, which would be 3200 kg. In the second scenario, a heavier load of 1500 kg is used to evaluate system performance under increased mechanical stress.

Due to the constant-flow hydraulic architecture, the test cycle is executed at discrete volumetric flow rates. In regular operation, the pump speed is adjusted according to the flow demand of each subtask. However, to ensure comparability across measurements, each test run is performed at fixed flow rates. Three discrete flow settings are selected: 23 l/min (motor speed of 1550 rpm and pump speed of 516 rpm), 40 l/min (2550 rpm | 850 rpm), and 100 l/min (6600 rpm | 2200 rpm). Each flow rate is tested in a separate experimental run.

Overall, this results in a total of 12 experiments. For the sake of clarity, an overview of all the experiments and their different settings can be found in Table 2. Each experiment listed in Table 2 contains of two runs, where one is conducted with the conventional system and the other one is conducted with the IM system.

3.3. Evaluation Metrics

To evaluate the machine's energy consumption, measurement data is recorded during operation. Energy usage is captured across multiple reference boundaries (see Figure 5) in order to better understand the impact of different consumers on the overall energy balance.

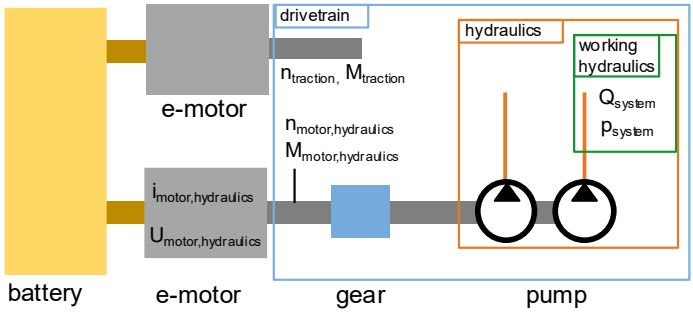

Figure 5: Schematic view of the energetic consumers of the telescopic loader including the reference boundaries.

The power input to the drivetrain encompasses the power for both the traction system and all hydraulic systems, the working hydraulics and auxiliary drives. So, the power of the whole drivetrain is calculated as:

$$P_{Drivetrain} = P_{Traction} + P_{Hydraulics}. \quad (3.1)$$

Hereby, $P_{Drivetrain}$, $P_{Traction}$, and $P_{Hydraulics}$ are powers in W. Moreover, the power of the traction system is:

$$P_{traction} = \omega_{traction} * M_{traction} = 2\pi * n_{traction} * M_{traction} \quad (3.2)$$

with $n_{traction}$ as a rotational speed in 1/s and $M_{traction}$ as a torque in Nm. Moreover, $P_{Hydraulics}$ is defined as:

$$P_{Hydraulics} = i_{Motor,Hydraulics} * u_{Motor,Hydraulics} \tag{3.3}$$

with $i_{Motor,Hydraulics}$ as a current in A and $u_{Motor,Hydraulics}$ as a voltage in V. It is to note that here, both the power consumption for the main and the secondary pump are included. However, this study focuses specifically on the working hydraulics.

Thus, the power output of the main pump is measured in addition to $P_{Hydraulics}$. For this, the system pressure, namely p_{System}, in the working circuit as well as the volumetric flow rate, Q_{System}, is measured. So, $P_{Hydraulics,Working}$ is calculated as:

$$P_{Hydraulics,Working} = p_{System} * Q_{System} \tag{3.4}$$

It is to note that losses introduced by the flow sensor are compensated analytically during post-processing to ensure accurate energy assessments.

Considering the different reference systems, two metrics are used to quantify the energy savings achieved using the IM system. The first one focuses just on the working hydraulics:

$$\delta_{Hydraulics,Working} = 1 - \frac{\int_{t_{start}}^{t_{end}} P_{Hydraulics,Working,IM} dt}{\int_{t_{start}}^{t_{end}} P_{Hydraulics,Working,Conventional} dt}. \tag{3.5}$$

Here, t_{start} and t_{end} is the total working cycle duration in s. The second one focuses on the whole drivetrain:

$$\delta_{Drivetrain} = 1 - \frac{\int_{t_{start}}^{t_{end}} P_{Drivetrain,IM} dt}{\int_{t_{start}}^{t_{end}} P_{Drivetrain,Conventional} dt}. \tag{3.6}$$

Beyond energy-related data, the position of the hydraulic cylinders and the chamber pressures are also recorded. Moreover, the operational state of the drive system is monitored via the rotational speed of the traction drive. Based on the collected measurement data, a comprehensive evaluation of the conductive hydraulic systems is performed with respect to energy consumption and overall system suitability.

4. EXPERIMENTAL EVALUATION

The experimental evaluation of both hydraulic systems is conducted using the setting shown in the previous section. In the following, the results are introduced and thoroughly discussed. For this, the time series data of two exemplary working cycles is presented in detail. Afterwards, the energy consumptions of both hydraulic systems are shown and compared.

4.1. Working Cycles

Figure 6 shows an excerpt of the sensor signals of experiment #2 (see Table 2). Here, the volume flow is set to 40 l/min and the weight of the load is 800 kg. Moreover, the Pick & Go task is performed. The diagram illustrates two repetitions of two representative test runs:

the conventional baseline system is shown on the left in blue, while the proposed IM architecture is depicted on the right in orange.

In the first step of the work cycle, indicated by (I) in the graph, the telescopic handler needs to pick up the load at position P1 on the test track. During this phase, the boom arm is moved to an elevated position without load. Under identical boundary conditions, the IM valve system exhibits a system pressure approximately 10 bar lower than that of the conventional system.

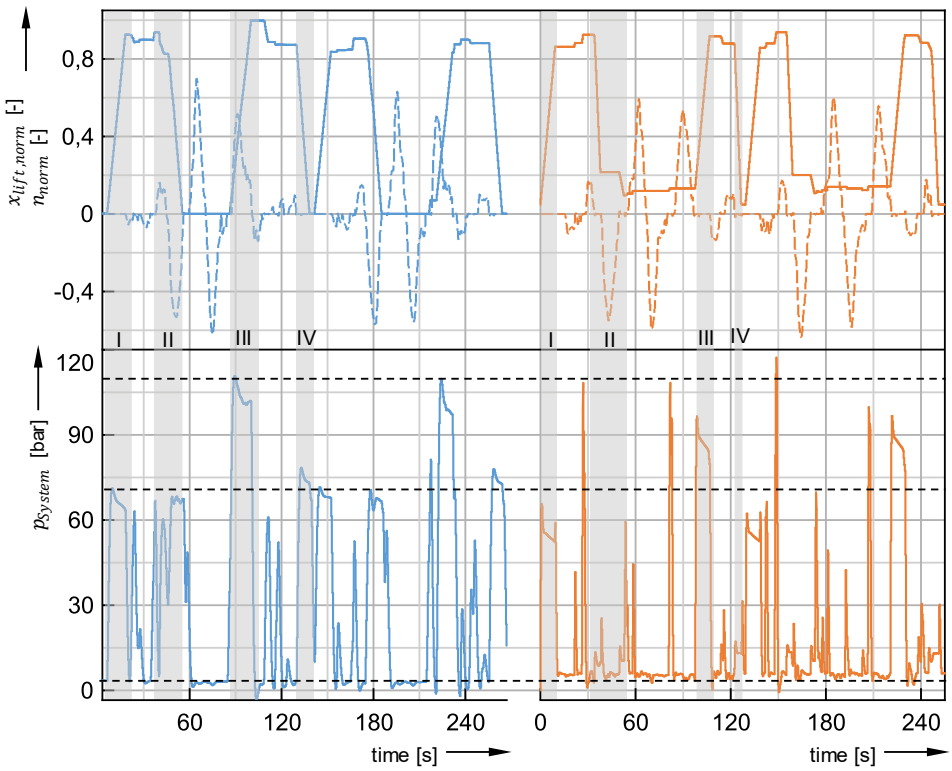

Figure 6: Excerpt of sensor signals from experiment #2 (800 kg | 40 l/min | Pick & Go).

In the second step, indicated by (II), the load is transferred to position P2. This involves lowering the boom arm under load from P1 to ground level. In the conventional system, a system pressure of 65 bar is observed, primarily required to actuate the load-holding valve. In contrast, the IM system operates at a significantly reduced pressure level of approximately 10 bar, which is the system's standby pressure. This comes from the gravity lowering functionality that the IM system offers since no load holding valves are required because of the decentralized mounting.

In the third step, (III), the load is lifted from position P2 back to P1, representing actuator movement under load. Similar to the behavior in (I), the IM system demonstrates a lower system pressure compared to the conventional design. In step four, (IV), the boom is lowered

without load. The pressure behavior mirrors that of (II), with the IM system enabling gravity-assisted lowering without the need for additional pressure.

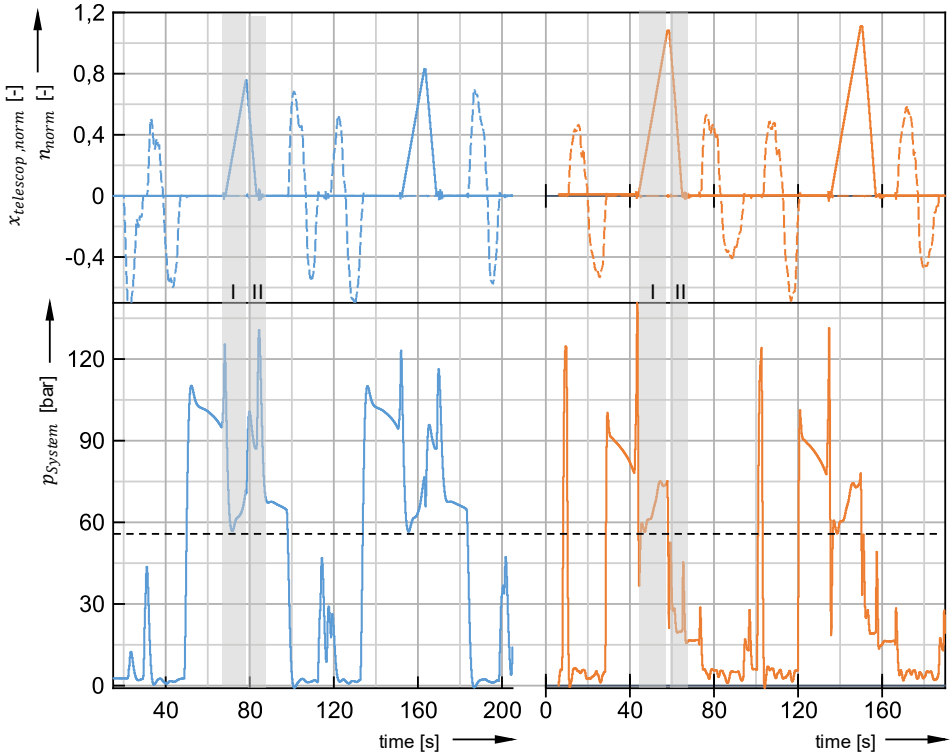

Figure 7: Excerpt of sensor signals from experiment #8 (800 kg | 40 l/min | Lifting).

Figure 7 shows an excerpt of sensor signals from two repetitions of experiment #8 (see Table 2). Again, the volume flow is set to 40 l/min and the weight of the load is 800 kg and the lifting task is performed.

As shown in Figure 7, the segments involving active drive mode without engagement of the working hydraulics exhibit recirculation behavior identical to that observed in experiment #2. Moreover, the lifting arm actuation remains as in the Pick & Go task. Thus, only the segments in which the telescopic cylinder is actuated, are marked in Figure 7.

Here, segment (I) of the cycle involves lifting the load to the target elevation. In this phase, the pressure profiles of both the conventional and IM systems show similar characteristics. In the subsequent lowering operation in segment (II), the conventional system requires a system pressure of 100 bar, primarily driven by the actuation of the load-holding valve. In contrast, the IM system operates at a reduced pressure level of 25 bar, which is sufficient to enable a stable and controlled movement. This pressure requirement is attributed to the static friction within the linear guide mechanism.

The data from both experiments demonstrate that the IM system requires significantly lower operating pressures within the working hydraulics. This reduction is primarily attributed to

minimized flow losses resulting from direct piping to the valves and the elimination of hydraulic components, i.e. the load holding valves.

Furthermore, the IM system exhibits substantially lower working pressures during cylinder retraction phases. In these scenarios, the observed pressure corresponds directly to the mechanical requirements of the task, rather than being influenced by auxiliary valve actuation. Due to the system's design, energy savings of up to 98% are achievable in lowering operations where no active hydraulic energy input is required. It is to note that the recirculating flow, inherent to the constant-flow architecture, is included in the overall energy balance and contributes to the system's efficiency profile.

Both working cycles, Pick & Go as well as the lifting task, show a clear tendency when comparing the pressure signatures from the conventional and the IM system. Since the first working cycle corresponds to a more realistic Pick & Go task, based on the unloading of the load on both positions, the following evaluation of the energy usage is going to focus on this particular working cycle with different load conditions as well as flow settings.

4.2. Energy Consumption

Figure 8 illustrates the energy balance of the working hydraulics, highlighting the energy savings achieved by the IM system relative to the conventional architecture as shown in equation (3.5). It is to note that the results are averaged over five runs with each system to ensure repeatability. Moreover, it ensured that the time taken to complete the working cycle remains constant over each run. This analysis, focused exclusively on the working hydraulic subsystem, reveals a clear dependency between load magnitude, volumetric flow rate, and achievable energy savings.

For the Pick and Go task, the IM system demonstrates energy savings ranging from 25% to 40%, depending on the operating point. The observed decline in energy savings with increasing flow rate is attributed to the diminishing influence of gravity-assisted lowering, as flow-induced losses become more dominant within the system.

The load dependency is primarily governed by the behavior of the load holding valves. Their actuation is based on a force equilibrium across the valve ports, with the working port contributing to the balance. Under high load conditions, the resulting cylinder pressure supports the process of valve opening, thereby reducing the pressure differential between the conventional and IM systems.

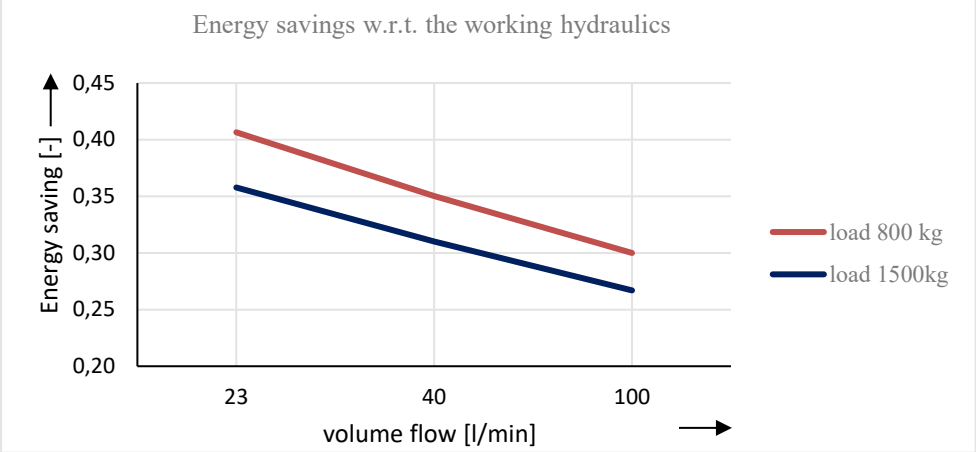

Figure 8: Energy savings $\delta_{Hydraulics,Working}$ of the IM system in the Pick & Go task w.r.t. the working hydraulics.

When extending the energy balance to the entire drivetrain, where the hydraulic consumers as well as the traction drive is included, the Pick & Go task reveals overall energy savings ranging from 15% to 30%. This behavior can be seen in Figure 9. A declining trend with increasing volumetric flow rate is again observed, driven by the same phenomenon of increasingly dominant flow losses.

In contrast to the behavior shown in Figure 8, the drivetrain-level analysis shows an increasing energy savings trend with rising load weight. As the load increases, the proportion of power demand attributed to the hydraulic subsystem grows relative to the electric drive. Consequently, the efficiency gains achieved within the hydraulic domain have a more pronounced impact on the overall energy balance.

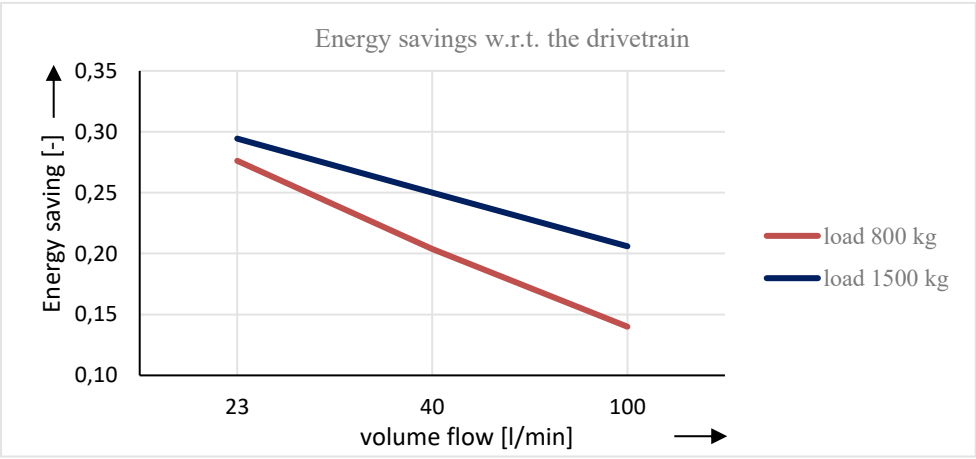

Figure 9: Energy savings $\delta_{Drivetrain}$ of the IM system in the Pick & Go task w.r.t. the drivetrain.

4.3. Practical Considerations

To emphasize the impact of the calculated energy savings, the potential impact of the telescopic loader's overall design on practical considerations is discussed. As listed in Table 1, the battery capacity of the machine used in this work is 63 kWh, which is just enough to use the machine for a working day of 8 hours with one loading cycle.

As stated before, the IM approach saves between 15% and 30% of energy, which can be seen as a range extension between 1.2 hours and 2.4 hours. This allows for more flexible machine usage, especially in areas where flexible shift models are required. Moreover, recharging is faster with a higher remaining battery capacity.

From a financial perspective, reducing the overall battery capacity up to 30% can significantly reduce the cost of the machine. Considering a retail price for off-highway applications of at least 300 € per kWh, the potential cost reduction lies in an area from 2835€ to 5670€ [12]. Additionally, the lower power usage might enable a redesign of the motor-pump unit and inverters, which can lower the price even more.

Overall, it is to mention that the energy gains of the IM approach can trigger further innovation and redesign of the whole machine. This underlines also the importance of taking a holistic approach on the design of modern mobile machinery, since hydraulic system, drive system, and the battery system significantly influence each other.

5. CONCLUSION

This work presents a comprehensive case study, highlighting the energy savings that a modern decentralized independent metering (IM) approach can be realized in comparison to a conventional hydraulic system design. To ensure practical relevancy, the accompanying experiments are conducted on an electrified telescopic loader, a machine which is heavily used in fields as e.g. agriculture and construction. Moreover, test cycles with a clear reference to real-life scenarios are used in order to come to a representative conclusion.

The case study clearly indicates that the decentralized IM approach can significantly reduce the power consumption of the machine's hydraulic circuit up to 40%. Related to the whole drivetrain, there is still a gain of up to 30% possible. Especially the gravity lowering functionality, which is possible because load holding valves are spared, makes nearly energy-free load lowering possible and accounts for a great amount of the savings. However, the pressure levels needed for cylinder extraction tasks are significantly lower using the IM approach.

This shows that redesigning conventional hydraulic circuits can be a great factor in making future machines more efficient. This is a benefit especially for electrified machines, since energy savings directly reduce the battery capacity needed. This reduces the space requirements of the electrical system, the weight of the machine, and the overall invest cost as well as the end users total cost of ownership. However, also mobile machinery using internal combustion engines can benefit from the presented IM approach, since a significant reduction in energy consumption reduces both fuel costs and emissions.

Despite the promising results, there is much room for future work on decentralized as well as centralized IM systems. So, stable control of IM systems is an ongoing challenge and requires modern control techniques. Moreover, the usage of the proposed architecture offers

possibilities like regeneration and recuperation, which can be further explored and might even further improve machine efficiency. Overall, it is to state that modern hydraulic architectures such as IM offer a great possibility to design future-proof efficient and sustainable mobile machines.

Holistic system simulation method for the analysis and evaluation of thermal management of electrified construction machinery using inverse hydraulic modelling

Dr.-Ing. Marcel Neu, Dr.-Ing. Fiona Tichi, Dr.-Ing. Martin Piechnick, Lars Holländer

marpitec GmbH, Marcel.Neu@marpitec.com

Abstract.

The electrification of construction machinery comes with new opportunities and challenges for the system architecture, leading to varying approaches and subsystem designs. Missing experiences from preceding product generations prevent an efficient comparison of system architectures early in the product development process. Thus, product development needs a tool for evaluating designs towards efficiency and energy consumption, taking functionality and environmental impacts into account. Holistic numerical system simulations enable quantitative analysis and allow comparison of concepts, without the need for tangible component designs. [1]

Electrified construction machinery is mainly described by a combination of mechanical components as well as hydraulic-, electric- and thermal circuits. A holistic system simulation describes the interaction between these domains from which two conflicting objectives arise. First, while the mechanic and hydraulic interaction is highly dynamic and takes place on short time scales, the thermal behaviour unfolds in the long-term, which leads to long periods of simulation time with high temporal resolution. Second, the complete, forward, coupling of a mechanical load simulation with the hydraulics has a high simulation complexity which comes down to extensive computational costs. [2]

As a research gap the need for an efficient holistic simulation method arises. The method shall represent all couplings relevant for the design while keeping the computational costs low, so that a quick evaluation of concepts becomes accessible. To do so, the main conflict between highly dynamic hydraulics and the long-term thermal behaviour needs to be resolved.

This contribution proposes an innovative simulation method to resolve the outlined conflict for holistic system simulations, enabling its use in the early stages of development. The main advancement is the reduction of the full bidirectional coupling of mechanics and hydraulics to a unidirectional coupling and a separation of the mechanic-hydraulic domains from the

thermal simulation. The mechanics is calculated with a multibody simulation. Standard tasks and work patterns are calculated to approximate realistic forces, torques and displacements as input for the hydraulic simulation. The hydraulic simulation is implemented inversely, meaning the valve positions, pressures, and volumetric flow rates required to fulfil the mechanical movement pattern are calculated incrementally, omitting the solution of the pressure buildup equation. To comply with the required long-term analysis for thermal behaviour the output of several sequential mechanic-hydraulic work patterns is concatenated and input into the thermal simulation. This simulation method allows the efficient comparison of different system architectures and variations of subsystems and enables the initial dimensioning of the hydraulic system according to the requirements.

The usage of this holistic simulation approach is conducted exemplary on an excavator. Slewing, boom motion and driving patterns are considered providing the load and displacement input for the inverse hydraulics. The thermal simulation got the outputs of the mechanic-hydraulic simulation comprising the required electrical quantities, thermo-hydraulic losses and environmental influences to determine the required thermal regulation for the individual subsystems. This information is used to assess different designs of the cooling circuits and showcasing the added value of efficient holistic system simulations via inverse hydraulic modelling at the same time.

Keywords. electrified construction machinery, inverse kinematics, system simulation, coupled thermal-kinematic-hydraulic simulation.

1. INTRODUCTION

Electrification of construction machinery gained significant importance lately, since regulations for pollutant emissions became stricter not only for on-road vehicles but also for off-road heavy-duty vehicles. [3, pp. 780, 781] [4, pp. 1, 2] The requirements deduced from the amended regulations led to a change in the drive technology towards electric and hybrid drive concepts. These drive concepts on one hand allow to meet the requirements for pollutant emissions [5, p. 1] but furthermore offer advantages regarding noise emission, energy efficiency by utilizing recuperation of kinetic and thermal energy and optimisation of subsystem's operating point and increased productivity. [3, pp. 780, 787, 788, 797–799]

On the other hand, new challenges arise from the electrification of construction machinery. The crucial design decision is the system architecture around the electric drive system including the electronical periphery. Besides the changed drive system recuperation and electrical storage systems are required, beyond others. [3, pp. 782, 783]

One important aspect to evaluate the different system architectures is the thermal management within the machine. This includes the electrical subsystems as well as temperature control of the cabin and hydraulic subsystems. As electrified construction machines are not only a new generation of machines but involve a new drive train and energy supply concept, there is limited experience available on preceding product generations and therefore on sufficient criteria for the evaluation of the system variant's performance and optimum system design [6, p. 3]. Hence, comparing the variants of system architecture and subsystem design require analysing them during the design phase. For the evaluation of the thermal management using simulation results is feasible to reduce experimental effort and verify development considerations, furthermore, accelerating the development phase by

identifying subsystems with the most potential for optimisation. To describe a system of electrified construction machinery properly, the interaction of kinematics, hydraulics and thermal behaviour within the system need to be considered in a holistic simulation approach. [7] Therefore this contribution follows the trend of coupling multiple physical domains and subsystems into a single simulation with its challenges and opportunities.[8]

2. FUNDAMENTALS

The characterization of a mechanical system with actuators, sensory and a control loop is known as a mechatronic system. As the aim of the examinations in this contribution is the thermodynamic characteristics, for evaluation the thermal management, the mechatronic system is extended to include the thermal domain, which then describes a multi physics or multi domain system. To simulate this multi physics system, each domain needs its individual modelling. Initial objective of holistic system simulations is the identification of suitable numerical tools to capture the system's characteristics. Subsequently the exchange of information and the calculation process need to be described. In the following chapter the fundamental principles for the holistic numerical approach utilized in this work to couple the afore mentioned physical domains efficiently are introduced, following the idea of assessing the thermal management for the whole system. [9]

Computational Dynamics (also referred to as multi-Body Dynamics) serves the purpose of assisting engineers during the analysis of kinematic and dynamic behaviour of complex mechanical systems comprising numerous moving bodies connected by joints. Ideally Computational Dynamics allow the prediction of the component's position, velocity and acceleration based on the external forces acting upon the individual mechanical parts. It utilises available computing power to reduce the effort for analytically/manually calculating the interaction between multiple bodies in an acceptable time. Computational Dynamics describes the mechanical domain, and its application is usually divided into rigid body and flexible body analysis, as well as kinematic determined and dynamic determined systems. While rigid body and kinematic analysis produce algebraic equations, the dynamic analysis induces second order partial differential equations to solve. The regular computational dynamics determines the accelerations, velocities and positions of the system under consideration based on the forces acting upon it. [10]

In certain cases, if the accelerations, velocities and positions for the system in question are known, it is possible to calculate the external forces in reverse. This approach is called inverse kinematic simulation. Consequently, the partial differential equations of the dynamic approach collapse to differential-algebraic equations which simplifies the solution procedure significantly. The comparison of forward and inverse simulation is depicted in Figure 2.1.

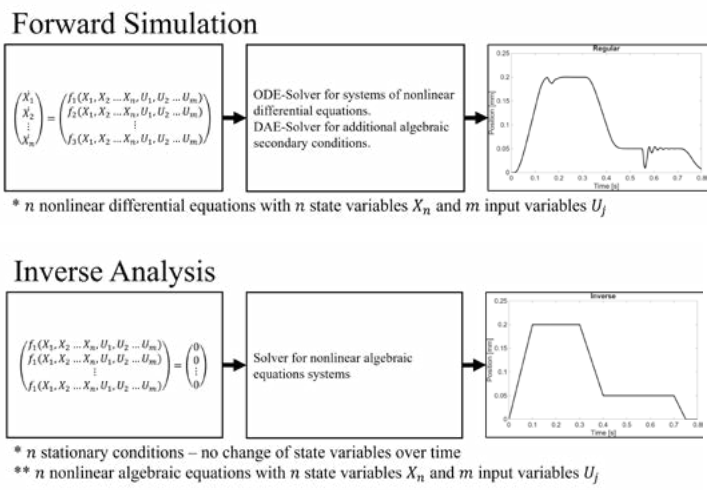

Figure 2.1: Forward Simulation a) in comparison to Inverse Analysis b) due to the inversion the equation system is simplified, while dynamic effects get eliminated from the analysis.

The approach of inverse kinematics is used frequently to analyse the forces needed to complete a functional task inside a technical system. [9,10,11,12]

Though Computational Dynamics only achieves a degree of accuracy compared to finite element calculations, which are much more accurate at a much higher computational cost, the granularity of Computational Dynamics meets the requirements for modelling complex mechanical systems. The same gradation in simulation tools is found in hydraulics, thermodynamics and electro dynamics. While for all three physical domains a continuum representation exists (i.e. CFD, CHT and CEM) the calculation with lumped parameter models, focussing on the interaction between components is used frequently for less effortful system analysis. [13,14]

Thermal simulations are primarily based on the Fourier's heat conduction equation to describe the heat flux through solid bodies. This form of heat transfer is dominating the heat development in a technical system. In addition, heat radiation and thermal convection are relevant depending on the system's physics and its boundary conditions. The main boundary conditions to be considered are the initial temperature of the system as well as its immediate environment and heat sources usually described by an input heat flux. [15, p. 265]

By reducing the hydraulic, electric and thermodynamic components to system level ordinary differential equations that describe the correlations, for example between volumetric flow rate into the cylinder and its stroke, the calculation of system dynamics is much more accessible than modelling the hydraulic cylinder using a continuous flow representation. The continuous flow representation is not only time-dependent but also a function of space and therefore leads to a complex system of computational expensive partial differential equations.

In hydraulic system simulations pressure or volumetric flow rates from fluid energy machines like pumps are specified along with control signals for the valves to analyse the

hydraulic system's response comprising piston or motor accelerations, velocities and positions. In combination with control circuits that feed those positions, velocities and accelerations into a control loop modifying the input variables, specific motions of the hydraulic system are realizable.

Analogue to inverse kinematics an inverse hydraulic analysis is applicable. Instead of specifying pressure, volumetric flow rates and valve positions, the desired state of motion and position of the hydraulic system is specified, and the needed pressures, volumetric flow rates and valve positions are deduced. As with inverse kinematic inverse hydraulic reduces the computational effort at the expense of the system dynamic behaviour, which is not representable anymore.

The lumped parametric calculation approach entails an increased demand of fitting the actual system components to the, mostly generic, component substitutes of the simulation tool, while allowing longer real-world time spans to be calculated.

But, although the simulation time for each individual domain is reduced drastically, the time span in which processes happen in the individual domains differs significantly, becoming particularly notable when comparing hydraulic and thermodynamic processes. The period required in the respective physical domains for a steady state to be reached is describable by its characteristic times that originate from an analogy to electrodynamic oscillatory circuits [15]. The characteristic time is calculable from the basic differential equation of the domain regarded. The analogy between hydraulics and electrodynamics is depicted in Figure 2.2, taken from [16].

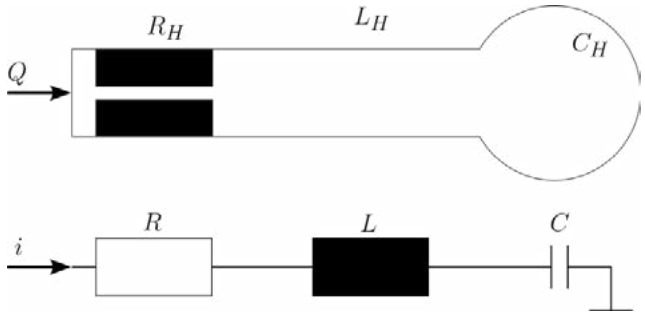

Figure 2.2: Principal illustration of the analogy between hydraulics and electrodynamics [16]

The circuit diagram can be transferred into the differential equation (1) and equation (2).

$$u = R \cdot i + L \cdot \frac{di}{dt} + \frac{1}{C} \cdot \int i dt \tag{1}$$

$$\Delta p = Q \cdot R_{\mathrm{H}} + L_{\mathrm{H}} \cdot \frac{dQ}{dt} + \frac{1}{C_{\mathrm{H}}} \cdot \int Q dt \tag{2}$$

Depending on the regarded component the equations vary. By transformation to the frequency domain, characteristic time constants are derived which indicate required period for a change in state of the component described. The analogies between electrodynamics circuits and the relevant domains for the analysis in this contribution are listed in Table 2.1.

Table 2.1: Electrodynamic Network Analogy for Hydraulics, Thermodynamics and Mechanical Systems

				Characteristic Times
Electrodynamics	Capacitor C	Inductor I	Resistor R	$\tau = RC, \frac{L}{R}, \sqrt{LC}$
Hydraulics	Hydraulic Capacitor $C_{\mathrm{H}} = \frac{V_0}{K_{\mathrm{Fl}}} = V_0\beta$	Hydraulic inertia $L_{\mathrm{H}} = l \cdot \frac{\rho}{A}$	Cylindrical pipe (Hagen-Poiseuille) $R_{\mathrm{H}} = \frac{12 \cdot \eta \cdot l}{\pi \cdot r^4}$	$\tau = RC, \frac{L}{R}, \sqrt{LC}$
Thermodynamics	Heat Capacity $C_{\mathrm{TH}} = C_{\mathrm{p}}, C_{\mathrm{v}} \left[\frac{\mathrm{J}}{\mathrm{K}}\right]$	-	Thermal Resistance $R_{\mathrm{TH}} = \lambda \cdot l \left[\frac{\mathrm{K}}{\mathrm{W}}\right]$	$\tau = \lambda \cdot l \cdot C_{\mathrm{p}}$
Mechanics	Spring $C_{\mathrm{m}} = k$	Inertia $L_{\mathrm{h}} = m$	Friction $R_{\mathrm{m}} = D$	$\tau = \sqrt{\frac{m}{c}}$

From this analogy the different characteristic times for the lumped parameter systems are calculable, which allows an estimation of the overall simulation time needed. A hydraulic network, typically consisting of valves, pistons and tanks, reaches its stationary state in the order of seconds. To capture the hydraulics dynamic behaviour, simulation time step sizes below $< 1 \cdot 10^{-3}$[s] are necessary. Based on experience a thermodynamic system reaches a stationary state in the order of minutes or hours, depending on its size, which leads to time step sizes bigger than 1 [s] to capture the systems dynamics. In many cases in Multiphysics, a problem emerges, if those domains are considered in combination within a single simulation approach, since this forces the calculation of thermodynamic effects on a hydrodynamic timescale if no measures are taken. A combined hydraulic and thermal simulation ultimately leads to a significant overhead in computational costs, which is why an innovative approach is needed to bring those two domains together.

3. RESEARCH OBJECTIVE AND APPROACH

The evaluation of newly developed electrified construction machinery and its subsystems, accordingly, regarding the thermal management is sensibly conducted using simulation tools for the system description. The relevant subsystems include mechanical kinematics, hydraulics and thermal processes, which raises the obstacle of conflicting time scales between the hydro-kinematic and the thermal characteristics of the system as derived in chapter 2. While the characteristic of hydraulic and kinematic subsystem is highly dynamic, the thermal behaviour is long-term in comparison. A holistic simulation of these domains, reconciling the significantly different time scales, requires innovative simulation methods, which outlines the research gap.

The objective of this contribution is to introduce a holistic simulation methodology, that enables coupling kinematics, hydraulics and thermodynamics while concurrently reducing simulation time and effort to a minimum.

The proposed solution provides for a reduction of the coupling between mechanic-hydraulic and thermal behaviour from bidirectional to unidirectional. This allows the simulations to be separated.

The mechanical part of the simulation is modelled as a multi body system, depicting the bodies' kinematics. Kinematics and hydraulics both are simulated inversely and unidirectionally coupled using the inverse kinematics' output as the inverse hydraulics' input. The hydraulics output combines the results of the hydraulic-mechanical coupling and is input of a subsequent forward thermodynamic simulation. To match the longer time span of thermodynamic phenomena the short-term hydro-mechanical simulation output is concatenated over time. [12]

Using this simulation methodology highly dynamic phenomena, mainly settling-in behaviour, in hydraulics are omitted to make the simulation less CPU-intensive. Furthermore, the hydro-mechanical simulation must be calculated only once, instead of repeatedly over the whole period the thermal behaviour takes up. Thereby, the thermal simulation becomes substantially more efficient and less effortful.

4. SIMULATION METHODOLOGY

The simulation methodology for modelling electrified construction machinery and similar applications according to thermal behaviour taking electric and hydraulic losses and external thermal influences like thermal radiation into account, bases on the idea of a holistic and simultaneously efficient simulation. The approach for a holistic model needs to handle the time scale difference between mechanical and hydraulic phenomena and thermal phenomena. This challenge is addressed by subdividing the simulation according to the time scale. The hydraulic-mechanical simulation is separated from the thermal simulation by decoupling the two simulations in one direction, so that the unidirectional coupling from the hydraulic-mechanical part to the thermal simulation remains.

The desire for efficiency furthermore demands low effort simulation methods for both, the highly dynamic mechanical and hydraulic part and the long-term thermal behaviour. For this reason, the mechanical and the hydraulic simulation are unidirectionally coupled, as well. This way it is possible to implement inverse simulations to the mechanics as well as the hydraulics. In comparison, the conventional forward simulation uses the input of manipulated variables e.g. force in mechanics or valve positions in hydraulics and simulates the causal system behaviour, outputting dependent variables like movements or pressure build-up, principally depicted in Figure 2.1 a). Whereas the inverse simulation illustrated in Figure 2.1 b) predefines the dependent variables, e.g. a position of components in a mechanical system and calculates backwards to determine the input variables' values required to achieve the predefined dependent variables. The inverse simulation is advantageous regarding computational effort and thus simulation time due to the omission of transient phenomena, especially oscillations, which moreover reduces the partial differential equation system to a nonlinear ordinary differential equation system.

Mechanical Simulation

The overall simulation methodology is presented in Figure 4.2. As described the mechanical simulation is implemented inversely as a multi body system (MBS) simulation, that is generally able to provide approximately realistic forces, torques and displacements for

standard tasks and work patterns of systems. The inverse mechanical simulation is reduced to a mere kinematic simulation, excluding the transient effects considered in a forward simulation, as mentioned in chapter 2. The highly dynamic transient effects are computationally expensive but their impact on the thermal behaviour of the system is insignificant, allowing for them to be neglected in a thermal analysis.

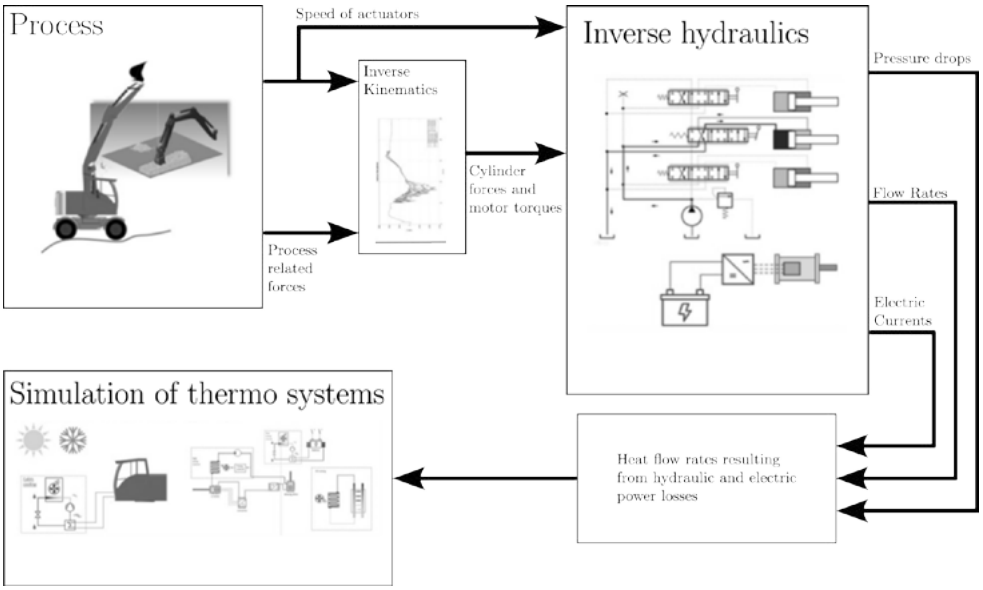

Figure 4.1: Overview of the simulation methodology.

For the inverse kinematic simulation of construction machinery, first the movements of all relevant components of the machine are defined, determining the free degrees of freedom (DoF) and considering restrictions of the component's connections in form of bearings and joints. This results in internal and external forces and torques. The external forces and torques arise from gravity and the interaction of the construction machine with the environment and are forwarded into the system where they cause internal forces and torques in the joints. The joints comprise bearings, swivel and thrust joints as well as the hydraulic cylinders also considered as thrust joints. In the unconstrained DoFs of the bearings and conventional joints, the movements are simply performed, since there is no counterforce or torque, while the forces and torques in the constrained DoFs are supported by the bearings. The hydraulic cylinders experience forces along the direction of piston movement since they can apply a counterforce. This counterforce is determined by the inverse kinematic simulation for each cylinder and describes the required actuator force to achieve the predefined movement and displacements, respectively. The determined cylinder forces subsequently serve as input for the hydraulic simulation. Compared to complex inverse kinematic problems like robotics, where iterative methods are necessary to reach a solution with inverse kinematics since a multivariant problem is looked at, the motion of an excavator or similar piece of equipment is quite simple with a small solution space. Therefore, the inverse kinematic solution is simpler and therefore more accurate. [17]

Hydraulic Simulation

The hydraulic subsystem is modelled using mechatronic system simulations with specified hydraulic and mechatronic components, e.g. cylinders with given Pivot-point. Like for the mechanic simulation inverse hydraulic simulation is used to exclude highly dynamic effects of a real hydraulic control system that are likewise neglectable for the overall result of the thermal system behaviour.

The inverse hydraulic simulation resorts to the inversely calculated required forces from the kinematic simulation. The inverse hydraulic uses the equation system, equivalent to the equation system in Figure 2.1 b) to calculate the required pressures and therefore volume flows in the cylinders, parameterised by their cross section and stroke, and valve positions as well as electric control signals for the system control for providing the desired actuator forces in the mechanical system.

The perfused valves, the piston movements and the electric currents for the control signals are subject to thermal losses. These losses represent the relevant thermal influence of the hydraulic subsystem on the overall machine and is consequently input to the thermal simulation. The simulated period is short, though, compared to the time span of thermal phenomena. And while the other thermal influences are nearly stationary the thermal influence of the mechanic and hydraulic system varies during operating of the construction machine and depending on the operating condition. To depict an average of the operating conditions, weighed with their assumed average duration, it is recommended to generate and simulate operation cycles in the mechanical and hydraulic subsystems. The determined thermal losses during the operation cycle are concatenated over time and used for the thermal simulation. The repeated operation cycles, provide a realistic approximation of the system's thermal behaviour in a real application, while in contrast a single operation only provides information about the thermal impact of this operation and neglects relevant further influences. The estimation is feasible for the initial system design and component dimensioning required to fulfil the requirements in terms of temperature management of the overall system.

Thermal Simulation

The thermal simulation is conducted conventionally forward. The concatenated heat input from the mechatronic and hydraulic simulation, arising from electric losses in motors, the inner resistance of the battery, inverters and hydraulic losses due to drops in pressure within the valves, transient losses in the compressor and exhaust heat in the converter are used as an input modelled either using the efficiency factor or if available characteristic curves. Furthermore, external heat sources like the environmental temperature and solar radiation on the cabin of the machine and internal heat sources like the air conditioning including the cooling cycle. The heat flux in between the subsystems and domains is calculated using dedicated connector elements describing the thermal transfer behaviour based on the fundamental thermodynamic equations as described in chapter 2 and local temperatures. The temperature changes and heat flux are provided as a result. From these outputs information about the temperature control or the overall thermal energy loss can be deduced. Further examples of potential interpreted results are presented in the following chapter, where the methodology is exemplary applied to an excavator.

5. Exemplary Application by Means of an Electrified Excavator

To demonstrate its operating principle and benefits the presented methodology is applied to a case study. The electrified excavator presented in the following is a generic design without a real-world equivalent but provides a level of detail close to a real-world system. For the mechanical domain the drivetrain and sewing drive as well as the excavator arm are modelled as multibody systems. The individual hydraulic cylinders for the excavator arm are supplied by a hydraulic circuit, depicted in Figure 5.2. The drivetrain, sewing drive, oil pump and coolant pumps are all driven by alternating current electric motors, which are supplied from power electronics, converting the direct current from the battery block to appropriate alternating currents for the electric motors. The multiple thermal circuits in the model compensate for the efficiency losses caused by transformation losses or friction, which produces heat. The oil of the hydraulic circuit is passed through a heat exchanger, modelled as a single fluid circuit giving off heat to a thermal mass, to compensate for the hydraulic losses. A low temperature coolant circuit is modelled for cooling the power electronics and the electric drives operating the pumps and drivetrain, comprising two cooling circuits with liquid ethylene glycol in one and coolant R134A in the other circuit, exchanging heat via contact to a chiller. Another coolant circuit with exchange of heat between fluid circuit and coolant circuit is deployed to regulate the battery system. Contrary to the oil cooling the coolant circuits for the power electronics and battery are temperature controlled since the electric components are only operable close to standard conditions. Finally, cabin air conditioning is included in the thermal domain analysis, which ultimately represents a temperature control giving off heat to a thermal mass, too. Separating the different cooling circuits allows to individually regulate each temperature in the most efficient working point of the component or subsystem. Aside from the cooling circuits heat radiation from the cabin towards the environment is considered as a heat sink as a counterpart to the solar radiation into the cabin.

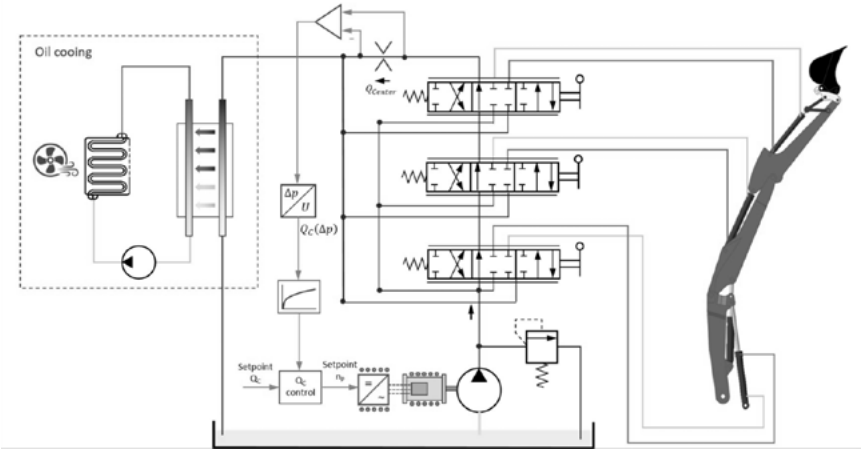

Figure 5.1: Schematic hydraulic circuit diagram of the excavator arm

In total the model consists of a mechanical, electrical, thermal and hydraulic dimension with, multiple, partly independent, circuits. A schematic overview of the system, including mechanical, hydraulic and thermal coupling of the excavator arm, is given in Figure 5.1.

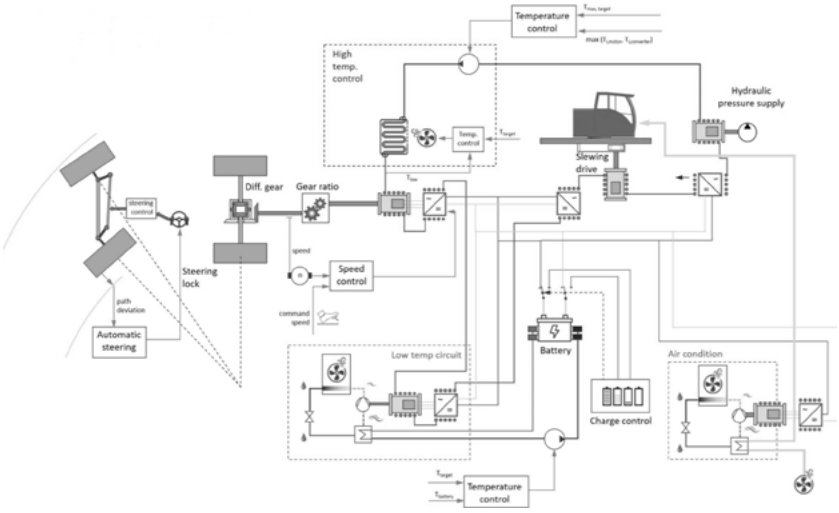

Figure 5.2: Electric actuators and cooling circuits of the exemplary excavator arm

To conduct a holistic system simulation and analyse the thermal management, which was implemented as described, a load cycle and environmental conditions are needed. The load cycle needs to represent realistic work pattern for the construction machine including slewing, drive patterns and boom motion. For the simulation the following work cycle is assumed:

- 5x Moving earth – based on a particle Simulation
- 1x acceleration/deceleration
- 1x uphill and downhill drive
- 1x idle slewing
- 1x idle boom motion

A single duty cycle takes four minutes and is looped 10 times for a single simulation to reach stationary conditions for each physical domain, which leads to a depicted real time of 40 minutes.

Figure 5.3 shows the drivetrain torque for the working cycle compared to the temperature development in the cooling circuit of the power electronics in Figure 5.4. The plots show how the thermal domain develops over multiple cycles while the drivetrain reaches its stationary states immediately. These results are consistent with the known discrepancy in the timescale between long-term thermal phenomena and considerably shorter-term mechanical, electrical and hydraulic phenomena. It also highlights the need to concatenate load cycles multiple times to obtain reliable information about the system behaviour.

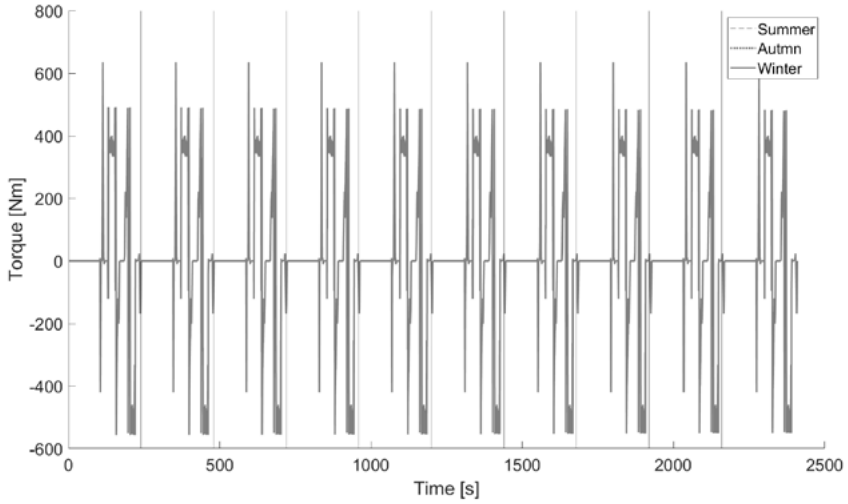

Figure 5.3: Torque progression over time of the drivetrain

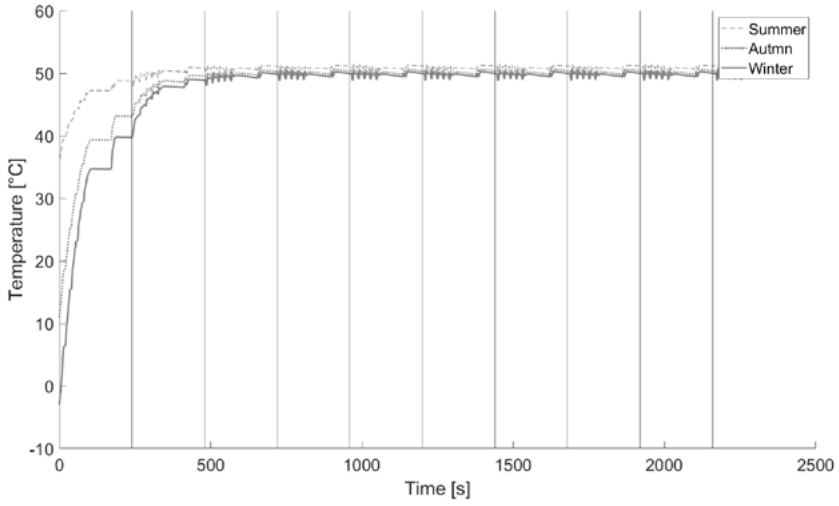

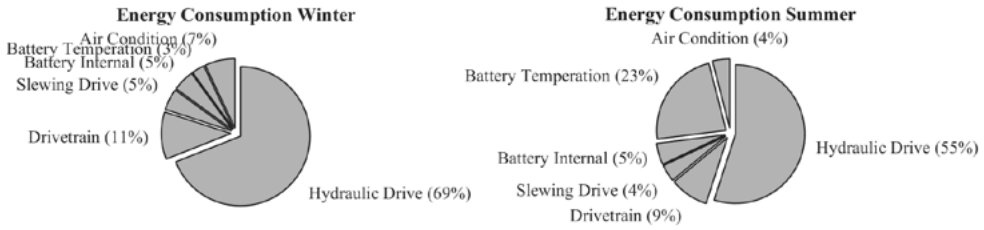

Figure 5.4: Temperature development over time of the power electronics coolant

Figure 5.4 also contains multiple plots for different environmental conditions that are tested to identify the dependency of the thermal management system on the environment. Therefore different, central European, seasons were taken as a basis:

- Summer: Temperature: 35 °C; Humidity: 78 %
- Autumn: Temperature: 11 °C; Humidity: 98 %
- Winter: Temperature: -3 °C; Humidity: 85 %

This analysis for different environmental conditions allows the evaluation of the relative energy consumption of the tested design. Figure 5.5 shows a comparison between summer

and winter according to the proportional energy consumptions arising after the system reached its stationary thermal operating conditions.

These evaluations are only possible because the system is considered holistically. It allows, aside from analysis of the total energy consumption, to identify design areas that are most promising for improvement. Furthermore, this example already emphasizes the cruciality of the environmental conditions for the design of thermal management systems. The battery cooling system for example has a significantly higher impact in the summer than the winter, compared to the other considered subsystems in this study. An analysis that ignores these differences could lead to flawed design.

6. DISCUSSION

The proposed simulation methodology serves as an analysis tool during the system development phase with the aim to enable a quantified evaluation and comparison of system concepts regarding the thermal aspects. Prerequisite for the use of the simulation methodology is, as with simulations in general, a sufficient level of details of the design to have the necessary information for a calculation available. This allows the methodology's application during the late concept and draft phase of the product development process. In this phase the simulation following the presented methodology allows a data-based comparison of different system architectures and an initial dimensioning of the components. Besides information about interrelations within the system and the impact of present influencing factors become known and understandable.

The simulation methodology omits the transient and highly dynamic processes of the mechanical and the hydraulic subsystem, as their impact on the long-term thermal development within the system is insignificant and therefore feasible to neglect. Furthermore, transient effects like friction and leakage are only represented to a limited extend by efficiency factors. These simplifications lead to a limited accuracy of the resulting values but still provides useful information about the main interrelations within the system and the main influencing factors as well as an estimation of the required subsystem and component dimensions. Another limitation of the inverse kinematics is that the exact and physically possible moving path of the components is not calculated. This is acceptable for the initial concept simulation because the exact moving path' do not influence the results for the forces substantially. For cases that require a detailed analysis of these effects as well as for the further steps of the product development process, an adaption of the methodology is recommended, resorting to transient forward simulations. As this approach revokes the decisive advantage of reduces computational and time effort, it is only sensible during later development phases or in separate simulations.

7. CONCLUSION AND OUTLOOK

Electrified construction machinery offers a variety of advantages, especially the compliance with the latest emission regulations. Using the simplifications of inverse kinematics and hydraulics, as well as the unidirectional coupling of mechanics to hydraulics and hydraulics to thermodynamics, the presented methodology enables a holistic and efficient simulation and evaluation of the thermal properties of a mechanic-hydraulic system, particularly designated for electrified construction machinery. This methodology allows for system understanding, system concept comparison and initial dimensioning during the early product development phases.

The example of the excavator demonstrates the applicability of the proposed simulation methodology on an academically level and provides the prospect on an application in a real system. As an outlook the verification of the methodology by a comparison to a fully coupled simulation and measurement data of a real example of an excavator are of interest to examine the accuracy of the simulation. To furthermore validate the application and the advantages of the simulation methodology the application in a practical development process is pending.

Abstract.

In the efforts to improve the energy efficiency of hydraulic systems, a key initiative may be to eliminate the throttle losses induced by hydraulic control valves. Existing solutions targeting this aspect include standalone electro-hydraulic variable-speed drives for control of hydraulic actuators such as cylinders and motors. A main challenge of this approach may be the electric component sizes, hence their cost, required to meet both the maximum force/torque and speed of a cylinder/motor, even though not concurrently. In case of systems with multiple hydraulic cylinders/motors to be actuated, the idea of realizing highly integrated systemwide drives in terms of so-called electro-hydraulic variable-speed drive networks have emerged in recent years. As opposed to standalone electro-hydraulic variable-speed drives, such drive networks enable power sharing not only on the electric side, but also on the hydraulic side. A consequence of this is that components may be downsized considerably in many applications, while maintaining a similar efficiency. However, the cost may still be prohibitively high in many industry segments, especially due to the number of electric machines and drives. This provides the incitement to investigate hydraulic drive networks enabling control via variable displacement machines rather than via multiple variable-speed electric machines. This approach may be feasible due to the presumed less cost of variable displacement machines compared to electric machines/drives. This paper analyses the feasibility of hydraulic drive networks using a single electric machine powering multiple variable displacement machines, organized in network configurations. Especially, emphasis is placed on the component sizing in such displacement-controlled drive networks when applied in a crane application. Furthermore, the resulting displacement-controlled drive networks are compared to existing individual displacement-controlled drive approaches, where it is found that significant reductions in variable displacement machine sizes may be enabled by drive network structures.

1. INTRODUCTION

Facing the current climate crisis, efforts to reduce carbon emissions are pursued throughout societies, including various industries. In this endeavour, machinery relying on hydraulic

All Open Access articles are peer-reviewed, distributed under the Creative Commons Attribution-Non Commercial 4.0 International

systems as means of power transmission is especially relevant to consider. This is partly because actuation in such machinery commonly is associated with large forces and power, and partly because traditional hydraulic systems rely on throttle valves to be controlled. That is, relying on control via loss adjustment. Consequently, traditional hydraulic machinery is inherently energy inefficient and associated with substantial energy losses and related emissions [1]. Hydraulic machinery may be stationary or mobile, and in the former case these are often already electrically powered, whereas the latter case remains powered by internal combustion engines in most cases. Trends suggests, however, that mobile hydraulic machinery are increasingly electrified by replacing internal combustion engines with battery powered electric machines. To enable an actual decarbonization of such machinery, the electric energy used must be provided by renewable energy sources, and furthermore, preferably only use as much energy as needed to minimize stress on the electric grid in a world where electrification of society is a key priority. Here, the energy inefficiency of traditional hydraulic systems poses a great challenge due to their high energy losses. As a first approach to reduce losses, variable-speed fixed or variable displacement pumps may be applied, allowing to reduce energy losses of hydraulic power supplies by adjusting shaft speeds to flow requirements, more optimal operating points etc. [2,3]. However, a substantial part of the losses in traditional hydraulic systems are the principal losses associated with throttle control, and to enable a real impact in terms of reduced energy consumption and emissions, these principal losses must be significantly reduced.

Approaches to achieve such reductions in energy consumption involves avoiding or limiting the use of control valves, and here electro-hydraulic standalone drives for actuation of e.g. hydraulic cylinders may be applied [4-8]. In systems containing two or more cylinders, however, it may be more feasible to consider more dedicated multi-axis electro-hydraulic drives such as the so-called HHEA [9,10] or so-called electro-hydraulic variable-speed drive networks [11-15]. Even though these electro-hydraulic systems suggest high energy efficiencies, the use of one or more electric machines per cylinder or motor to be actuated, may cause drive cost to be prohibitively high in an industrial setting. An approach to reduce the number of required electric machines may be so-called displacement control, where the control is shifted from speed variability to displacement variability. A recent displacement control approach suggests this to be combined with traditional valves for low power functions [16,17]. The topic of displacement-controlled drives has been considered extensively, see e.g. [18-21]. However, a one-pump per actuator requirement may also here cause cost levels to be prohibitively high [21]. To overcome this challenge the integration of on/off valves was proposed in [22], allowing to control individual actuators in a sequential way [21]. A drawback of this approach, however, is that concurrent control of all actuators is not possible.

An alternative approach mitigating the abovementioned challenges with displacement control, may be to organize multiple variable pumps on a common shaft in network configurations, similar to electro-hydraulic variable-speed drive networks. That is, having the same offset with a common shaft with multiple pumps as e.g. [18-22], but implement *appropriate* short circuit connections between cylinder chambers and *appropriate* hydraulic connections between pump and actuator ports in a network kind of way, forming *displacement-controlled drive networks* (DCDNs). This paper presents an analysis of displacement-controlled drive networks and their design in the context of a crane application. It is shown that the total required pump displacement may be significantly

reduced compared to *conventional* displacement-controlled multi-actuator drive systems, while allowing concurrent control of all actuators. The nomenclature used throughout the paper is explained in the Appendix.

2. CRANE APPLICATION & DESIGN REQUIREMENTS

The drive designs considered in the following are based on the load imposed by the two-axis knuckle boom crane depicted in Figure 1.1. Any drive system considered must enable a payload mass of up to $m_L = 5000$ [kg], moving at 200 [mm/s] both vertically and horizontally throughout the operating space, i.e. $\dot{x}_L = \pm$ 200 [mm/s], $\dot{y}_L = \pm$ 200 [mm/s]. The following serves as a case study the load and speed requirements have been chosen to provide reasonable flow and pressure levels and are not related to specific application tasks.

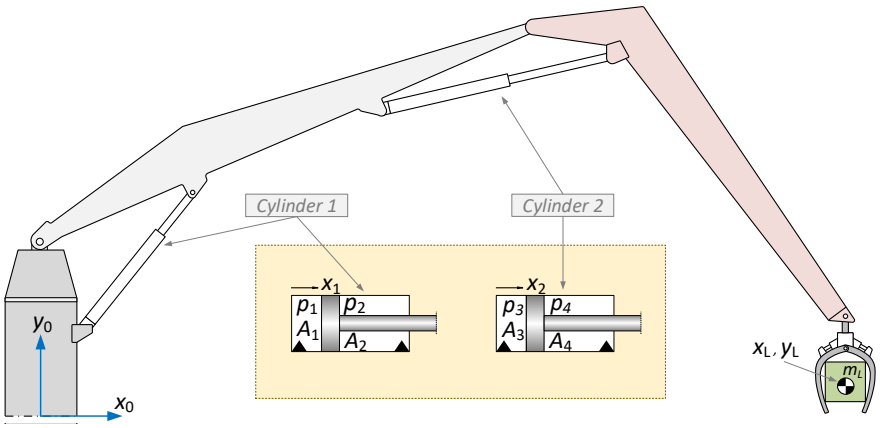

Figure 1.1. Two-axis knuckle boom crane application for investigations.

The hydraulic piston forces for the two cylinders are given by Eqs. (1.1).

$$F_{L1} = A_1 p_1 - A_2 p_2 \quad , \qquad F_{L2} = A_3 p_3 - A_4 p_4 \tag{1.1}$$

Using the crane parameters considered in [11] and a payload of 5000 [kg], the piston forces appear as depicted in Fig. 1.2. when considering the operating space spanned by the cylinder pistons.

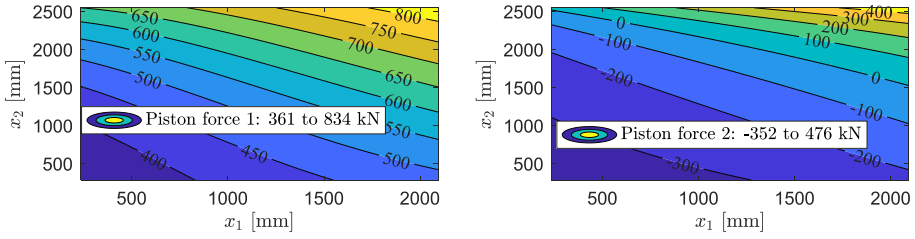

Figure 1.2. Cylinder forces ([kN]) of knuckle boom crane at payload of 5000 [kg].

The piston speeds evaluated at these extreme payload speeds, $\dot{x}_L = \pm$ 200 [mm/s], $\dot{y}_L = \pm$ 200 [mm/s], are depicted in Fig. 1.3., accounting for the gearings induced by the crane mechanism itself.

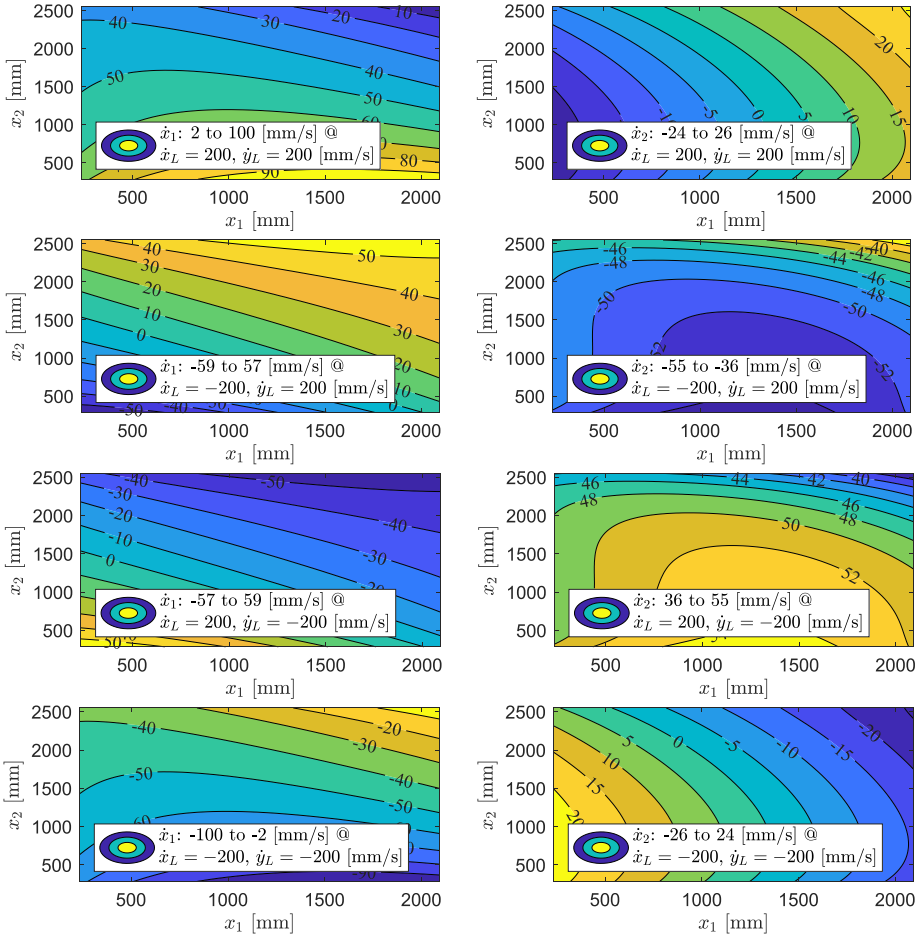

Figure 1.3. Cylinder piston speed at max./min. payload speeds and piston positions.

The piston forces and piston velocities depicted in Figures 1.2. and 1.3. serves as design requirements in the following sections.

Note: The following disregards the pilot supplies for the swivel control mechanisms and other flow losses as well as torque losses. Furthermore, all drives considered are assumed to operate at a constant shaft speed of 3000 [rpm].

3. INDIVIDUAL DISPLACEMENT CONTROLLED DRIVES

As mentioned in the introduction, individual displacement-controlled (IDC) drives have been proposed in several versions and for several applications [18-22]. Here the case of a multi-actuator IDC drive without switching valves are considered as a benchmark for displacement-controlled drive networks (DCDNs), as this allows for individual control of both cylinder pistons simultaneously, which is also the objective for the DCDNs. For the crane application the dual cylinder IDC drive depicted in Fig. 2.1 is considered.

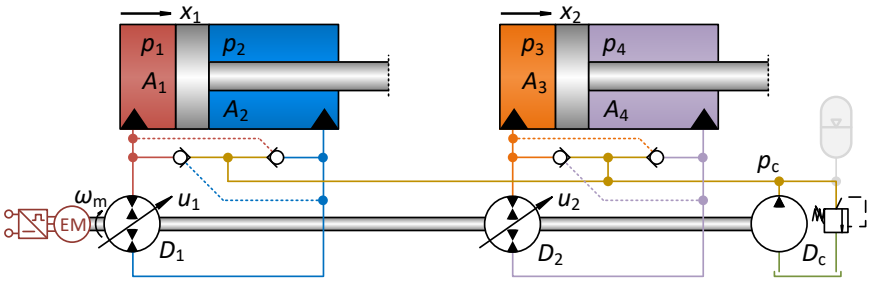

Figure 2.1. Individual displacement-controlled drive for crane application.

In literature IDC drives are generally equipped with an accumulator attached to the charge pump outlet, forming a charge line having the purpose of compensating the cylinder differential flows, flow losses and fluid exchange related to thermal management and filtering, and to supply the swivel control valves [22]. Hence, if no fluid exchange functionality is implemented as is the case in Fig. 2.1, the charge pump displacement size may be rather small. On the other hand, if no accumulator is desired, the charge pump must be sized to handle the cylinder differential flows (and in practice also flow losses and pilot flows). Considering traditional transmission pumps, these are equipped with a build-in charge pump. From these considerations, three different cases may be established.

Case 1: IDC without accumulator, but with charge pump

Case 2: IDC with accumulator and charge pump

Case 3: IDC with accumulator, but without charge pump (utopia)

Here Case 1 and Case 2 may be applied in practical use, and Case 2 is a common implementation. Case 3 is highly idealized and could work only if flow losses were absent and is thus a utopia. However, this case serves as an idealized benchmark. The theoretically required displacement sizes for all three cases are considered in the following. It should be noted that for all three cases the maximum steady state pressure here is 190 [bar].

3.1. Case 1 sizing – IDC with Charge Pump & No Accumulator

Considering Fig. 2.1 and the Case 1 conditions, the displacement machine flows in a steady state are given by Eqs. (3.1), (3.2).

$$Q_1 = D_1 u_1 \omega_m = \begin{cases} A_1 \dot{x}_1, & p_1 \geq p_2 \\ A_2 \dot{x}_1, & p_1 < p_2 \end{cases} \quad , \quad Q_2 = D_2 u_2 \omega_m = \begin{cases} A_3 \dot{x}_2, & p_3 \geq p_4 \\ A_4 \dot{x}_2, & p_3 < p_4 \end{cases} \tag{3.1}$$

$$Q_c = D_c \omega_m = (A_1 - A_2)\dot{x}_1 + (A_3 - A_4)\dot{x}_2 \tag{3.2}$$

From the cylinder piston forces and speed ranges of Figures 1.2 and 1.3, the required individual displacements and the total displacement are obtained as Eqs. (3.3).

$$D_1 = 123\ [\text{ccm}]\ ,\ D_2 = 48\ [\text{ccm}]\ ,\ D_\text{c} = 70\ [\text{ccm}] \rightarrow D_\text{tot} = 241\ [\text{ccm}] \tag{3.3}$$

3.2. Case 2 sizing – IDC with Charge Pump & Accumulator

Due to the application of both a charge pump and an accumulator, the charge pump could be chosen to only compensate flow losses (and in reality, also the swivel control valve pilot flow) at the specified shaft speed. Here, the sizing takes offset in charge pump sizing applied in the Bosch Rexroth A4VG series [23], with relevant information outlined in Table 1.

Table 1: Charge pump vs. nominal pump sizes for A4VG [23].

A4VG	**28**	**40**	**56**	**71**	**90**	**125**
Nominal size in [ccm]	28	40	56	71	90	125
Charge pump size [ccm]	6.1	8.6	11.6	19.6	19.6	28.3
Charge pump size in % of nominal size	22	22	21	28	22	24

For the A4VG [23], the charge pumps are averagely sized at 23% of the nominal pump size. To be conservative (sizing in favour of Case 2), the charge pump size is here assumed to be 20% of the total nominal pump size required. In this case, the displacement sizes appear as Eqs. (3.4).

$$D_1 = 123\ [\text{ccm}]\ ,\ D_2 = 48\ [\text{ccm}]\ ,\ D_\text{c} = \frac{D_1+D_2}{5} = 34\ [\text{ccm}] \rightarrow D_\text{tot} = 205\ [\text{ccm}] \tag{3.4}$$

3.3. Case 3 sizing – IDC without Charge Pump

As Case 3 assumes that no charge pump is required, total displacement simply corresponds to the sum of the nominal displacement, also required in Case 1 and Case 2, and is hence given by Eqs. (3.5).

$$D_1 = 123\ [\text{ccm}]\ ,\ D_2 = 48\ [\text{ccm}]\ ,\ D_\text{c} = 0\ [\text{ccm}] \rightarrow D_\text{tot} = 171\ [\text{ccm}] \tag{3.5}$$

3.4. IDC Shaft Torque Requirements

In evaluating the resulting torque applied to the common drive shaft, the chamber pressures are estimated as follows with cylinder forces $F_{\text{L1s}} = (A_1 - A_2)p_\text{c}$, $F_{\text{L2s}} = (A_3 - A_4)p_\text{c}$.

$$p_1 = \begin{cases} \dfrac{A_2 p_c + F_{L1}}{A_1} & , \quad F_{\text{L1}s} < F_{\text{L1}} \\ p_c & , \quad F_{\text{L1}s} \geq F_{\text{L1}} \end{cases} \quad , \quad p_2 = \begin{cases} p_c & , \quad F_{L1s} < F_{L1} \\ \dfrac{A_1 p_c - F_{\text{L1}}}{A_2} & , \quad F_{L1s} \geq F_{L1} \end{cases} \tag{3.6}$$

$$p_3 = \begin{cases} \dfrac{A_4 p_c + F_{\text{L2}}}{A_3} & , \quad F_{\text{L2}s} < F_{\text{L2}} \\ p_c & , \quad F_{\text{L2}s} \geq F_{\text{L2}} \end{cases} \quad , \quad p_4 = \begin{cases} p_c & , \quad F_{\text{L2}s} < F_{\text{L2}} \\ \dfrac{A_3 p_c - F_{\text{L2}}}{A_4} & , \quad F_{\text{L2}s} \geq F_{\text{L2}} \end{cases} \tag{3.7}$$

The common shaft torque for the IDC drives is then given by Eq. (3.8).

$$\tau_\text{IDC} = D_1 u_1 (p_1 - p_2) + D_2 u_2 (p_3 - p_4) + D_\text{c} p_\text{c} \tag{3.8}$$

Here, the factors D_1u_1 and D_2u_2 are obtained using Eqs. (3.1) and Eqs. (3.9), noting that the shaft speed ω_m is constant.

$$D_1u_1 = \frac{Q_1}{\omega_\mathrm{m}} \quad , \quad D_2u_2 = \frac{Q_2}{\omega_\mathrm{m}} \tag{3.9}$$

Evaluating Eq. (3.8) with Eqs. (3.9) for the cylinder force maps Fig. 1.2. and the cylinder velocity maps Fig. 1.3., the maximum shaft torque for the three cases is given by Eqs. (3.10), (3.11) and (3.12).

$$\text{Case 1: } \tau_\mathrm{IDC}|_\mathrm{max} = 139 \text{ [Nm]} \tag{3.10}$$

$$\text{Case 2: } \tau_\mathrm{IDC}|_\mathrm{max} = 127 \text{ [Nm]} \tag{3.11}$$

$$\text{Case 3: } \tau_\mathrm{IDC}|_\mathrm{max} = 116 \text{ [Nm]} \tag{3.12}$$

The reason for the reduced maximum shaft torque of benchmark case 2 and 3 compared to benchmark case 1 is attributed the reduced charge pump sizes.

4. DISPLACEMENT CONTROLLED DRIVE NETWORKS

Displacement controlled drive networks (DCDNs) for dual cylinder systems may basically appear as depicted in Fig. 4.1. It is desired to use as few displacement machines as possible, while maintaining controllability of both cylinder pistons and the system sum pressure as in [11]. Hence, a single short circuit connection between two chambers should be deployed, necessitating three displacement machines to achieve the desired level of controllability. This, in turn, provides 36 unique ways of realizing the drive connections, which should be considered in context of the design requirements discussed in Section 2.

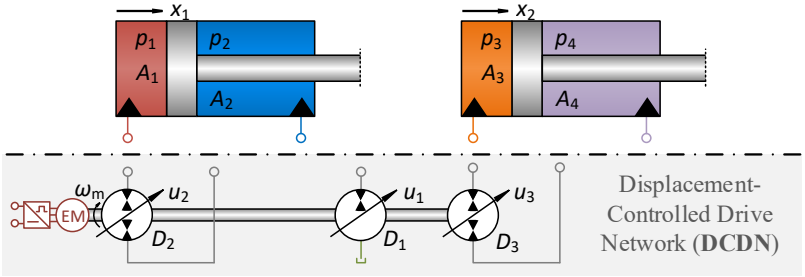

Figure 4.1. Displacement-controlled drive network (DCDN) for crane application.

4.1. DCDN Sizing Example

As an example on component sizing of one of the 36 unique configurations, consider the DCDN in Fig. 4.2. Here, the rod-side chamber of cylinder 1 is short circuited with the bore side chamber of cylinder 2, forming the combined volume *23*. Furthermore, the bore side chamber of cylinder 1 is connected to the common volume 23 via pump 2 and volume 23 is also connected to the rod side volume of cylinder 2 via pump 3 (notation 1 ↔ 23 ↔ 4). Finally, the tank volume 0 is connected to volume 23 via pump 1 (notation 0 ↔ 23).

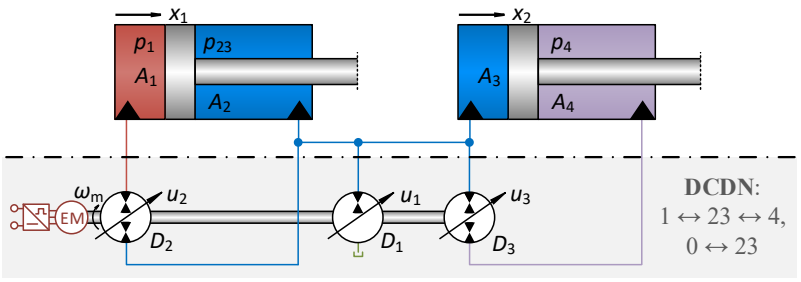

Figure 4.2. Displacement-controlled drive network 1 ↔ 23 ↔ 4, 0 ↔ 23.

The displacement machine flows in a steady state, assuming flow losses absent, are obtained considering flow continuity and are given by Eqs. (4.1)-(4.3).

$$Q_1 = D_1 u_1 \omega_\mathrm{m} = (A_1 - A_2)\dot{x}_1 + (A_3 - A_4)\dot{x}_2 \tag{4.1}$$

$$Q_2 = D_2 u_2 \omega_\mathrm{m} = A_1 \dot{x}_1 \tag{4.2}$$

$$Q_3 = D_3 u_3 \omega_\mathrm{m} = A_4 \dot{x}_2 \tag{4.3}$$

When considering the cylinder piston force and speed ranges in Figures 1.2. and 1.3., the required displacement sizes in Eq. (4.4) are obtained.

$$D_1 = 70\ [\mathrm{ccm}]\,,\ D_2 = 123\ [\mathrm{ccm}]\,,\ D_3 = 26\ [\mathrm{ccm}] \rightarrow D_\mathrm{tot} = 219\ [\mathrm{ccm}] \tag{4.4}$$

This is comparable to the IDC drive, Case 1, as no accumulator is used. It is notable that total required displacement for the IDC of Case 1 is 241 [ccm], whereas it is only 219 [ccm] for the DCDN example considered here.

4.2. Sizing Results for all 36 DCDNs

Applying the same sizing method for all 36 unique DCDNs, the total required displacements presented in Table 2 are obtained. It should be noted that the maximum steady state pressure depends on the short circuit applied, hence this is also specified in Table 2. The DCDNs requiring the lowest and highest displacement are depicted in Fig. 4.3 to the right and to the left, respectively.

From the sizing results in Table 2 it is evident that, even though requiring 9% less displacement compared to the IDC in Case 1, the DCDN example of section 4.1 is not the one requiring the lowest amount of displacement.

The sizing results emphasize the importance of architecture selection, and its influence on required displacement when considered for a certain application. The DCDN denoted 1 ↔ 23 ↔ 4, 0 ↔ 1 is the architecture that requires the lowest amount of displacement, 155 [ccm], whereas the DCDN denoted 13 ↔ 4 ↔ 2, 0 ↔ 2 requires the highest displacement with 337 [ccm] which is more than twice that of DCDN 1 ↔ 23 ↔ 4, 0 ↔ 1.

Table 2: Sizing results for all 36 unique DCDNs.

Configuration	Max. pressure	0 ↔ 13	0 ↔ 2	0 ↔ 4
13 ↔ 2 ↔ 4	294 [bar]	163 [ccm]	234 [ccm]	294 [ccm]
13 ↔ 4 ↔ 2	294 [bar]	197 [ccm]	**337 [ccm]**	268 [ccm]
2 ↔ 13 ↔ 4	294 [bar]	156 [ccm]	225 [ccm]	216 [ccm]
Configuration	Max. pressure	0 ↔ 14	0 ↔ 2	0 ↔ 3
14 ↔ 2 ↔ 3	269 [bar]	199 [ccm]	244 [ccm]	251 [ccm]
14 ↔ 3 ↔ 2	269 [bar]	205 [ccm]	319 [ccm]	250 [ccm]
2 ↔ 14 ↔ 3	269 [bar]	184 [ccm]	253 [ccm]	191 [ccm]
Configuration	Max. pressure	0 ↔ 23	0 ↔ 1	0 ↔ 4
23 ↔ 1 ↔ 4	190 [bar]	216 [ccm]	171 [ccm]	231 [ccm]
23 ↔ 4 ↔ 1	190 [bar]	313 [ccm]	204 [ccm]	268 [ccm]
1 ↔ 23 ↔ 4	190 [bar]	219 [ccm]	**155 [ccm]**	279 [ccm]
Configuration	Max. pressure	0 ↔ 24	0 ↔ 1	0 ↔ 3
24 ↔ 1 ↔ 3	190 [bar]	262 [ccm]	191 [ccm]	198 [ccm]
24 ↔ 3 ↔ 1	190 [bar]	331 [ccm]	196 [ccm]	260 [ccm]
1 ↔ 24 ↔ 3	190 [bar]	247 [ccm]	183 [ccm]	254 [ccm]

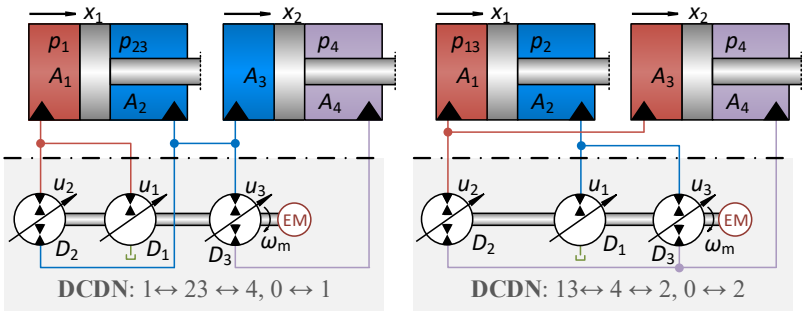

Figure 4.3. DCDNs with min. (left) and max. (right) required total displacement.

4.1. DCDN Shaft Torque Requirements

Numbering the 36 unique DCDN architectures from $i = 1 \ldots 36$, the instantaneous power of the i^{th} DCDN architecture is given by Eq. (4.5) where $\tau_{\mathrm{DCDC},i}$ is the total torque acting on the common shaft.

$$\tau_{\mathrm{DCDC},i}\omega_{\mathrm{m}} = \left(D_{1,i}u_{1,i}\Delta p_{1,i} + D_2 u_2 \Delta p_{2,i} + D_{3,i}u_{3,i}\Delta p_{3,i}\right)\omega_{\mathrm{m}} \tag{4.5}$$

Indeed, when the shaft speed ω_{m} is constant, the swivel angles $u_{1,i}, u_{2,i}, u_{3,i}$ must inevitably be adjusted such that the total shaft torque of any of the 36 DCDNs is identical for any identical operating point and given by Eq. (4.6), whereas the individual displacement machine torques may differ among the different DCDNs.

$$\tau_{\mathrm{DCDC},i} = D_{1,i}u_{1,i}\Delta p_{1,i} + D_2 u_2 \Delta p_{2,i} + D_{3,i}u_{3,i}\Delta p_{3,i} \tag{4.6}$$

The instantaneous displacements may be obtained as Eq. (4.7).

$$D_{1,i}u_{1,i} = \frac{Q_{1,i}}{\omega_{\mathrm{m}}} \quad , \quad D_{2,i}u_{2,i} = \frac{Q_{2,i}}{\omega_{\mathrm{m}}} \quad , \quad D_{3,i}u_{3,i} = \frac{Q_{2,i}}{\omega_{\mathrm{m}}} \tag{4.7}$$

Evaluating Eq. (4.6) with Eqs. (4.7) for the cylinder force and velocity maps in Fig. 1.2. and Fig. 1.3, the maximum shaft torque for all 36 DCDNs is given by Eq. (4.8).

$$\tau_{\mathrm{DCDN}}|_{\max} = 139\ [\mathrm{Nm}] \tag{4.8}$$

This is coincident with the IDC Case 1 and is a consequence of not including any hydraulic energy recuperation abilities, the specified shaft speed and not considering torque losses.

5. Comparison of Required Displacements

To provide an overview of what can be gained in terms of component downsizing using a DCDN compared to IDC drives, all sizing results are depicted in Figure 5.1 for comparison.

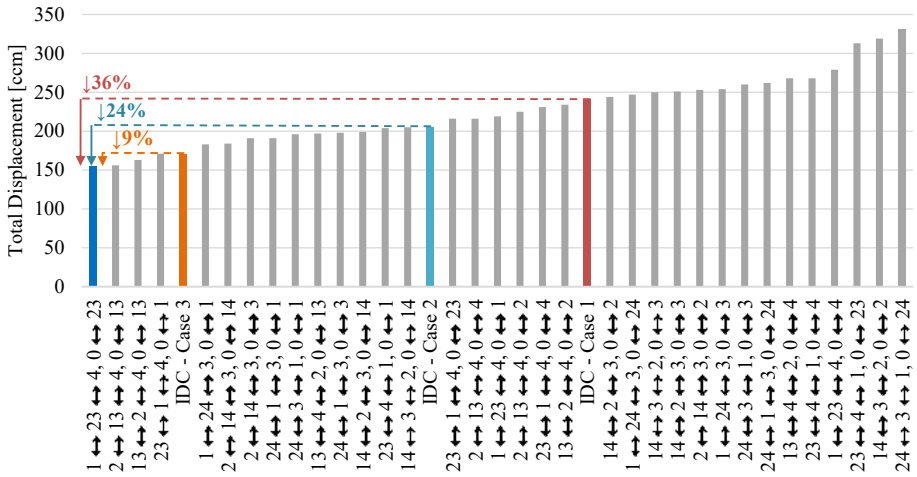

Figure 5.1. Ideal DCDN and IDC drive sizing results for the crane application.

Considering IDC Case 1, which is the case most comparable with the DCDNs as no accumulators are used, the DCDN subject to the lowest amount of displacement allows a total displacement reduction of 36%. Compared to the more conventional IDC Case 2, the same DCDN allow for a displacement reduction of 24%, and 9% when compared to the utopian IDC Case 3. The highest DCDN displacement requirement, on the other hand, by far exceed those of all IDC cases. These results emphasize the downsizing perspectives of DCDNs compared IDCs implying that cost may be significantly reduced.

6. SUMMARY & OUTLOOK

This paper considers the possible feasibility of displacement-controlled drive networks when compared to individual displacement-controlled drives applied to a dual axis crane application. The presented study takes offset in idealized cases, not considering losses such as torque and flow losses. Special attention is given to displacement requirements, and the possibility to reduce installed displacement using displacement-controlled drive networks. As benchmarks to the displacement-controlled drive networks, three cases for individual displacement-controlled drives are considered, namely being a case with a charge pump but no accumulator, a case with both a charge pump and an accumulator and a utopian case with no charge pump but with an accumulator. For the crane application considered, the use of a displacement-controlled drive network allows for a reduction in required displacement of 36% compared to the individual displacement-controlled drive without accumulator and a reduction of 24% compared to the individual displacement-controlled drive with accumulator. These results suggest that the cost of using displacement-control may be significantly reduced compared to earlier reports in literature, potentially rendering such drives commercially feasible.

In the endeavour to further develop displacement-controlled drive network technology, multiple topics should be addressed. The work presented in this paper takes offset in the static loads of the chosen crane application, however, future design developments should also consider the impact of transient loads. Especially, loads resulting from acceleration and rapid motion reversal may significantly influence the common shaft torque as well as the flow balance of a displacement-controlled drive network, and really any displacement-controlled drive system, and should be taken into consideration.

From a cost point of view, it is preferred to use as small component sizes as possible. However, transient loads may cause flow and torque/current saturation preventing a system to perform as intended, and hence peak demand conditions should be considered with great care. Such challenges may be mitigated by the system level controls via the pressure and flow coupling introduced in displacement-controlled drive networks, allowing to distribute hydraulic energy in alternative ways compared to individual controlled drive networks. Furthermore, the bandwidths of displacement control mechanisms and electric machine/inverter drive assemblies should be considered to ensure that these allow the system level controls to maintain proper behaviour of a system, both under rapid changes in motion commands and as well as under impact loads.

To this end, the use of charge pumps in displacement-controlled drive networks may also have a perspective and should be considered in future research. This approach is not considered in the work presented in this paper, where the use of three variable displacement machines with two cylinders allows the control of the lower pressure level in the system. A further advantage of the presented approach is, that excess energy of a fixed charge pump is not dissipated in the tank, hence the energy losses are anticipated to be less compared to individual displacement-controlled drives. This, however, depends on the energy consumption of the additional swash plate control mechanism introduced with the network solutions. Other losses introduced in displacement-controlled drive networks as well as individual displacement-controlled drives, are associated with idle conditions when the cylinders are inactive. These idle losses may be mitigated by adjusting the shaft speed command to the instantaneous flow command.

APPENDIX

The nomenclature used in this paper is outlined in Table 3 below.

Table 3: Nomenclature used.

Symbol	Description
A_1, A_2, A_3, A_4	Cylinder piston areas
D_1, D_2, D_3	Max. displacement of displacement machine
D_c	Displacement of charge pump
$F_{\mathrm{L}1}, F_{\mathrm{L}2}$	Piston pressure forces
m_L	Crane payload
p_1, p_2, p_3, p_4	Cylinder piston pressures
p_c	Charge pressure
$\Delta p_1, \Delta p_2, \Delta p_3$	Displacement machine pressure differences
Q_1, Q_2, Q_3	Displacement machine flows
Q_c	Charge pump flow
u_1, u_2, u_3	Normalized swivel angles
$\dot{x}_L, \dot{y}_L$	Payload speed components
$\dot{x}_1, \dot{x}_2$	Cylinder piston speeds
ω_m	Shaft speed
$\tau_{\mathrm{IDC}}, \tau_{\mathrm{DCDC}}$	Common shaft torques

Biographies

Lasse Schmidt received the M.Sc. degree in engineering (mechatronics) from Aalborg University, Denmark, in 2008. From 2008 he was with the application engineering group of Bosch Rexroth A/S, Denmark, and from 2010 an industrial Ph.D. fellow also associated with Aalborg University. He received the Ph.D. degree in robust control of hydraulic cylinder drives in 2014. Subsequently, he has been a postdoctoral researcher at AAU Energy while concurrently being with Bosch Rexroth AG. Hereafter he became an Assistant Professor with AAU Energy. He is currently an Associate Professor with AAU Energy and heading research activities related to electro-hydraulic drive network technology, a field in which he is the founder of the fundamental design and control principles. He is the main author or co-author of nearly 70 scientific peer-reviewed publications, most of them on topics related hydraulic drives and systems control. Lasses current research interests are in design and control of electro-hydraulic drive networks and their integration into both mobile working machines and industrial systems.

Mikkel van Binsbergen-Galán received the B.Sc. and M.Sc. degrees, both from Aalborg University, Denmark, in 2020 and 2022 respectively, where he is currently working towards the Ph.D. degree at AAU Energy. His research interests are related to design and control of electro-hydraulic drives, actuators and systems, with special focus on electro-hydraulic variable-speed drive technology.

Development of a flow-optimised slip-in servo cartridge valve for high-performance applications

Abstract.

Hydraulic drive technology remains essential in applications demanding high force, power density, and precise dynamic control. Systems such as die-casting machines require extremely high flow rates to manage large cylinder volumes, rapid motion sequences, and fast pressure build-up and release. This paper presents the development methodology of a new, flow-optimized generation of hydraulic slip-in servo cartridge valves tailored to such high-performance requirements. The process includes the derivation of performance criteria from demanding use cases, the identification of key influencing parameters, and the formulation of a suitable design approach. State-of-the-art simulation methods and extensive experimental investigations are employed to evaluate design variants and optimize flow efficiency, dynamic behaviour, hysteresis, repeatability, and positioning accuracy, while enabling digital control and sensor integration. The result is benchmarked against relevant performance indicators. The study demonstrates how combining high dynamics with high flow capability provides a technical advantage in modern hydraulic systems and supports industrial efforts to reduce carbon footprints. A case study illustrates system integration and quantifies the resulting performance benefits.

Keywords. Hydraulic servo cartridge valve; slip-in valve; CFD; FEA; high-flow hydraulics; dynamic response; open-die forging press.

1. INTRODUCTION

Hydraulic drive technology remains essential in industrial applications that require high force density, compact installation space and reliable control behaviour. Many systems operate with large cylinder volumes and high operating pressures while demanding fast motion profiles and accurate pressure regulation. As a result, substantial hydraulic flow must be controlled with precision, particularly during rapid pressurisation and equally fast release or decompression phases. Applications such as die casting machines, open die forging presses and large injection moulding units exemplify these combined requirements and place correspondingly high demands on the components used.

All Open Access articles are peer-reviewed, distributed under the Creative Commons Attribution-Non Commercial 4.0 International

Slip-in servo cartridge valves provide a suitable basis for such environments because they combine high flow capacity with the controllability of servo-actuated designs. Their architecture supports efficient flow guidance, low pressure losses and stable closed loop behaviour across a wide range of dynamic operating conditions. By virtue of their fundamental characteristics, valves of this class thus provide specific advantages in high performance hydraulic systems.

The present work discusses the development of a new flow optimised generation of such valves, named X700 [1]. The approach follows a structured methodology that integrates application driven requirement analysis, numerical design and simulation, and iterative experimental refinement. By combining mechanical, hydraulic and electronic design aspects within a coordinated development process, a new valve series has been created that offers significantly improved flow efficiency and dynamic control behaviour.

The resulting design is evaluated using representative performance metrics and is examined in a system context through a case study of an open die forging press. This example illustrates how the characteristics of the new valve generation influence manifold architecture, system dynamics and energy efficiency, and how the systematic development approach supports tangible improvements in demanding hydraulic applications.

2. DEVELOPMENT METHODOLOGY

The development of high-performance hydraulic servo cartridge valves at Axxeron Hydrolux follows a structured and repeatable methodology that combines virtual analysis and physical testing within iterative loops. This approach ensures that functional, structural and dynamic requirements are met with a high degree of reliability before a new valve design is released for field use.

2.1. Requirements Analysis and Definition of Performance Targets

The process begins with a systematic requirement analysis for the relevant classes of applications. Flow demands are derived from cylinder dimensions, volumetric stroke requirements and acceptable speed profiles, whereas upper pressure limits are determined from structural load cases of the hydraulic system. Requirements concerning dynamic response, hysteresis and control precision arise from the motion control tasks of the target machine. Energy related aspects, such as permissible pilot stage leakage and acceptable pressure losses, further influence the performance targets. The result of this phase is a consolidated and quantified specification that governs all subsequent development stages.

2.2. Virtual Development Cycle

The first development loop takes place in the virtual domain. Three-dimensional CAD models of sleeve, poppet, cover and pilot interface form the foundation for numerical analyses. Strength evaluation is performed using finite element methods to assess static and cyclic loading up to the intended nominal operating pressure. This ensures that critical elements such as flow windows, seat transitions and connecting threads provide sufficient safety margins. The methodology includes both static load analyses and pressure cycling evaluations, with results systematically reviewed against design rules.

Flow behaviour is evaluated using computational fluid dynamics. Throughout the entire stroke range, simulations provide detailed information on pressure distributions, velocity

fields, potential cavitation and flow induced hydraulic forces. The numerical development workflow, illustrated in Figure 2.1, supports the comparison of alternative geometries under identical boundary conditions and assists in identifying variants that combine low pressure losses with favourable dynamic characteristics. By iterating CAD design, FEA and CFD within the virtual loop, only the most promising concepts are transferred into physical prototypes.

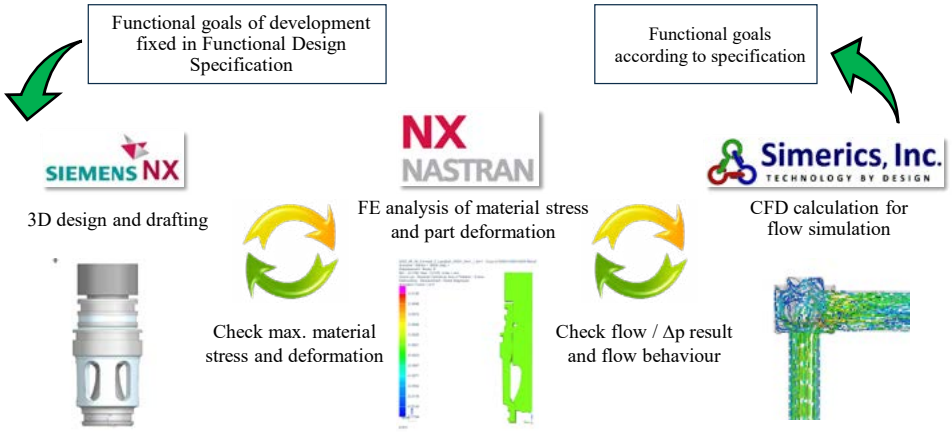

Figure 2.1. Iterative numerical development in continuous refinement loop.

2.3. Experimental Development Cycle

After virtual optimisation, selected variants are manufactured as prototypes and subjected to a standardised functional testing programme. This includes the measurement of flow characteristics in both flow directions at controlled pressure drops, typically ranging from a few bars to double digit values, depending on the intended application scenario. Dynamic evaluation involves step response measurements at pilot pressures up to 210 bar and frequency response tests across a representative bandwidth. Threshold, hysteresis, and drift behaviours are measured at different temperatures to assess control accuracy under varying environmental conditions. The complete experimental workflow is depicted in Figure 2.2.

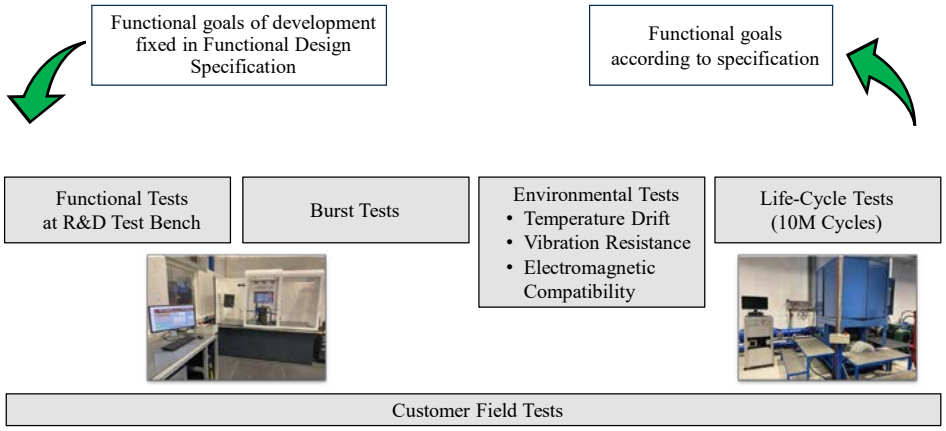

Figure 2.2. Iterative experimental development involving various types of testing.

These experiments validate the simulation results and provide insight into frictional behaviour, guiding tolerances and poppet position stability. Any deviation between measured and predicted behaviour triggers an additional virtual development loop, ensuring alignment between numerical predictions and hardware performance.

2.4. Static and Dynamic Validation Testing

Once a prototype demonstrates stable operation under functional conditions, it enters the structural verification phase. This includes pressure cycling tests with amplitudes up to the intended nominal operating pressure and endurance tests amounting to several million switching cycles. These tests assess the long-term stability of the main stage, potential wear mechanisms of guiding surfaces and drift behaviour of measurement and pilot components. Static burst pressure tests to several times the nominal operating pressure serve as an additional safety measure. Together, these assessments demonstrate that the valve design withstands the mechanical loads expected throughout its life cycle.

2.5. Environmental Qualification Testing

Environmental qualification ensures that the valve performs reliably under demanding industrial conditions. Vibration tests with multi axis excitation up to 30 g and shock tests up to 50 g evaluate mechanical robustness. Thermal cycling and temperature dependent measurements assess the stability of materials, electronics and hydraulic components across the intended ambient conditions. Electromagnetic compatibility testing confirms the robustness of the integrated electronics with respect to both emitted interference and immunity to external disturbances.

2.6. Consolidation and Release for Field Testing

Only when virtual, functional, structural and environmental evaluations all converge does a design enter field testing. Pre series valves are installed in selected customer machines, enabling long term observation under real operating conditions. These tests confirm dynamic behaviour, leakage stability and robustness against contamination and installation tolerances. The feedback from this stage closes the development loop and supports the final release for series production.

3. APPLICATION OF THE DEVELOPMENT METHODOLOGY TO THE NEW VALVE SERIES

The methodology described in Section 2 was applied to the development of the X700 series, a new generation of two-way slip-in servo cartridge valves intended for applications with exceptionally high flow demand and stringent dynamic requirements. While the individual development steps follow the generic process, several aspects of the X700 project required particular attention due to the unusually high flow-to-size ratio and the intended operating pressure of 420 bar across the entire flow range from NG32 to NG100.

3.1. Derivation of Application Specific Requirements

The requirement analysis was carried out with a focus on die casting machines and metal forming presses, as these applications represent some of the most demanding use cases for servo cartridge valves. A comparative assessment of design drivers, shown schematically in Figure 3.1, highlighted flow capacity, operating pressure and dynamic response as primary

influencing parameters for both application classes. Press systems additionally emphasised failsafe behaviour and the need for compact manifolds, while die casting machines placed stronger emphasis on control precision during fast injection and decompression phases. Based on these boundary conditions, the X700 development targets included significantly higher flow performance compared to earlier cartridge generations, reduced pressure losses through the main stage, and improved dynamic behaviour through the use of direct drive pilot valves and integrated digital electronics.

3.2. Virtual Development and Design Evolution

The virtual development stage started from a baseline design as used in conventional servo cartridge valves. Early variants followed established geometries with drilled radial bores and cylindrical poppets, which provided a useful reference but proved insufficient to achieve the targeted flow levels. Subsequent design iterations explored alternative sleeve window shapes and modified poppet contours. The systematic comparison of these variants through FEM and CFD simulations led to the identification of a geometry that allowed a substantial increase in effective flow cross section while maintaining acceptable stress levels. This evolution is illustrated in Figure 3.2, which shows how the transition from drilled bores to shaped flow windows enabled larger port diameters and lower local pressure losses.

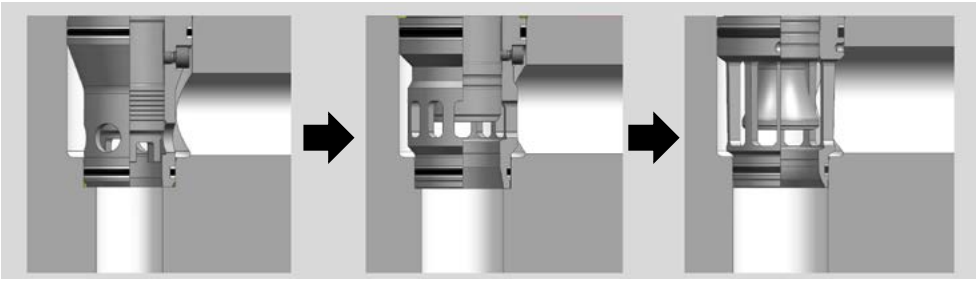

Figure 3.2. Evolution of main stage sleeve and poppet geometry.

Structural analysis confirmed that the resulting geometry provided sufficient safety margins under both static loading at 420 bar and dynamic pressure cycling. CFD simulations demonstrated improved flow characteristics and a favourable force balance over the stroke range, which was essential for ensuring stable poppet motion under high flow rates. Figure

3.3 and Figure 3.4 summarise typical FEA and CFD results processed during the design evaluation.

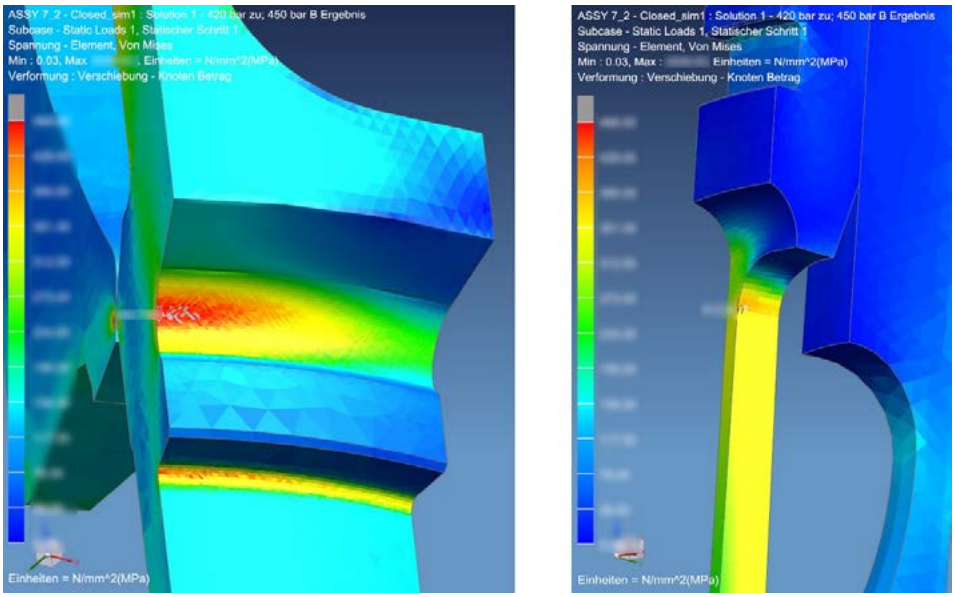

Figure 3.3. FEA-based stress distribution used to verify structural integrity.

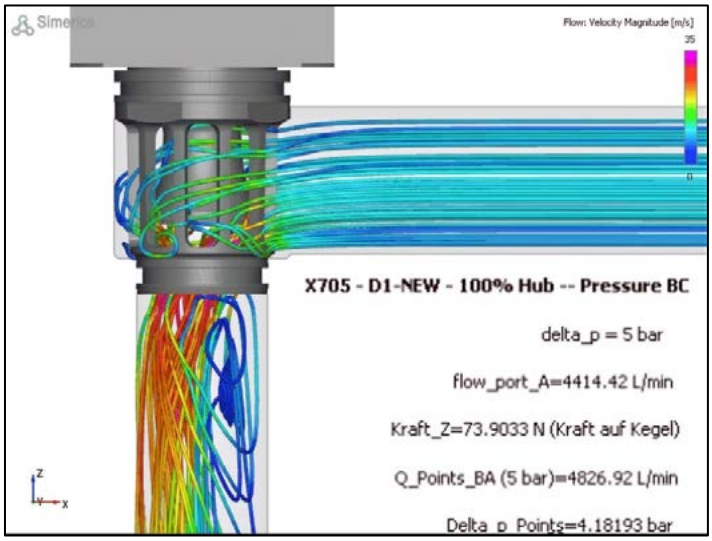

Figure 3.4. CFD-based evaluation of velocity field and flow induced forces.

3.3. Experimental Verification and Iterative Refinement

The experimental development phase follows the methodology outlined in Section 2 and typically reveals aspects of the valve behaviour that cannot be predicted with full precision using numerical tools alone. This is an inherent characteristic of hydraulic systems operating at very high flow rates, where small geometric deviations or local pressure effects may

influence the dynamic response. In the case of the X700 development, such an iterative refinement step occurred during functional testing of early prototypes. While the overall flow behaviour and pressure loss characteristics closely matched the CFD predictions, one prototype variant showed a lightly oscillatory poppet motion in a narrow operating range at high flow demand. This observation was not treated as an anomaly but as a natural part of the iterative process, in which simulation and physical testing complement each other.

A combined analysis of measurement data and targeted CFD studies revealed that, in this particular geometry, the hydraulic force balance at certain intermediate stroke positions was sensitive to small variations in the surrounding pressure field. As shown by result in Figure 3.5, the pressure acting on the poppet surfaces could shift slightly under these conditions, producing alternating net forces that caused a lightly damped dynamic response. Since such behaviours are difficult to capture fully in simplified simulation models, this finding demonstrated the value of the iterative test and refine loop that is integral to the applied development methodology. Several modified poppet geometries were subsequently analysed and manufactured. Among these, one variant achieved a consistently stable force balance across the full stroke range while maintaining the targeted flow performance. The refinement confirmed that virtual models and physical testing converge most effectively when such iterative corrections are incorporated into the development process as planned and expected steps.

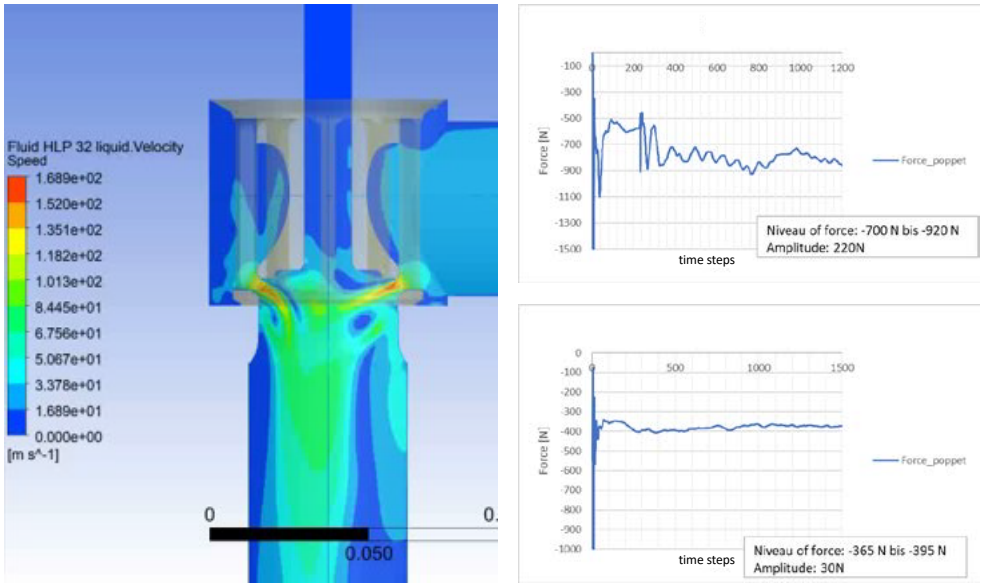

Figure 3.5. Flow-induced force imbalance as identified during prototype testing.

3.4. Qualification and Validation for Series Release

After resolving all functional and dynamic issues, the X700 prototypes were subjected to the standard qualification programme described in Section 2. This included extended endurance testing with up to ten million switching cycles at elevated pressure levels, verifying fatigue behaviour, wear and long-term stability of the main stage mechanics, the pilot valve and the displacement transducer. Structural safety was confirmed through burst pressure tests

conducted up to a multiple of the rated pressure. Environmental testing demonstrated robustness against vibration, shock loads and thermal cycling, while EMC qualification ensured the immunity of the integrated electronics against electromagnetic disturbances. These results validated the valve for field installation. Pre series units of the X700 were subsequently tested in selected industrial machines to verify performance in operational conditions. The field tests confirmed the high flow capacity, excellent dynamic behaviour and low leakage levels predicted in simulation and demonstrated in laboratory tests.

4. DEVELOPMENT RESULTS

The X700 series represents the consolidated outcome of the virtual and experimental development loops described in Sections 2 and 3. The resulting valve family covers ISO sizes 32 to 100 and is designed for an operating pressure of 420 bar across all variants. Its performance characteristics reflect the accumulated effects of the flow optimised main stage geometry, the direct drive pilot concept and the iterative refinement of dynamic behaviour and stability margins. Figure 4.1 provides an overview of the final valve design and its structural elements.

Figure 4.1. Final design of the X700 servo cartridge valve series.

Across the entire size range, the valves exhibit a consistently high flow efficiency. The shaped sleeve windows and coordinated poppet contour minimise pressure losses in both flow directions, so that the valves reach required flow levels at comparatively low command signals. This behaviour enhances the achievable dynamic response, because the cylinder velocity rises more quickly after a change in the command value. The measured dynamic flow characteristics and excitation responses shown in Figure 4.2 illustrate this relationship for representative size and cavity configurations. The curves confirm that the valves translate command signals into valve opening and subsequently into stable and repeatable flow behaviour across the full operating range.

The dynamic response of the valves is supported by the direct drive pilot stage, which provides rapid actuation without the pilot oil consumption associated with traditional two-

stage concepts. The integrated electronics ensure a stable closed-loop relation between command value and poppet position, even under varying pilot pressures and temperatures. This contributes to the low hysteresis and high repeatability observed in testing, which remain within the targets established during the requirement analysis. The low internal leakage of the pilot stage enhances energy efficiency, particularly in cyclic operation where leakage-related losses accumulate significantly over time.

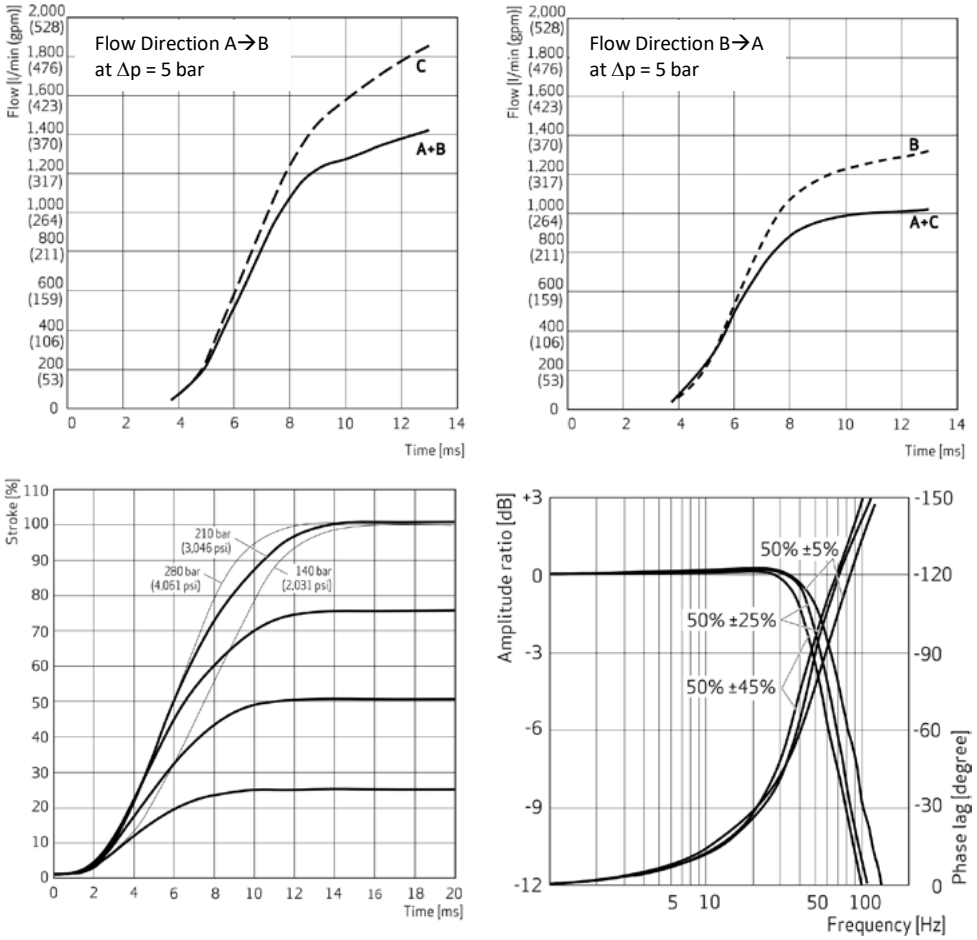

Figure 4.2. Characteristic dynamic flow response, step response, and frequency response for size 32. [2]

When assessing the achieved performance relative to predecessor products and competing valve families, the X700 series demonstrates a clear step forward. For a given valve size, the flow-optimised geometry provides noticeably higher flow capacity than previous slip-in servo cartridge designs, and the direct-drive pilot concept delivers a more favourable combination of dynamic response and control precision. In this regard, the essential improvement lies in the enhanced capability to quickly, but in a stable and controlled fashion ramp up volumetric flow, i.e. to provide a superior flow rate increase. This is shown exemplarily for one size in the comparison in Figure 4.3. Notwithstanding, the available

flow performance exceeds that of comparable servo cartridges in many size classes by a substantial margin, enabling downsizing of one or more valve sizes in typical installations. As an example, Figure 4.4 exhibits the increased dynamic response of cylinder velocity in an existing die-casting machine, where the previously installed size-50 valve was outperformed by the newly developed size-40 valve. This improvement is not only a result of geometric changes but a direct consequence of the systematic application of the development methodology, in which simulation, testing and iterative refinement were closely aligned.

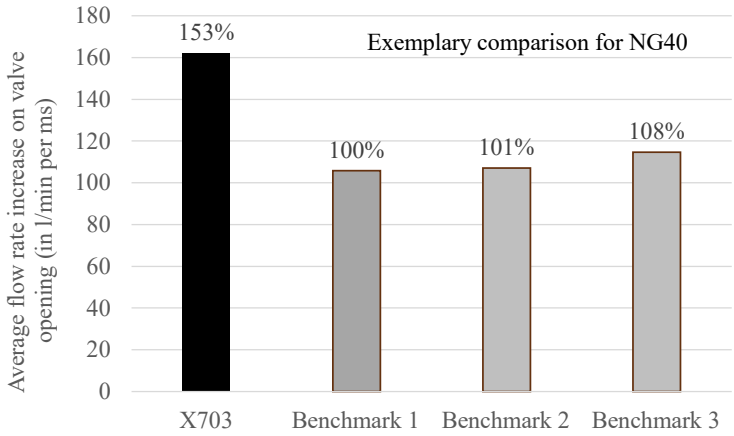

Figure 4.3. Flow performance indicator for exemplary Size 40.

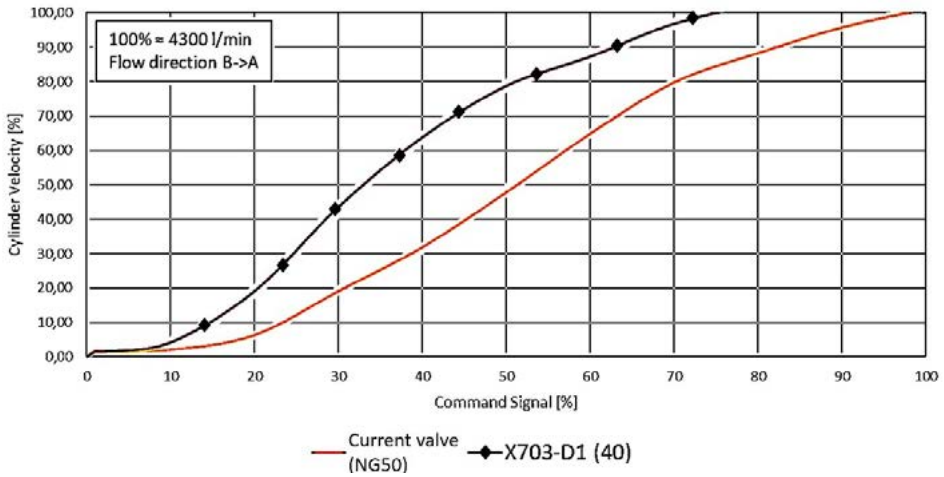

Figure 4.4. Increased dynamic performance at downsizing in a die-casting machine.

The X700 series therefore establishes a new level of performance within its class. The valves combine high flow capacity with stable dynamic behaviour and robust closed loop control. Their characteristics support the implementation of compact manifold layouts with reduced pressure losses and allow machine builders to achieve faster cycle times and higher productivity. The series is well suited for applications in which both high volumetric flow and precise motion control are required, as demonstrated in the case study of Section 5.

5. CASE STUDY: INTEGRATION IN AN OPEN-DIE FORGING PRESS

The improvements achieved in the development of the X700 series become particularly evident when the valves are integrated into a demanding hydraulic system. A representative example is an open die forging press in the 50–55 MN class, which combines large cylinder volumes, high operating pressures and stringent requirements for cycle time and repeatability [3]. Figure 5.1 depicts an exemplary press implementation. The hydraulic system must provide fast approach motions, accurately controlled forging strokes and rapid decompression, while executing a high number of cycles over the machine's lifetime. Figure 5.2 illustrates the typical functional layout and working cycle of such a press and the role of servo cartridge valves in the inlet and outlet flow paths (all pictures courtesy of SMS group GmbH, Mönchengladbach).

Figure 5.1. Exemplary open-die forging press.

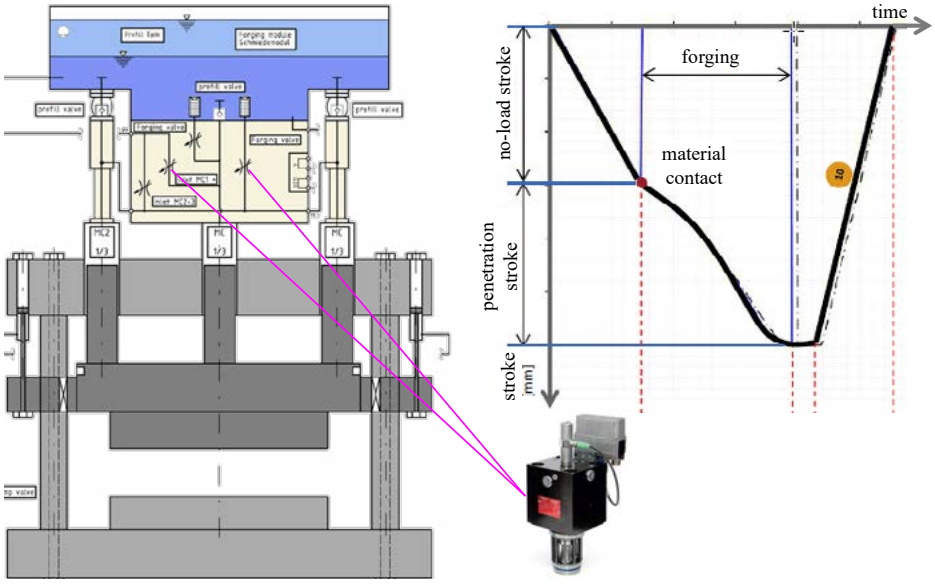

Figure 5.2. Simplified layout and working cycle of the open-die forging press.

5.1. Integration of the Valves into the Forging Manifold

In the hydraulic manifold originally used for this press class, several large servo cartridges are installed in parallel to achieve the required pressurisation and decompression flows. The configuration includes multiple valves of nominal size 125, complemented by size 80 units, and results in a structurally robust but comparatively heavy and voluminous manifold. With the introduction of the X700 series, the same functional capacity can be achieved using smaller nominal sizes, because each valve provides higher flow capability relative to its ISO size. This enables a simplified configuration based exclusively on size 100 and size 80 valves and leads to a reduction in manifold mass of about 35 %. A direct comparison of the two configurations is given in Table 5.1. Figure 5.3 visualises the achieved result in the revised, compact manifold.

Table 5.1: Valve configurations before and after introducing the new valve series.

Configuration	Inlet Valves	Outlet Valves	Manifold Mass
Before	1 × size 125 + 1 × size 80	3 × size 125	~16 200 kg
After (X700)	2 × size 100	2 × size 100 + 2 × size 80	~12 000 kg

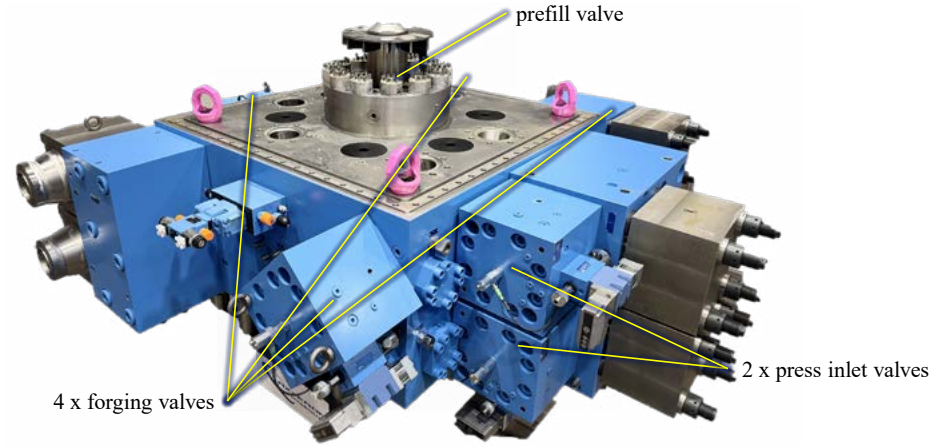

Figure 5.3. Improved manifold configuration and layout using X700 valves.

5.2. Effect on System Dynamics and Cycle Performance

The influence of the new valve configuration becomes clear when examining typical forging cycles. The flow optimised main stage of the X700 series enables the valves to reach high volumetric flows at comparatively low command signals. For example, size 100 valves of the series provide rated flows clearly above 10 000 l/min at a pressure drop of 5 bar, with recommended maximum flows significantly higher when using optimised cavity designs. This behaviour shortens the time required for pressure build up and exhaust. During the decompression phase, the updated manifold can release the hydraulic fluid from the main cylinder more rapidly than the previous design, despite using smaller nominated valve sizes. The corresponding reduction in non-productive time within each cycle contributes to a higher throughput of the press. At the same time, the stable closed loop characteristics of the X700 series support precise control of the forging stroke, so that the higher dynamics do not come at the expense of positioning accuracy or repeatability.

5.3. Energy Related Effects and System Efficiency

Beyond the dynamic aspects, the introduction of the new valve series also influences the energy demand of the forging system. The reduced pressure losses across the main stage, achieved through the flow optimised geometry, lower the hydraulic power needed for a given motion profile. In addition, the direct drive pilot valves used in the series exhibit significantly reduced internal leakage compared to traditional pilot operated concepts. For size ranges up to size 100, the pilot leakage remains below approximately 1.4 l/min at 100 bar, which is substantially lower than the values associated with earlier two-stage solutions.

Figure 5.4. Integration of the forging manifold into the machine structure.

In a forging environment with thousands of cycles per shift, such differences accumulate measurably. Lower leakage reduces the continuous energy losses in the system, while improved flow efficiency decreases the peak power required from the hydraulic power unit. The downsized manifold, with its 35 % lower mass and reduced volume, and thus improved integration into the overall machine structure as shown in Figure 5.4, further supports efficient operation by reducing the total amount of oil in circulation and associated thermal loads. Together, these effects help operators reduce operating costs and support current efforts to lower the carbon footprint of industrial processes.

5.4. Summary of Case Study Findings

The open die forging press illustrates how the X700 series translates component level improvements into system level benefits. Increased flow capability per valve enables a more compact manifold with fewer very large cartridges and a significantly lower structural mass. Dynamic response and control precision are improved, leading to shorter non-productive phases and higher throughput. The reduced pressure losses and low pilot leakage contribute to lower energy demand. Together, these findings show how the systematic development methodology supports the design of more efficient and competitive hydraulic systems.

6. CONCLUSIONS AND OUTLOOK

The development of the X700 series shows that a systematic combination of numerical simulation, experimental refinement and structured qualification enables tangible advances

in hydraulic servo cartridge technology. Building on this foundation, several extensions of the concept have already emerged that broaden its applicability.

One development path concerns variants with moderately reduced performance levels. These valves follow the same design principles as the X700 series but are adapted for applications with lower dynamic requirements or reduced operating pressures. By simplifying selected elements of the main stage and electronics, these variants offer a cost-efficient option for less demanding industrial environments while retaining the characteristic stability and controllability of the base design.

At the upper end of the performance range, versions designed for higher operating pressures have also been realised. These valves extend the pressure capability from the standard 420 bar to 450 bar and are intended for applications that require increased load capacity or additional structural safety margins. Their design and qualification follow the same methodological steps as the standard series, ensuring consistent behaviour across the extended operating range.

In parallel, work continues on new control concepts derived from the same architecture. A digitally pressure compensated flow control valve is currently being developed, combining the mechanical robustness of the slip in cartridge format with electronically controlled flow characteristics. This concept enables more flexible integration into digital machine control systems and supports advanced functions such as remote parameterisation, integrated diagnostic information and coordinated motion control.

Together, these developments demonstrate that the underlying methodology not only supports high performance solutions such as the X700 series but also provides a scalable basis for future hydraulic product families.

Abstract.

Because alternating flow passes through the damping orifice in a pressure control valve, the size and location of the contraction region are not well understood. However, it is known that the flow coefficient of the orifice is significantly affected by the contraction coefficient of the jet. If the flow coefficient of the damping orifice fluctuates depending on the frequency of the alternating flow, a 40% change in the flow coefficient poses a risk of a 6 dB increase or decrease in the gain margin of the pressure control system. This research was motivated by this risk, predicted from a 1D model of the pressure control valve. There is a high need to reduce the risk to stability of the pressure control system inside an aircraft jet engine fuel control device, whose operating range varies significantly depending on flight conditions. The authors previously presented the above risk in reference [1]. When considering the dynamic characteristics of an orifice, they approximate it as an LRC circuit. In this case, L in the LRC circuit is corrected for the fluid inertia of the short choke tube, and the R element can be approximated as the orifice opening area, and the C element can be approximated as the fluid compressibility upstream of the orifice. Comparison with CFD frequency response demonstrated its validity. The remaining issues include the effect of the damping orifice delay on the differential pressure control valve, understanding the effect of the damping orifice amplitude, deriving the correction value for the *L* element, and confirming the flow pattern that the alternating flow has on the orifice. This paper reports on the progress of the results of these investigations and also mentions the remaining issues.

1. INTRODUCTION

Most jet engine fuel metering units today combine a fuel metering valve, which can control the metering port opening area to a desired value through feedback control using a digital controller, with a differential pressure control valve, a type of pressure control valve, which maintains a constant differential pressure across the fuel metering valve. Because the flow velocity of the fuel metering valve is proportional to the square root of the differential pressure and regulated to constant, the fuel metering flow is proportional to the metering port opening area.[11][12] As noted in [1], the differential pressure control valves, which is a type of pressure control valve used in the fuel control units of aircraft jet engines must achieve both stability and responsiveness over a wide operating range. Among these valves, the dynamic characteristics of the differential pressure control valve, which maintains a constant differential pressure across the fuel metering valve, are particularly important because they directly affect the stability of the fuel flow rate itself. On the other hand, pressure disturbances are directly applied to the differential pressure across the metering valve; however, the control of the metering valve opening area is performed by feedback control. By designing the bandwidth of the fuel metering valve to be low, the system becomes robust against high-frequency disturbances, and the effects of pressure disturbances can be more easily compensated by the feedback control. The configuration of a differential pressure control valve is shown in Figure 1.

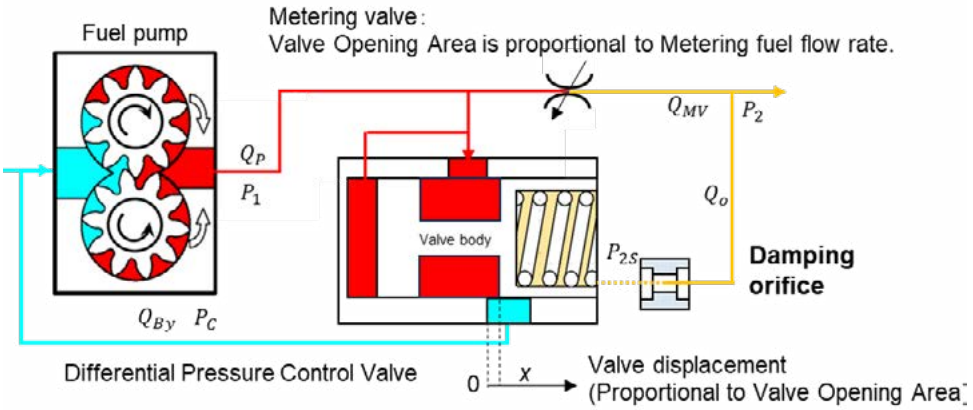

Figure 1 Schematic Diagram of a Pressure Control Valve [1]

Typically, the differential pressure sensing valve operates by multiplying the differential pressure between the control pressure and the reference pressure by the valve's pressure-receiving area to generate a fluid force. This force balances against a preloaded spring force to determine the valve's position. Additionally, a reaction force from the valve's damping resistance is applied, imparting dynamic characteristics to the spring-mass system. Differential pressure control valves must respond sufficiently quickly to changes in fuel flow and maintain adequate stability margin across the entire operating range. This prevents unexpected fuel flow overshoot. To achieve this, the damping ratio of the valve body's spring-mass system is increased beyond the limit damping ratio using a damping orifice, reducing the rate of change of phase margin with frequency. The proportional gain is set so that the crossover frequency satisfies the lower limit of the responsiveness requirement, while ensuring sufficient stability margin is always maintained under the valve spool geometry and operating conditions.

In the pressure control valve's spring-mass system, a damping orifice is placed in series with the valve spool and is used to provide damping force ideally proportional to valve velocity. Typically, the damping force exhibits a characteristic proportional to the square of the flow rate through the orifice, resulting in zero damping force at valve standstill and significant nonlinearity. [2] [6] [7] In the damping orifice, the flow pattern through the orifice, such as the direction of flow rotation, is considered to exhibit symmetry in both positive and negative directions. Furthermore, the effect of changes in flow pattern on the orifice's Pena-Contractor section is expected to vary significantly with frequency.

However, there are few studies on the frequency response, flow pattern, contraction coefficient, and flow coefficient of the damping orifice in hydraulic pressure control valves. Oshima et al. [2] and Miyashita [3] reported experimental results on the frequency response of damping orifices, but did not mention flow patterns. Furthermore, research on pulsating flow by Nakano et al. [4] has been conducted, sharing many commonalities from a modelling perspective. However, in alternating flow, the average flow velocity is zero. Since the damping force has polarity and is proportional to the square of the flow velocity, the damping force becomes zero in the valve's steady state and varies significantly with velocity amplitude. If the damping force were zero, the valve's spring-mass system would not be damped and would continue oscillating at a constant amplitude. When the valve vibrates, the damping force acts, reducing the amplitude. A method to estimate the valve amplitude in this state has not yet been established.

On the other hand, Iimura et al. [10] studied the equivalent electrical circuit model and transfer function of the Pitot tube orifice in air pressure control applications. The Pitot tube is a type of air speed indicator and a pressure measurement device, so its input is pressure and its output is pressure. While similarities exist in the shape of the transfer function and other aspects, differences between aircraft and liquid systems, as well as the disparity between pressure and flow rate as inputs, necessitate an evaluation of this similarity.

2. PURPOSE

This study reports on further investigations into the results obtained by modelling the frequency characteristics of the damping orifice in a pressure control valve using unsteady CFD analysis and a Bond graph model, aiming to clarify the dynamic characteristics of the damping orifice. Specifically, it reports on the effect of damping orifice delay on differential pressure control valves, understanding the influence of damping orifice amplitude, deriving correction values for L-elements, and confirming flow patterns affecting orifices in alternating flow.

3. 1D MODELLING AND SIMULATION

3.1. Equations of the Pressure Control valve and the Damping orifice

We derive the linearized transfer function of the differential pressure control valve receiving flow from the flow source. The derivation of the differential pressure control valve transfer function below is based on Reference [5][6][7][8]. Furthermore, regarding the dynamic characteristics of the damping orifice, we add the differential pressure caused by fluid inertia occurring in the short pipe section of the orifice restriction, as described in Reference [1]. The objective is to verify changes in crossover frequency and phase margin in response to variations in the damping force or damping ratio within the differential pressure control

valve. However, the purpose of this paper is to outline the impact of changes in the damping orifice on the entire differential pressure control system. NOMENCLATURE lists the symbols used in deriving the transfer function.

Equation (3.1) shows the equilibrium of forces acting on the valve body of a differential pressure control valve. For simplification, the fluid viscous resistance and friction force of the spool valve are approximated as zero, and the viscous resistance is only the damping force from the damping orifice. Similarly, the fluid force is also assumed to be negligible. These simplifications do not compromise the generality for high-precision spool valves. The motion equation of the valve body is balanced by the fluid dynamic force due to the differential pressure acting on the valve's pressure-receiving area and the spring force. Here, x denotes the valve displacement of the differential pressure control valve, M is the mass of the spool valve, C is the viscous resistance coefficient, k is the spring constant of the pressure control valve, A_R is the receiving area of the spool, P_1 is the pressure upstream of the pressure control valve, and P_2 is the pressure downstream of the metering valve.

$$M \cdot \ddot{x} + C \cdot \dot{x} + k \cdot x = A_R \cdot (P_1 - P_2) \tag{3.1}$$

The damping force generated by the damping orifice of the differential pressure control valve is expressed by equation (3.2). Here, P_{2s} is the pressure in the spring chamber obtained from P_2 after passing through the damping orifice.

$$F_o = A_R \cdot (P_{2s} - P_2) \tag{3.2}$$

The damping orifice is modelled below. The differential pressure across the damping orifice is defined by equation (3.3). Here, P_O is the differential pressure of the damping orifice, and PL is the pressure due to fluid inertia as it passes through the short pipe section of the damping orifice. In addition to the pressure loss due to the orifice restriction, the pressure changes originating from the inertial force generated in the short pipe section of the restriction is also formulated. The pressure downstream of the metering valve is governed by the dynamic characteristics of the jet engine and changes sufficiently slowly, so its time variation can be considered negligible, resulting in equation (3.4).

$$P_{2s} - P_O - PL = P_2 \tag{3.3}$$

$$\frac{d}{dt} P_2 \cong 0 \tag{3.4}$$

The relationship between flow rate and pressure loss for the damping orifice is shown in Equation (3.5). Here, ρ represents the fluid density, Q_o represents the flow rate through the orifice, A_o represents the orifice opening area, and C_d represents Coefficient of discharge flow r*ate* of the orifice.

$$P_O = \frac{\rho}{2} \left(\frac{Q_O}{C_d \cdot A_o} \right)^2 \tag{3.5}$$

Fluid inertia is shown in Equations (3.6) and (3.7). This paper considers the pressure due to the inertial effect occurring in the short pipe of the orifice.[6] [7] Here, L represents the length of the pipe of the damping orifice.

$$PL = IL \frac{d}{dt} Q_o \tag{3.6}$$

$$IL = \frac{\rho \cdot L}{A_o} \tag{3.7}$$

Equation (3.8) represents the flow rate applied to the damping orifice from the differential pressure control valve.

$$Q_{In} = A_R \cdot \dot{x} \tag{3.8}$$

Substituting the equations for each element into equation (3.3) yields equation (3.9). Linearizing equation (3.9) results in equations (3.10) and (3.11).

$$P_{2s} = \frac{\rho}{2}\left(\frac{Q_O}{C_d \cdot A_O}\right)^2 + IL \cdot \frac{d}{dt}Q_O \tag{3.9}$$

$$\Delta P_{2s} = R \cdot \Delta Q_O + IL \cdot \frac{d}{dt}\Delta Q_O \tag{3.10}$$

$$= \rho \frac{(\Delta P_O)_0}{(Q_O)_0} \tag{3.11}$$

The upstream pressure at the dumping orifice is calculated by integrating the difference between the inflow rate and the flow rate through the orifice using Equation (3.8), as given by Equation (3.12). [6] [7] B represents Bulk modulus of fluid. V_s represents the volume upstream of Spring room. Here, Equation (3.13) represents the spring effect of the hydraulic pressure.

$$P_{2S} = \int \frac{B}{V_s}(A_R \cdot \dot{x} - Q_O)dt + P_{2S0} \tag{3.12}$$

$$C_I = \frac{B}{V_s} \tag{3.13}$$

Taking the Laplace transform of equation (3.12) and substituting equation (3.8) yields equation (3.14). Here, Δ indicates a prefix of variable for micro-time perturbation and C_I represents the C element of damping orifice Volume. And s represents Laplace operator. Q_{In} represents the input flow rate of damping orifice.

$$\Delta P_{2S} = \frac{1}{s} C_I (Q_{In} - Q_O) \tag{3.14}$$

Substituting equation (3.9) into equation (3.14) gives the relationship between Q_{In} and Q_o as equation (3.15).

$$\frac{\rho}{2}\left(\frac{Q_O}{C_d \cdot A_O}\right)^2 + IL \cdot \frac{d}{dt}Q_O = \frac{1}{s} \cdot C_I \cdot (Q_{In} - Q_O) \tag{3.15}$$

The transfer function from linearized Q_{In} to Q_o is derived from equations (3.16) to (3.17). Here, R represents the R element of orifice restriction.

$$R \cdot \Delta Q_O + IL \cdot \frac{d}{dt}\Delta Q_O = \frac{1}{s} \cdot C_I \cdot (\Delta Q_{In} - \Delta Q_O) \tag{3.16}$$

$$Q_O = \frac{C_I}{IL \cdot s^2 + R \cdot s + \cdot C_I} Q_{In} \tag{3.17}$$

$$\Delta P_{2s} = \frac{C_I \cdot (R + IL \cdot s)}{IL \cdot s^2 + R \cdot s + \cdot C_I} Q_{In} \tag{3.18}$$

Furthermore, from equations (3.1) and (3.8), the damping coefficient C is obtained as shown in equation (3.19). Since the characteristics of the damping orifice vary significantly with amplitude, applying a sinusoidal frequency sweep input to the nonlinear state equations and performing a Fourier transform on the input and output yields a transfer function nearly equivalent to a linear transfer function. That is, equation (3.20) shows the second-order nonlinear state equation. By applying a frequency-swept input to Q_{In} while varying the amplitude, the frequency response curve for each amplitude can be obtained.

$$C \cdot \dot{x} = A_R \cdot \Delta P_{2s} = \frac{{A_R}^2 \cdot C_I \cdot (R + IL \cdot s)}{IL \cdot s^2 + R \cdot s + \cdot C_I} \dot{x} \tag{3.19}$$

$$\begin{bmatrix} \dot{P_{2s}} \\ Q_O \end{bmatrix} = \begin{bmatrix} C_I(Q_{In} - Q_O) \\ \frac{1}{IL}\left(\Delta P_{2s} - \frac{\rho}{2}\left(\frac{Q_O}{C_d \cdot A_o}\right)^2\right) \end{bmatrix} \tag{3.20}$$

In the motion equation of the valve body for a pressure control valve, damping resistance is dominated by the damping orifice. For precision valves, friction and fluid viscous resistance can be considered negligible. The control pressure for a differential pressure control valve varies due to the compressibility of the fluid and the bypass flow rate of the differential pressure control valve. Equation (3.21) relates the upstream pressure of a differential pressure control valve to the inflow rate into its volume. Here V represents the volume upstream of metering valve. Q_P, Q_{By} and Q_{MV} represent the input flow rate of damping orifice, the metering fuel flow rate and the flow source discharge flow rate.

$$P_1 = \int \frac{B}{V} \left(Q_P - Q_{By} - Q_{MV}\right) dt + P_{10}) \tag{3.21}$$

Equation (3.22) relates the orifice area of a pressure control valve to its flow rate based on Bernoulli's law. [6][7] Here A_{By} represents Pressure control valve opening area. k_V represents the pressure control valve opening area per displacement.

$$Q_{By} = C_d \cdot A_{By} \sqrt{\frac{2 \cdot (P_1 - P_c)}{\rho}} = C_d \cdot k_V \cdot x \sqrt{\frac{2 \cdot (P_1 - P_c)}{\rho}} \tag{3.22}$$

Equation (3.23) shows the linearized transfer function between the upstream pressure of a differential pressure control valve and its bypass valve orifice area.

$$\Delta P_1 = \frac{-2 \cdot (P_1 - P_c)_0}{Q_P} \cdot \left(\frac{Q_{By}}{A_{By}}\right)_0 \cdot \frac{1}{1 + \frac{V}{B} \cdot \frac{2 \cdot (P_1 - P_c)_0}{Q_P} s} \cdot k_V \cdot \Delta x \tag{3.23}$$

Figure 3.1 shows a block diagram of the overall linearized transfer function of the differential pressure control valve. In the open-loop transfer function depicted in this block diagram, the crossover frequency and the phase delay at that frequency can be used as evaluation metrics for responsiveness and stability. By satisfying each required value, it is possible to determine whether responsiveness and stability can be achieved simultaneously.

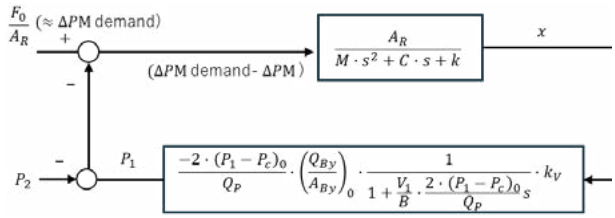

Figure 3.1 Block Diagram of Differential Pressure Control Valve

3.2. Frequency Response Results for Damping Orifice

Frequency response simulations were performed using a sinusoidal frequency sweep input to vary the amplitude in the state equation for the damped orifice (Equation 3.20). Frequency Response Simulation Conditions is shown Table 3.1. Figure 3.2 shows the time series of the waveform of a sinusoidal sweep of the orifice input flow rate. The input waveform is the same, but the flow rate amplitude is different. Figure 3.3 shows the time series response of the normalized orifice differential pressure. Figure 3.4 also shows the normalized response when the internal inertance of the orifice is changed. Each frequency response diagram is shown in Figures 3.5 and 3.6. When the input amplitude and the response is small, as shown in Figure 3.3 a) or b), the amplitude increases with frequency relative to the input, exhibiting a peak frequency. However, as the input amplitude increases, as seen in Figure 3.3, the peak amplitude tends to decrease. The frequency response diagrams with varying amplitude in Figure 3.5 show a first order/second-order response at small amplitudes. As the amplitude increases, the open-loop gain of the orifice's LCR circuit decreases, phase margin increases, and the response approaches a first-order lag shape. For the short pipe section of the orifice, it was confirmed that the frequency changes with pipe length, like the linear analysis.[1]
In addition, Figure 3.6 shows the change in the Bode diagram due to changes in inertance. The results are almost the same as those obtained by Fourier transform analysis. [1]

3.3. Effect of Damping Orifice Transfer Function on the Response of a Differential Pressure Control System

We investigated whether the transfer function of Equation (3.18) affects the frequency response diagram of a differential pressure control system. The transfer function of the damping coefficient in Equation (3.18) was substituted for the damping coefficient in Equation (3.1). Figure 3.7 shows the block diagram before and after the substitution.

(a) Differential Pressure Control Valve Block Diagram (No Orifice Delay)

(b) Differential Pressure Control Valve Block Diagram (With Orifice Delay)

Figure 3.7 block diagrams of the Pressure control valve

The transfer function of the pressure control valve with and without orifice delay was calculated by varying the valve amplitude under the conditions listed in Table 3.2. Figure

3.8 shows the Bode diagram. Table 3.2 lists the pressure control valve parameters. The orifice delay has a resonance point at approximately 10000 rad/s (1.6 kHz), which was previously thought to have a small impact due to a frequency band sufficiently different from the bandwidth of the pressure control valve. However, due to factors such as the phase lead element, it can affect the stability and responsiveness of the pressure control valve.

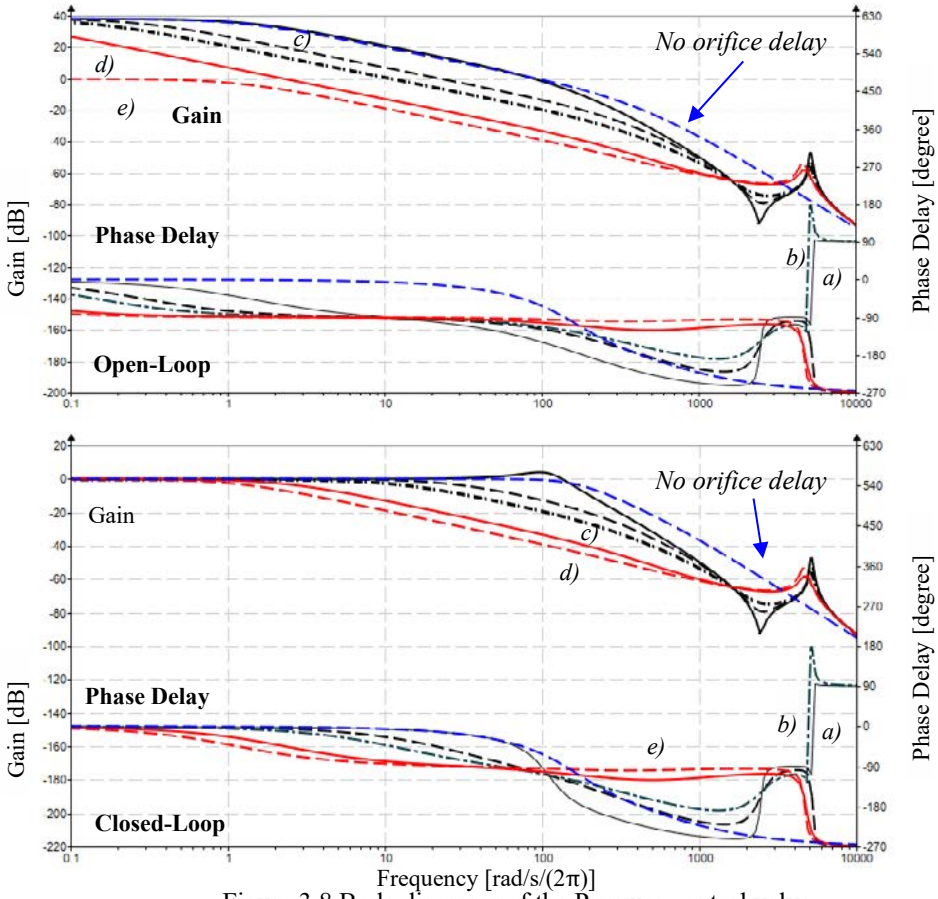

Figure 3.8 Bode diagrams of the Pressure control valve

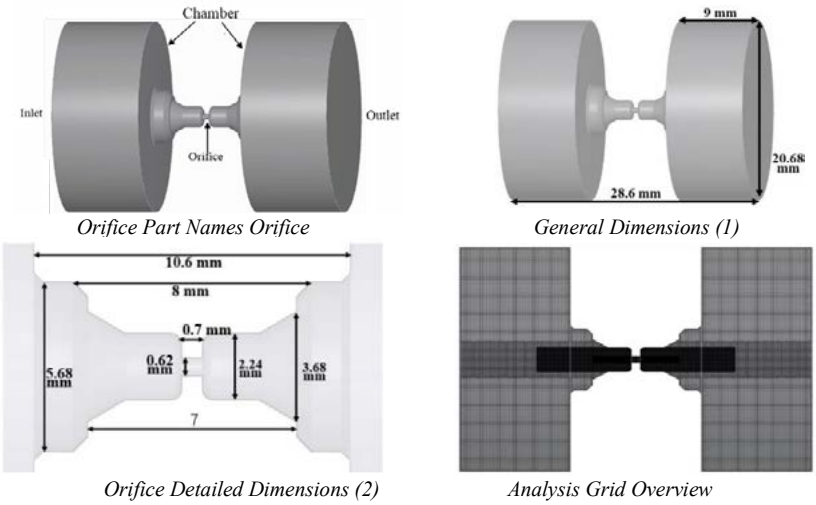

Table 3.2 Parameter of Pressure Control Valve and simulation conditions

Simulation Condition	***Dimension***	***Parameter***
Inertance of orifice	*kg/m⁴*	1.739E+6,
R of orifice	*kg/(s·m4)*	a):1.728e+9, b):8.639E+9, c):1.728E+10, d): 8.639E+10, e): 1.728e+11,
Inertance of orifice	*kg/m⁴*	1.739E+6, 2)
C of orifice	*kg/(s²·m4)*	4.067E+14
Resonant Frequency of The Valve	*rad/sec*	176.14
Mass of Valve	*kg*	0.05
Resistance of Valve	*N/mm/s*	0.2
Open-loop Gain	*ND*	80

It was found that greater stability is achieved when the proportional element or orifice flow rate is large, and resistance: R is high. Because the purpose of this paper is to examine the dynamic characteristics of the orifice, the operating conditions are not yet clear. It was found that even in systems with fast orifice dynamics, the pressure control valve is affected by a frequency band that differs by more than one order of magnitude. A more detailed study will be conducted separately after determining the specifications of the pressure control valve.

4. CFD ANALYSIS

The CFD model used in this study is shown in Figure 4.1. In examining the flow patterns, a simpler orifice model was also considered. However, the unique flow characteristics of the orifice's alternating flow were also reproduced in the model described in [1], so that model is omitted for simplicity's sake. The flow patterns were examined at the timing of changes in flow rate. The 3D model and simulation conditions are shown in Table 4.1, and the simulation model is shown in Figure 4.1. Figure 4.2 shows the velocity diagram near the orifice's short-view and the velocity distribution at the short-view cross section for each simulation. Figure 4.3 also shows the pressure distribution near the orifice. These analyses revealed no contraction within the orifice's short-pipe passage. Furthermore, during the alternating flow transition, a cylindrical flow remained at the orifice exit without changing flow direction, and no fluid flow entered from the orifice's axis when the flow reversed. Therefore, fluid is thought to be entering from the radial direction. Furthermore, the orifice contraction occurs at the orifice entrance and immediately shifts to the opposite side when the flow alternates. Table 4.2 shows the flow coefficient for each orifice frequency at flow amplitude rate:6.3mL/min. Although there is almost no contraction in the flow pattern, the flow coefficient is decreasing. It is thought that the flow rate at the throttle changes because of compressibility and inertia, which is why the flow coefficient changed. However, it is thought that it will be necessary to separate the effects of compressibility and inertia in the future.

5. DISCUSSION

5.1. Considerations on the Shift in Orifice Resonance Frequency

In our previous paper, we used transient CFD frequency responses to derive the orifice resonant frequency (the frequency at which the sinusoidal response of the orifice differential pressure to the applied flow rate lags approximately 90 degrees in phase). However, the reason for the approximately 63% decrease in resonant frequency in the 1D modelling was unclear. Based on the flow patterns in the CFD analysis, the inertial length: L, which is proportional to the inertial resistance $\rho \cdot L/A_O$ in the 1D model, appears to be 2.5 times larger in the CFD model. Velocity contours show that a uniform flow from the orifice extends beyond the length of the short pipe. In this paper, we examine the flow patterns and conclude that the increase in inertial length is due to two factors. One factor is additive mass. As shown in [11], when a cylindrical object moves through a fluid, it entrains and simultaneously moves a mass of fluid $3/8 \cdot \rho \cdot (D_O/2)^3$. This increases the inertial length of the fluid by $3 \cdot \pi \cdot D_O/4$. Since $D_O = 6 \cdot L/7$ for this orifice, L is expected to be extended by approximately 0.75 times. Furthermore, attachment is expected to occur at both ends of the fluid passing through the short pipe. While additional mass typically occurs at the end face of a spool valve, in this flow, it is expected to attach to the cylindrical fluid in the short pipe. The second factor is that the fluid flow entering and exiting the orifice is similar to the flow field passing through the curtain area of a nozzle/flapper valve, and thus simultaneously moves the cylindrical fluid at the height of the curtain area. Flow along the orifice axis creates a flow pattern that obstructs the flow at both the inlet and outlet of the orifice. Because the flow velocity is slower outside the orifice, the cylindrical flow passing through the orifice continues to flow away from the orifice. When the flow direction is reversed in the orifice's alternating flow, the axial flow near the orifice is obstructed, resulting in radial flow. From a macroscopic perspective, the 90-degree flow bend is like the flow within the curtain area of a nozzle/flapper. This is thought to increase the inertial length, which is equivalent to the curtain area height d/2 ($\cong 3/7L$). Figure 5.1 shows a conceptual diagram of inertial length correction around the orifice. Due to the above two factors, the

inertial length is thought to increase by approximately 2.2 times. If a shape factor that approximates the radial flow near the orifice to the curtain area can be identified in the future,

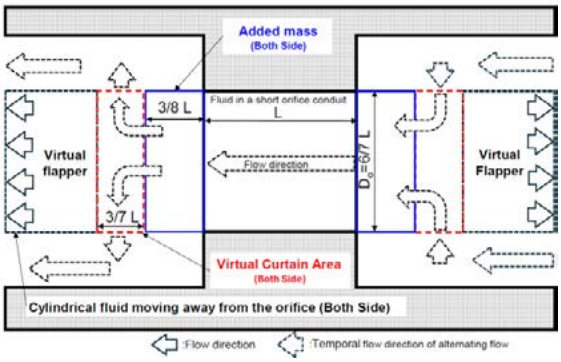

Figure 5.1 Simplified flow pattern near an orifice

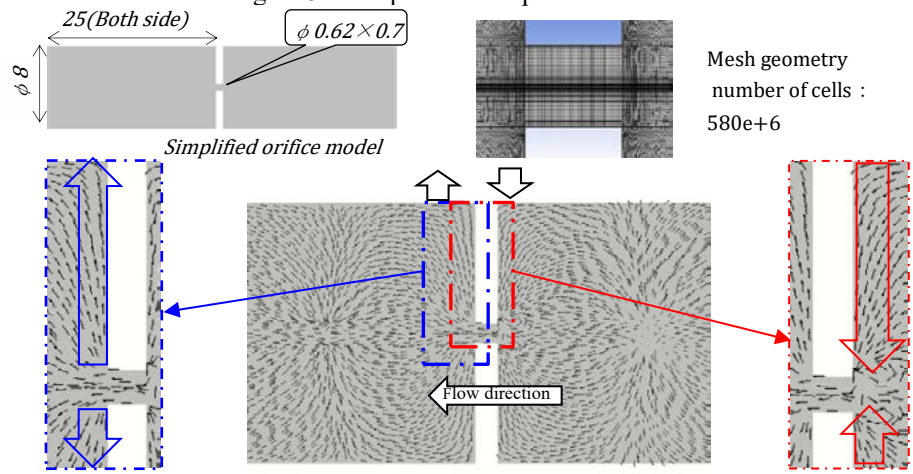

Figure 5.2 Unsteady CFD analysis results for orifice frequency response (vector diagram)

it is expected that the accuracy of deriving the inertial length will improve. Figure 5.2 shows the results of the orifice frequency response analysis using a simplified geometry model with ANSYS CFX, presented as a vector diagram.[13] The frequency is set at $400 \cdot 2\pi[rad/s]$, and the flow rate amplitude is equivalent to that in Table 4.1. ANSYS CFX was used to easily obtain the vector diagrams. As indicated by the arrows in Figure 5.2, the flow pattern on both sides of the orifice exhibits radial inflow (inside of red hollow arrow) and outflow (inside of blue hollow arrow). This flow field is characteristic of the curtain area and occurs just before the direction of the alternating flow changes. It is considered that the radial outflow is generated as the flow from the previous cycle is overtaken and collided with by the flow of the subsequent cycle.

5.2. Considerations on the Shift of the Orifice Natural Vibration

Confirmation of the local discharge coefficient using CFD suggests that no contraction occurs within the orifice. Although contraction does occur before and after the orifice, due to flow symmetry, the location of contraction shifts instantly to the orifice inlet, making the effect of alternating frequency on contraction small. On the other hand, the delay in high

frequencies through the orifice is likely to have a significant impact on the flow difficulty. First, we must further investigate whether orifice impedance has any effect on reducing the discharge coefficient. This will require defining the orifice's impedance characteristics using a 1DCAE approach rather than a flow field approach and correlating them with the discharge coefficient as necessary.

6. CONCLUSION

The following was revealed through 1D and 3D orifice simulations.

- In the LCR circuit model of orifice alternating flow, the inertance increased by approximately 2.5 times in the unsteady CFD analysis, and the co-movement frequency decreased by approximately 63%. This is thought to be mainly due to the added mass and the fluid within the curtain area of the virtual nozzle flapper moving simultaneously with the fluid within the pipe. The virtual curtain area is formed by the end face of the added mass, the orifice outlet flow rate, and the surface (virtual flapper) where the axial velocity becomes zero when the flow direction inside the orifice reverses.
- The orifice discharge coefficient is thought to be largely unaffected by the frequency of the alternating flow. Backflow does not occur in short pipes, and the contracted flow that occurs at the orifice inlet quickly moves to the orifice outlet (the inlet after the alternating flow) due to the alternating flow.
- As shown in the example above, the effect of the alternating flow frequency on the discharge coefficient of the steady-state orifice restriction equation is thought to be small. However, the impedance of an LCR circuit is generally affected by the frequency of the alternating flow, and this effect is thought to be dominant.

Abstract.

This study proposes a design method for interacting sliding parts in hydraulic pumps that optimizes both performance and reliability within practical computation time. Conventional design analyzes each part individually using EHL (Elasto-Hydrodynamic Lubrication), overlooking interactions and causing redesign delays. The new approach integrates lubrication-mechanism-structure coupled analysis, Taguchi-based sensitivity analysis, and response surface optimization to determine optimal shapes. Validation using an elastic body model showed only a 7% error compared to the rigid model. Compared to the current design, total loss decreased by about 30%, improving overall efficiency by 4%. This technology enables faster development without compromising reliability.

Keywords. Hydraulic pump efficiency, Sliding part design, Coupled analysis, Response surface Optimization.

1. INTRODUCTION

Figure 1.1. shows the before-after design of the sliding part. In the conventional sliding part design, EHL (Elasto-Hydrodynamic Lubrication) analysis of each sliding part is performed, and the shape is determined individually. Therefore, the interaction between multiple sliding parts is overlooked, and redesign and verification are required to achieve both performance and reliability, resulting in an increase in development time.

In this study, a complex sliding part design method that can determine the optimum shape that achieves both reliability and performance in practical calculation time was constructed by simultaneously designing multiple complex sliding parts by the strong coupled analysis of mechanism and lubrication, extracting design parameters of sliding parts by the sensitivity analysis using the Taguchi method, and performing the optimum solution calculation using the response surface.

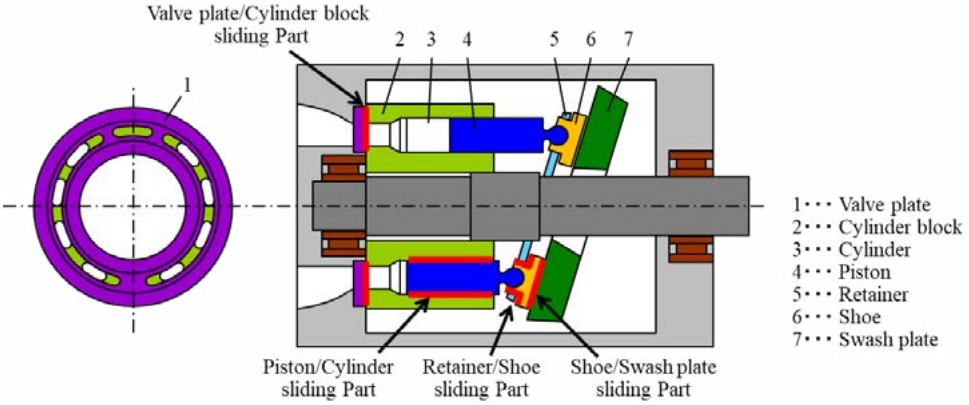
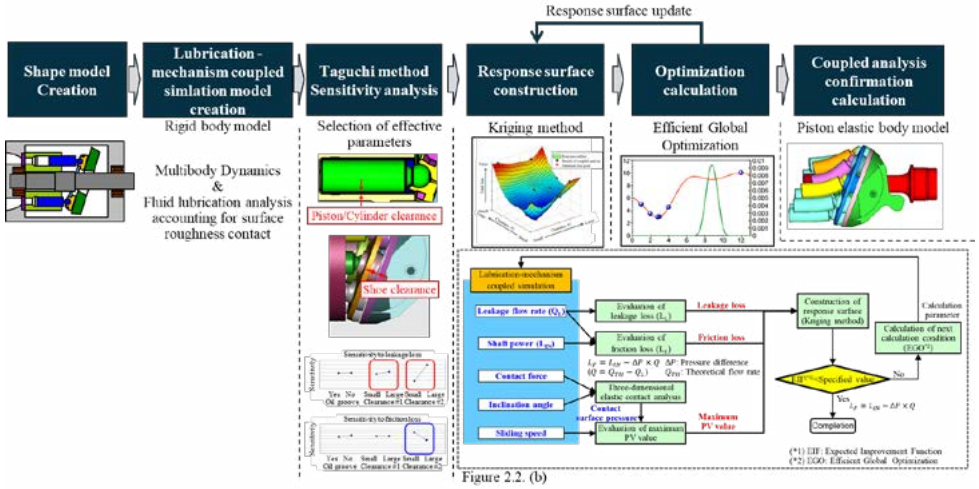
2. OPTIMIZATION DESIGN METHOD FOR THE INTERACTION OF MULTIPLE SLIDING PARTS

2.1. Analysis Object

Figure 2.1.1. shows the analysis object. In this study, a simultaneous optimization design method of multiple sliding parts for a swash plate hydraulic pump was verified. In order to achieve both reliability and performance, it is necessary to ensure the integrity of the sliding surface and reduce the power loss. The sliding parts of a swash plate type hydraulic pump are (1) valve plate and cylinder block, (2) piston and cylinder, and (3) shoe and swash plate. In order to improve the output of a hydraulic pump, it is necessary to design the clearance of each sliding part in consideration of the increase of friction loss and seizure of the sliding surface due to insufficient clearance.





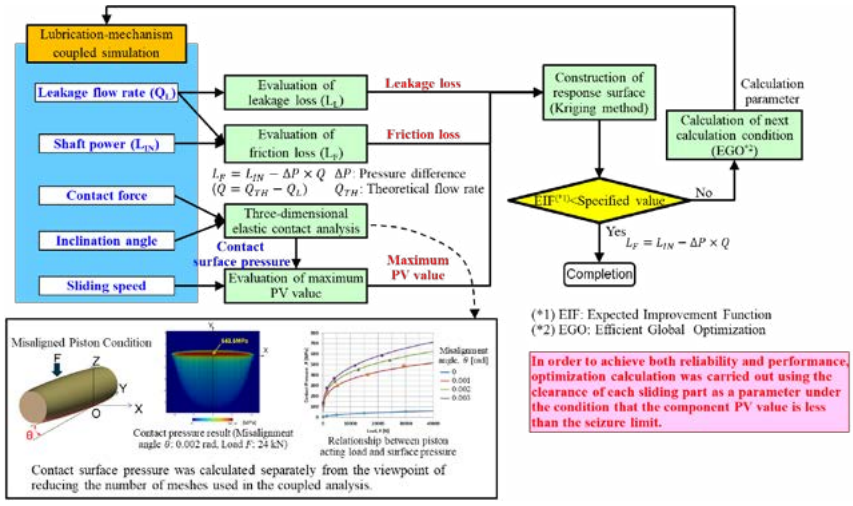


Figure 1.1.1. Analysis Object

2.2. *Design flow for optimization of sliding part*

Figure 2.2.1. shows the design flow for simultaneous optimization of sliding part. The calculation load of the elastic body model is more than 5 times as high as that of the rigid body model (calculation time 20hr per 90deg of axial rotation angle), and it takes time to obtain the optimum design dimensions. Therefore, the rigid body model was used for the coupled analysis in the sensitivity analysis and optimization calculation, which require calculation of multiple cases, and the calculation time was shortened by separately considering the elastic effect in contact with the map data of the 3D elastic contact analysis. For the final verification, the coupled analysis of the elastic body model was confirmed with the optimum solution obtained by the rigid body model.

(a) Overall design flow

(b) Details of Optimization Calculation

Figure 2.2.1. Flow Chart of Simultaneous Optimization Design of Sliding Parts

2.3. Lubrication-Mechanism-Structure Coupled Analysis simulation

The lubrication-mechanism-structure coupled analysis code FIRST developed by IST in Germany was used to construct an analysis model for multiple sliding surfaces. FIRST can couple the mechanism analysis by multibody dynamics with the modified Reynolds equation and the mixed lubrication analysis considering the roughness by the Greenwood-Tripp model, and the analysis considering the interaction of each sliding surface is possible. In addition, the analysis considering the elastic deformation of the parts is also possible by using the structural model of the degenerate parts by the Structural Analysis Tool (ANSYS).

In this study, the main sliding surfaces, (1) valve plate and cylinder block, (2) piston and cylinder, (3) shoe and swash plate, were modeled as sliding surfaces, and the other parts were modeled by connecting spring-damper elements.

As an input condition, the cylinder pressure fluctuation curve obtained by one-dimensional simulation was used as a pressure load on the piston and a pressure boundary condition on the sliding surface.

Using this model, the power loss and efficiency were evaluated based on the driving torque when the pump shaft was forced to rotate and the amount of leakage from each sliding surface.

2.4. Selection of High-Sensitivity Design Factors

In order to select design factors to be used in the optimization calculation, sensitivity evaluation of leakage loss and friction loss for each sliding part was carried out by the Taguchi method. The control factor for the sensitivity analysis is shown in Figure 2.4.1. Three factors (Presence or absence of cylinder oil groove, piston/cylinder clearance, shoe/swash plate clearance) were selected to carry out the sensitivity analysis. Among these three factors, the shoe has a pressure pocket at the bottom where the oil pressure from the cylinder is introduced, and the oil pressure balance is set to float freely. Therefore, the shoe floats from the swash plate during the compression stroke, and leakage occurs through the gap between the shoe and the swash plate, which is considered to have a large effect on the leakage loss. In addition to the leakage loss, the piston/cylinder gap has an effect on the contact pressure at the contact point, which greatly affects the contact PV value of the sliding surface. The cylinder oil groove is provided to improve the loading capacity of the oil film by introducing the high-pressure oil to the side surface of the piston.

Figure 2.4.2. shows the results of the sensitivity evaluation. The shoe/swash plate clearance showed the highest sensitivity for both leakage loss and friction loss, suggesting that it is an important parameter to minimize the total loss. The piston/cylinder clearance showed the highest sensitivity for leakage loss.

Based on the results of the sensitivity analysis, the shoe/ swash plate clearance and the piston/cylinder clearance were set as two design variables for optimization.

Sensitivity parameter	Set value
Cylinder oil groove	Yes, No
Piston/cylinder clearance	Small, Large
Shoe/Swash Plate clearance	Small, Large

2.5. Optimal Solution Calculation Using Nonlinear Approximation Surface

2.5.1. Calculation method

The lubrication- mechanism-structure coupled analysis is a large-scale numerical analysis, and the calculation time is several hours to several days per case. By adopting the optimization method using the response surface, the number of analysis cases to obtain appropriate design dimensions can be reduced. In this study, the Kriging method, which is suitable for approximating nonlinear functions, was used as a response surface construction method. The response surface by the Kriging method includes not only the distribution of the function value itself but also the uncertainty (approximation error) information that can be included in the estimated function value. Efficient Global Optimization (EGO), which is an optimization algorithm to improve the accuracy of the response surface, was adopted with this information. In EGO, the expected improvement (EI), which is an index expressing how much the estimation accuracy can be improved when a new sample is added to a certain point and the response surface is reconstructed, is evaluated. Then, the location where the EI value is maximum is searched, and a new sample point is added to reconstruct the response surface. By repeating these operations, the improvement of the approximation accuracy of the response surface and the search for the global optimum solution can be achieved simultaneously. Compared with the conventional optimization method (genetic

algorithm), it is reported that the number of calculations required to obtain a solution with the same accuracy is less than 1/20 [1]. Therefore, it is expected that the solution can be obtained in a practical time. In this study, the response surface was generated using Dakota, an open source optimization tool developed by Sandia National Laboratories, USA, and the optimum solution was searched by EGO.

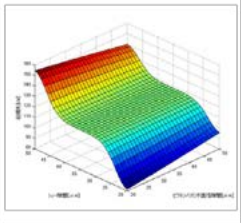
In the optimum solution search, a constrained nonlinear optimization was performed to minimize the total loss by keeping the PV value below the criterion value within the range of design variables (Piston/cylinder clearance, shoe/swash plate clearance) specified in the optimization problem.

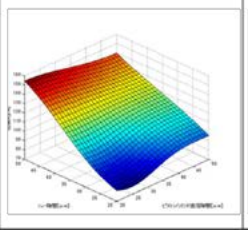
In the coupled analysis model used for the optimization calculation, all parts were treated as rigid bodies and the analysis mesh of the sliding surface was made relatively coarse to reduce the calculation time. Considering the periodicity of the pump behavior, the analysis range was limited to 1/4 rotation of the main shaft. As a result, the calculation time per 1 case was about 16 hr, and the optimum solution could be obtained within a practical period. However, the analysis accuracy of the contact pressure could not be guaranteed because the sliding surface analysis mesh is coarse and the number of contact nodes per piston piece may be 1 to several points. Therefore, the contact pressure of the piston was separately calculated based on the three-dimensional elastic contact model from the contact load of each contact region (the upper end of the piston and the small mouth of the cylinder) and the inclination angle of the piston with respect to the cylinder obtained from the analysis result of the coupled analysis.

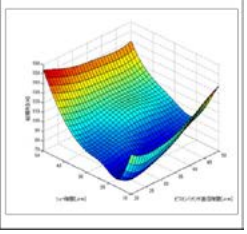
2.5.2. Optimization calculation result

Figure 2.5.1. shows the response surface at steps 0, 3, and 10 of optimization, and Figure 2.5.2. shows the final response surface and analysis points.

An initial response surface was created based on the analysis result of 4 points used in the sensitivity analysis, and the optimization calculation was executed. As a result, the amount of movement of the search point fell below the criteria at step 10, and it was judged to be convergence. The initial response surface showed a monotonic decreasing trend for each design variable with low estimation accuracy. However, the optimum point appeared at the tip of the bowl-shaped region at step 10.

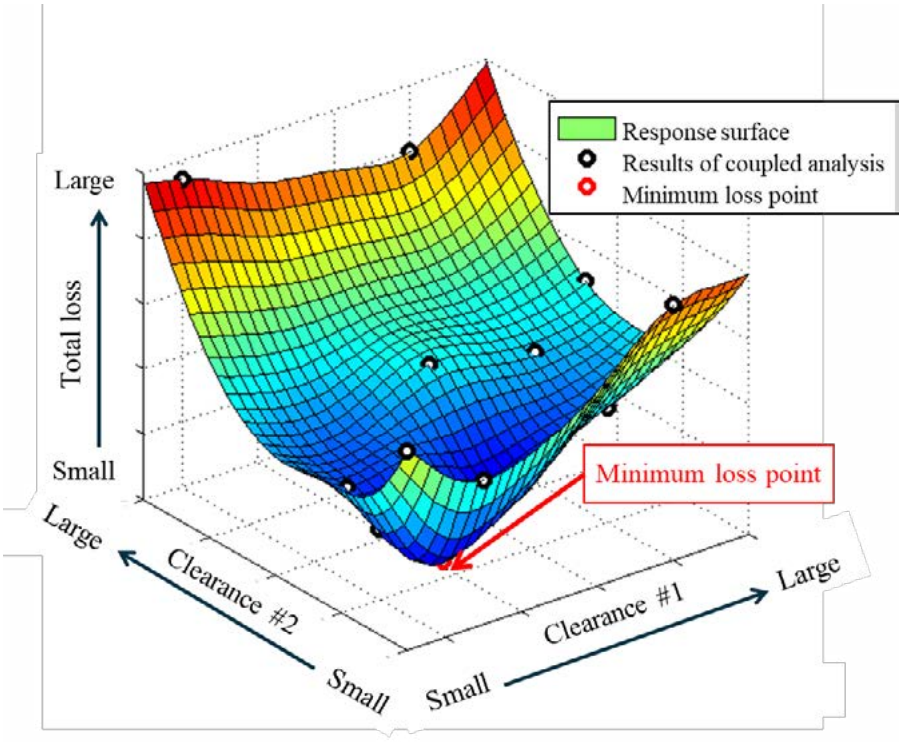






Number of optimization steps	#0 (Initial)	#3	#10 (Convergence)
Response surface			

Figure 2.5.1. Optimization steps



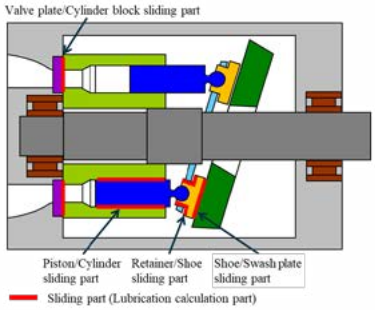


Figure 2.5.2. Optimal solution and kriging surface after convergence

2.5.3. Confirmation of Optimum Solution by Elastic Body Model

Figure 2.5.3. shows the comparison result between the rigid body model and elastic body model. In the optimization calculation, the rigid body model was used to reduce the calculation time. In order to confirm the validity of the optimization result using the rigid body model, an analysis was performed considering the elastic behavior of the piston at the optimum point. Comparing the rigid body model with the elastic body model, the error of the calculation result of the total loss was about 7%, and there was no significant difference in the distribution of the oil film thickness, oil film pressure, and contact pressure (the calculation time of the elastic body model was 4-10 times longer than that of the rigid body model).

Comparison of Loss Calculation Results

	Total loss (-)	Error (%)
Elastic body model	1.07	-
Rigid body model	1	7

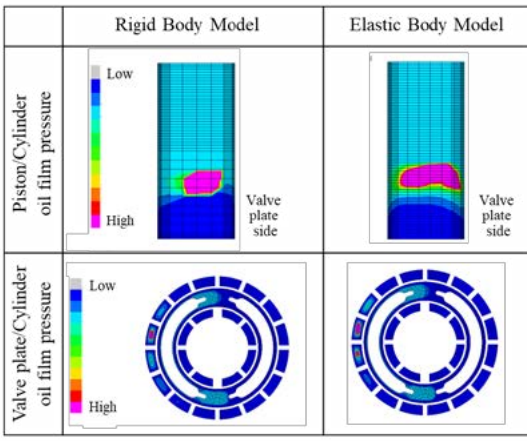

Figure 2.5.3. Comparison of Elastic and Rigid Analysis Result

2.5.4. Comparison of the Optimization Result and the Current Design Result

Figure 2.5.4. and Figure2.5.5. show the comparison between the analysis result and the optimization result and the current design result. Comparing the current design point with the optimization result, it was confirmed that the total loss was reduced by about 30%, and the corresponding improvement in total efficiency was 4%.

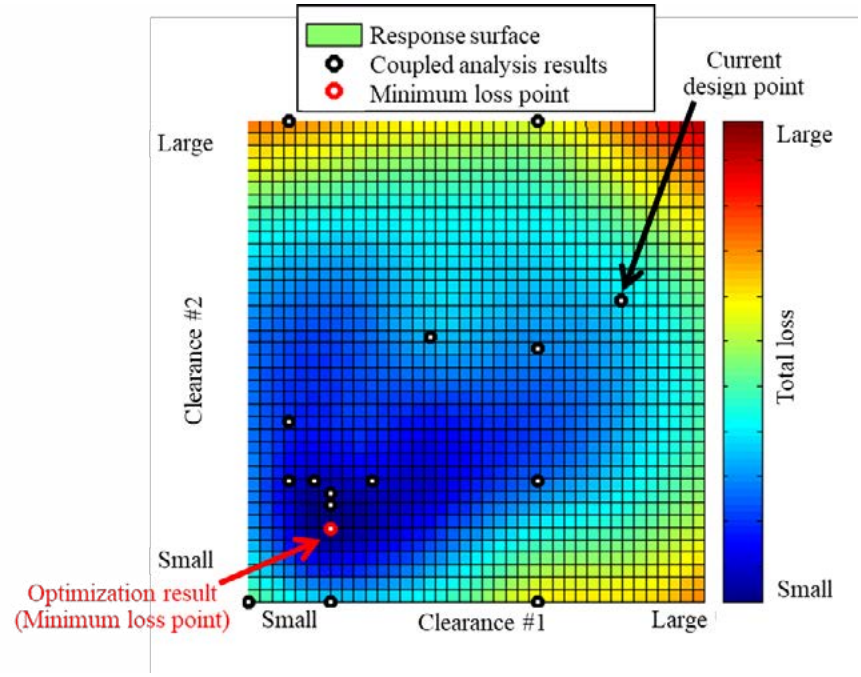

Figure 2.5.4. Response Surface Contour of total loss and tolerance zone of clearance

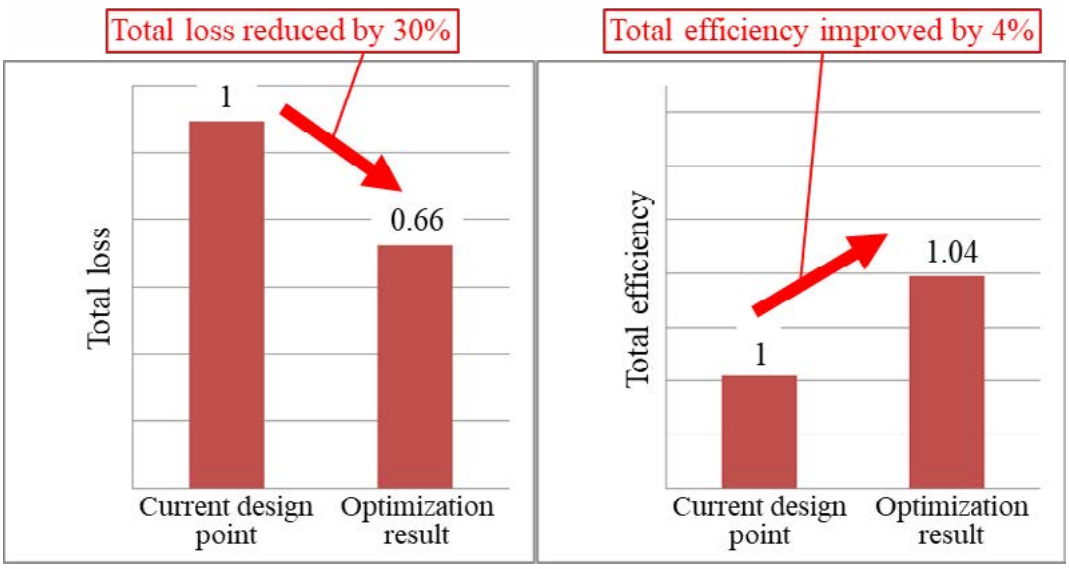

Figure 2.5.5. Comparison between the optimization result and the current design result

3. SUMMARY

By constructing a sliding part design technology that combines lubrication-mechanism-structure coupled analysis and nonlinear optimization technology, it is possible to design a sliding part shape that achieves both performance and reliability of a hydraulic pump in a short period of time, and it is expected to avoid an increase in the development period.

Performance Improvement of Pressure Compensated Flow Control Valve Using Virtual Engineering

Harsh Maniar[1], Ujas Patel[1] and Nirav Patel[1]

[1]Bosch Rexroth (I) Pvt Ltd, harsh.maniar@boschrexroth.co.in; ujasp.patel@boschrexroth.co.in; niravkumardahyalal.patel@boschrexroth.co.in

Abstract.

This paper addresses the performance challenges associated with pressure compensated flow control valves, particularly in maintaining effective pressure compensation at higher flow rates. The primary objective is to investigate how various design parameters influence the valve ability to maintain consistent flow under pressure variations. Given the complexities and resource demands of physical testing across numerous design variants, a more efficient approach is required. This study uses virtual engineering techniques to create a simulation model of the valve, enabling a comprehensive analysis of the impact of different design parameters on its performance.

Keywords. Pressure compensation, Flow control valve, Flow force, CFD, Mathematical model.

1. INTRODUCTION

Hydraulic systems are widely used in both industrial and mobile applications because of their high-power density and ability to generate large output forces [1]. Actuator motion control is required in most hydraulic applications, which can be achieved by regulating the flow rate of hydraulic oil. Table 1 summarizes the different components used to control flow rate in hydraulic systems.

Components	Remarks
Fixed displacement pump	- Requires a mechanism to regulate pump speed. - Cannot provide independent speed control for multiple actuators.
Variable displacement pump	- More expensive compared to fixed displacement pumps. - Cannot provide independent speed control for multiple actuators.
Flow control valves	- Allow independent speed control of multiple actuators.
Closed loop control with servo system	- Provides precise control of flow rate. - Involves higher complexity and cost.

Table 1: Overview of different components for flow rate control.

All Open Access articles are peer-reviewed, distributed under the Creative Commons Attribution-Non Commercial 4.0 International

Flow control valves regulate the flow rate by varying the throttle area. Such valves are commonly referred to as throttle valves. They are available from several manufacturers, including F valves (Bosch Rexroth), T valves (Yuken), and Q valves (Atos). The main limitation of throttle valves is that the regulated flow rate depends on the pressure drop across the valve. To maintain a constant flow independent of pressure variations, pressure compensation is employed in valves. Pressure compensated flow control valves (referred as PCFCV here) are offered by several manufacturers, including FRM valves (Bosch Rexroth), F valves (Yuken), QV valves (Atos).

A new design of a pressure-compensated flow control valve for water hydraulics was developed [2]. The valve dimensions were determined by solving the simplified equations in MATLAB. Experimental investigations were then carried out on the prototype valve, which revealed the following key findings:

- The pressure–flow characteristics indicated that an increase in pressure led to a slight decrease in flow rate.
- Incorporation of flow-force compensation reduced the rate of flow reduction with increasing pressure.
- Flow-force compensation using an O-ring further improved the pressure–flow characteristics; however, it also introduced a negative impact on hysteresis.

[3] analysed such a valve using (i) steady-state analysis with a nonlinear model and (ii) dynamic response analysis with a linearized model. The nonlinear model was used to extract parameters for the frequency response model, from which flow-gain and pressure-coefficient transfer functions were derived. The study also examined the effect of various design parameters on valve dynamics, including critically compensated, over-compensated, and under-compensated conditions. Similar investigations have been reported in [4], [5], [6], focusing on the analysis and performance evaluation of pressure-compensated flow control valves.

Performance improvement of pressure compensated flow control valve can be done by improving flow control accuracy, effective pressure compensation and output flow stability. In reference [7] shows influence of main orifice shape on accuracy of flow control. They identified two shapes (triangle and circular) for proportional flow control valve. They created characteristic curves for valve using CFD data in conjunction with MATLAB/SIMULINK. [8] performed dynamic analysis of two stage poppet valve for flow control. The effect of flow forces on force equilibrium to maintain constant outflow is studied.

The present study aims to develop a methodology for predicting the performance of pressure-compensated flow control valves (PCFCVs) using CFD. For this purpose, 2FRM6 valve from Bosch Rexroth is used. Furthermore, the study seeks to enhance valve performance by investigating the influence of various design parameters on its dynamic and steady-state behaviour

2. FLOW CONTROL VALVE: 2FRM6

2.1. Working of 2FRM6

The 2FRM6 is a pressure- and temperature-compensated two-way flow control valve. Figure 2.1 illustrates its schematic layout. The valve housing (1) accommodates a main sleeve (3) and a compensator sleeve (9). The main sleeve contains a main orifice (5) of triangular shape, the opening of which is regulated by the throttle screw (8). This screw moves axially within the main sleeve and is externally adjusted through the control knob (2).

The compensator spool (4), located within the compensator sleeve (9), governs the pressure-compensation mechanism. Flow from the main orifice discharges through circular holes in both the compensator spool and sleeve. The compensator spool is free to move axially to an equilibrium position determined by the balance of forces acting on it. Specifically, fluid pressure acts on its lower face via the nozzle (7) and on its upper face via the main orifice (5). The resulting position of the spool adjusts the throttling area, thereby compensating for pressure variations. Additionally, the spring (6) applies a restoring force on the compensator spool, which varies with the relative positions of the throttle screw and spool.

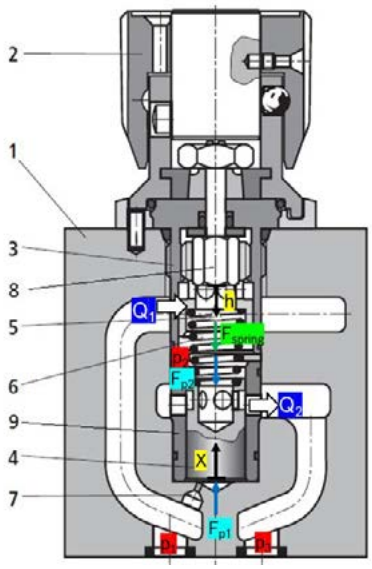

Figure 2.1: Schematic representation of 2FRM6: 1-Housing, 2-Adjustment knob, 3-Main sleeve, 4- Compensator spool, 5- Main orifice, 6- Spring, 7- Nozzle, 8- Throttle screw, 9-Compensator sleeve.

Subsequent section presents the approach used to estimate the performance of the 2FRM6 valve using CFD simulations. Before detailing the CFD methodology, a mathematical description of the valve operation is provided to illustrate how the equilibrium position of the compensator spool governs the flow characteristics. This formulation establishes the foundation for the subsequent numerical analysis by linking hydraulic forces and spring forces to the valve's operating points.

2.2. Mathematical Description of 2FRM6

Flow through main orifice is described by standard orifice equation as:

$$Q_1 = c_{d1} A_{main} \sqrt{\frac{2(p_1 - p_2)}{\rho}} \tag{2.1}$$

Similarly, the flow through compensator orifice can be described as:

$$Q_2 = c_{d2} A_{compensator} \sqrt{\frac{2(p_2 - p_3)}{\rho}} \tag{2.2}$$

where, c_{d1} and c_{d2} are discharge coefficients of main and compensator orifices, respectively, and A_{main} and $A_{compensator}$ are the effective flow areas of main orifice and compensator orifice. For simplicity, the downstream pressure p_3 can be assumed equal to tank pressure, which is taken as zero.

In valve performance evaluation, the main throttle area A_{main} is fixed according to the control knob setting. The discharge coefficients c_{d1}, c_{d2} are generally unknown and can be determined experimentally or through CFD simulations.

At steady state, the flow through both orifices must be equal ($Q_1 = Q_2$). By equating Eqs. (2.1) and (2.2), the intermediate pressure p_2 can be expressed as:

$$p_2 = \frac{c^2}{1 + c^2} p_1 \tag{2.3}$$

where, $c = \frac{c_{d1} A_{main}}{c_{d2} A_{compensator}}$.

The position of the compensator spool is determined from the equilibrium between the hydraulic and spring forces:

$$F_{spring} = F_{hyd} \tag{2.4}$$

The spring (6) is compressed between the throttle screw and compensator spool, and its force can be written as:

$$F_{spring} = F_0 + kx \tag{2.5}$$

where F_0 is the initial compression force dependent on the throttle screw position ($F_0 = f(h)$), k is the spring stiffness, and x is the axial displacement of the compensator spool. F_{hyd} consists of all type of forces acting on compensator, i.e., force due to pressure, flow, and friction. Considering only pressure force for simplicity one can express it as:

$$F_0 + kx = \frac{p_1 A}{1 + c^2} \tag{2.6}$$

A is area of compensator where pressure acts. Since c depends on $A_{compensator}$, which in turn depends on the spool displacement x, Eq. (2.6) is nonlinear and can be solved iteratively to determine the compensator position for a given inlet pressure p_1. Once the equilibrium position is known, the corresponding flow rate can be calculated using Eq. (2.1).

3. PERFORMANCE EVALUATION OF 2FRM6 USING CFD

The mathematical model provides a framework for understanding the steady-state behaviour of the 2FRM6. However, the model has inherent limitations. The discharge coefficients of the main and compensator orifices (c_{d1} and c_{d2}) are generally unknown and cannot be predicted analytically accurately without detailed flow information. Furthermore, while the model accounts for the pressure forces acting on the compensator spool, it neglects the effects of flow-induced forces and other secondary effects such as friction. These simplifications limit the predictive capability of the mathematical model for precise performance evaluation and hence, CFD simulations are employed. By combining the mathematical understanding of spool force balance with CFD-predicted pressure distributions, the equilibrium position of the compensator spool and the corresponding flow–pressure characteristics of the valve can be reliably evaluated.

3.1. Simulation Strategy

For each simulation, the main throttle screw was fixed at a prescribed position, while multiple axial positions of the compensator spool were considered to capture the variation in pressure and flow. This procedure can be repeated for different main spool positions to cover the full operational range of the valve. In the present study, the main spool position, h, is set to 2.8 mm, and five different compensator positions are considered.

For each compensator spool configuration, CFD simulations were performed to obtain the detailed pressure and velocity distributions. The resulting pressure fields were then combined with the spring force acting on the compensator spool to evaluate the equilibrium position using the force-balance relation. This procedure allowed the determination of the operating point corresponding to each spool configuration, from which the flow–pressure characteristics of the valve were obtained.

The computational domain was discretized using a hybrid mesh generated with commercial software. Mesh was refined in the vicinity of the orifices and the compensator spool to accurately resolve the pressure gradients. A representative mesh snapshot is shown in Figure 3.1, illustrating the resolution in critical regions.

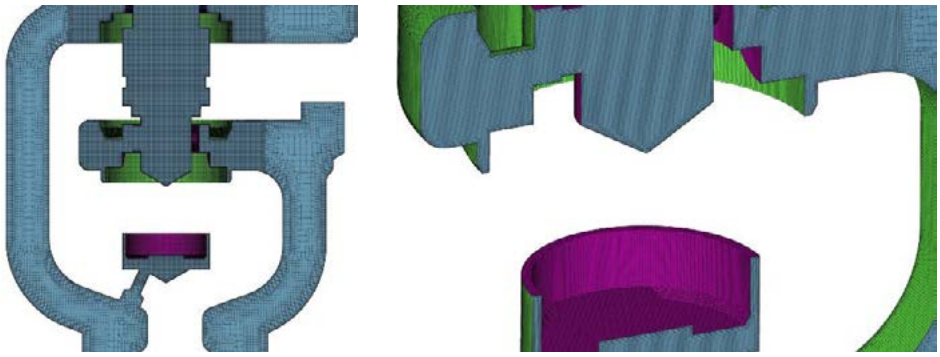

Figure 3.2: Snapshot of discretized domain.

3.2. CFD Model Setup and Parameters

Steady-state CFD simulations were performed using commercial software to resolve the pressure and velocity fields within the 2FRM6 valve. The fluid was treated as incompressible and isothermal, with properties corresponding to HLP46 hydraulic oil at 40 °C. Boundary conditions were applied as follows: a prescribed pressure at the inlet (upstream of the main orifice) and zero-gauge pressure at the outlet (tank). No-slip conditions were applied at all solid surfaces, including the valve housing and spool.

Software provides a wide range of turbulence modelling options. Among them realizable $k-\epsilon$ model [9] was selected, as it is widely regarded as a suitable choice for simulating turbulent flow in hydraulic valves and has been successfully employed in several previous studies [10], [11]. The boundary values of turbulent kinetic energy (k) and dissipation rate (ϵ) were specified using standard relations:

$$k = \frac{3}{2}\left(\frac{V}{TI}\right)^2 \tag{2.7}$$

$$\epsilon = k^{3/2}/L \tag{2.8}$$

Here, V is free stream velocity estimated using orifice equation and using a discharge coefficient of 0.7. TI is turbulence intensity assumed as 3%. L is the turbulence length scale taken as port radius.

4. RESULTS

This section presents the results obtained from the CFD simulations described in the previous section. The subsequent section will focus on the validation of these CFD results through comparison with experimental data.

4.1. Experimental Validation

Figure 4.1 shows the experimental test bench used to measure the performance of the 2FRM6 valve. The throttle screw of the valve was set to the fully open condition (scale position 10), which corresponds to the maximum flow capacity. CFD simulations were carried out for the same configuration, and the figure also presents a comparison between experimental measurements and CFD predictions. The results demonstrate that the CFD predictions are in very good agreement with the experimental data. Next section, provide in detail discussion on valve performance.

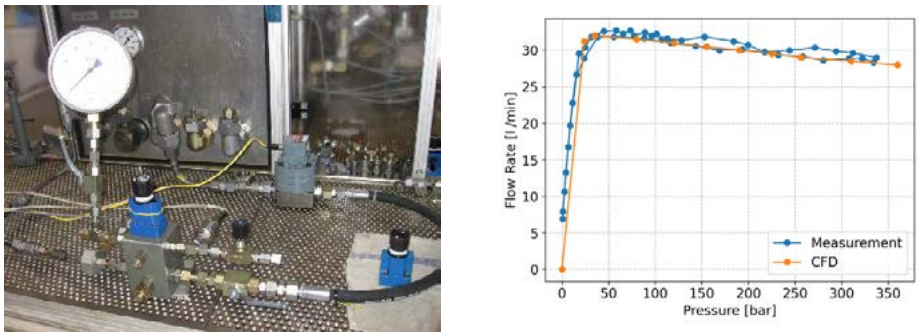

Figure 4.1: Experimental test bench and comparison of CFD and measurement data.

4.2. Discussion on Valve Performance

In a pressure-compensated flow control valve, the performance curve exhibits a distinct characteristic of maintaining nearly constant flow irrespective of pressure variations. At low flow rates, the pressure drop increases gradually, governed primarily by the resistance of the valve geometry. As the flow continues to rise, the compensator mechanism becomes active, adjusting its position in response to the pressure differential across it. Once the compensator engages, any further increase in flow is restricted because the compensator movement effectively reduces the available flow area. This behaviour is represented graphically by a plateau region in the performance curve, where the flow rate remains constant despite variations in pressure. After the plateau region, where the valve maintains nearly constant flow, the performance curve may exhibit a slight fall in the flow rate. This decline occurs due to nonlinear effects that influence the valve dynamics. Maximum flow capacity of 2FRM6 valve is 32 l/min, with the decline in flow rate being highest at this maximum and lower at reduced rates. The force balance can be disturbed by factors like friction in the compensator mechanism and the flow forces acting on the spool. It is important to note that when the inlet pressure is the same, this flow force is higher at increased flow rates and lower at reduced flow rates. These nonlinearities reduce the effective control of the compensator, causing a gradual decrease in flow rate even though the pressure differential remains high. The width of the plateau depends on flow rate and the extent of nonlinearities.

CFD simulations predict the decline in flow even without modeling effects such as friction, indicating that flow forces are the dominant source of nonlinearity in this case. Figure 4.2 illustrates the forces acting on the compensator at a flow rate of 32 l/min, along with the corresponding spring force. As the stroke increases (i.e., as the flow area decreases), the flow force rises sharply compared to the spring force. This rapid increase in flow force causes the compensator to move further than required for ideal pressure compensation, resulting in an excessive reduction in flow area. Consequently, the flow rate decreases at higher pressures.

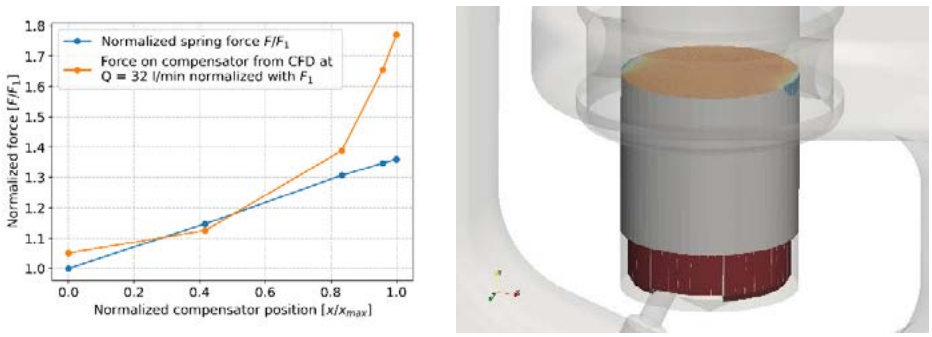

Figure 4.2: Flow force from CFD and pressure profile on compensator surface.

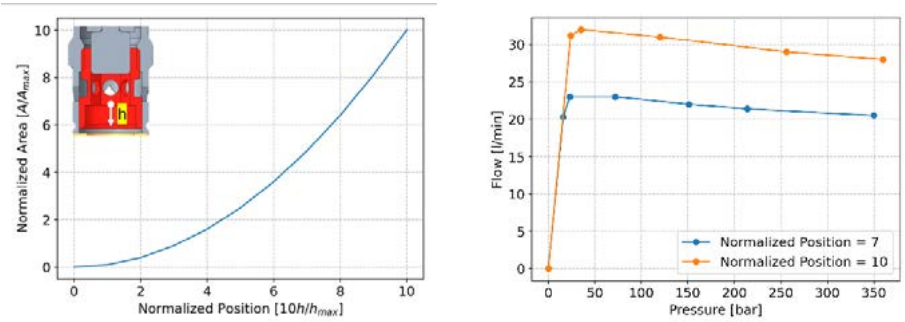


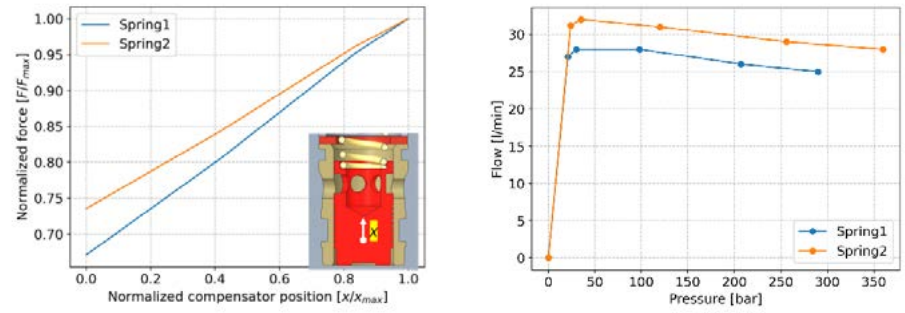
4.3. Influence of Design Parameters

The performance of a pressure-compensated valve is strongly affected by its design parameters. Key elements such as the main orifice, spring, compensator design determine how the valve responds to flow and pressure variations. Understanding the influence of these parameters is essential for optimizing valve behaviour, achieving the desired flow control,

and ensuring stable operation under different operating conditions. This section presents the influence of these design parameters on the valve performance.

4.3.1. Main Orifice Area

The main orifice (5) shown in Figure 2.1 plays a crucial role in the valve operation. While the orifice area determines the set flow rate through the valve, the orifice shape controls how this area changes with the movement of the throttle screw. Triangular-shaped orifices are commonly preferred to achieve a gradual increase in flow area. Figure 4.3 illustrates the variation of orifice area with different throttle screw positions and presents the characteristic curves of the valve for two set positions. It can be observed that changing the throttle screw position affects only the set flow, without altering the overall valve behaviour.

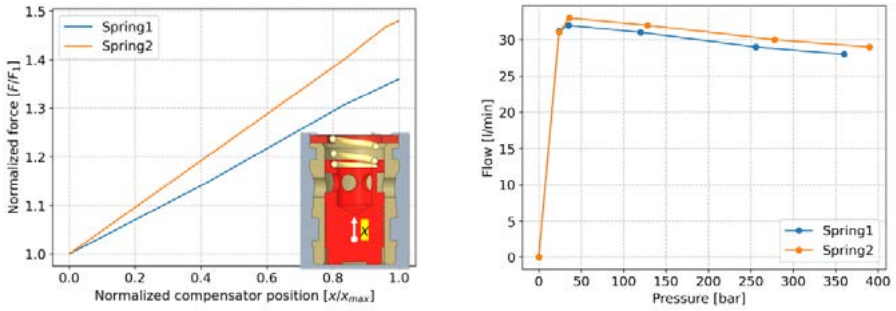


(a) (b)

Figure 4.3: (a) Variation of the main orifice area with the throttle screw position, (b) Performance curves corresponding to two different set positions of the throttle screw.

4.3.2. Influence of Spring

The spring in a pressure-compensated valve plays a crucial role in determining its operational characteristics. The regulation of flow rate under varying pressure conditions is primarily governed by the force balance between the spring and the compensator. The spring's initial compression force (F_1), its rate, and any nonlinearity directly influence the valve's response.

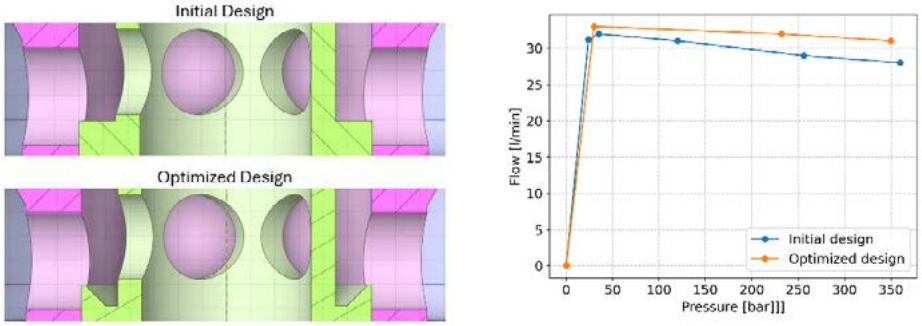


(a) (b)

Figure 4.4: (a) Normalized spring force with normalized compensator position, (b) Performance curves corresponding to two different springs.

Figure 4.4 illustrates the influence of the initial spring compression force on valve performance. Figure 4.4(a) shows the normalized spring force plotted against the compensator position. In this study, the initial compression of the same spring was increased while maintaining the same spring rate. As the spring rate remains unchanged, the force at $x/x_{max} = 1$ also increases, and this value is used for normalization. Two characteristic curves corresponding to different initial forces are presented. Increasing the initial compression force raises the valve's set pressure. As shown in the figure, with spring 1 the flow is set to 27 l/min at 21 bar, whereas with spring 2 it increases to 31 l/min at 24 bar.

Figure 4.5 shows influence of spring rate on performance curve. Figure 4.5(a) shows normalized force for spring1 and spring2 for different compensator position. Spring force is normalized by initial compression of the spring. It can be observed that with changing spring rate there is minor change in set flow, however, it does not influence the remaining characteristic of the flow.



(a) (b)

Figure 4.5: (a) Normalized spring force with normalized compensator position, (b) Performance curves corresponding to two different springs.

The variation of flow rate with inlet pressure is governed by the force balance between the compensator and the spring. As discussed earlier (see Figure 4.2), the nonlinear nature of the flow-induced force acting on the compensator plays a decisive role in defining the valve's pressure–flow characteristics. To achieve a stable response, the spring must generate a corresponding nonlinear force. This can be realized through a conical spring with variable stiffness.

4.3.3. Compensator Design

The design of the compensator plays an important role in determining the overall performance of a pressure-compensated flow control valve, as the flow-induced forces act directly on its surface. By optimizing the compensator geometry—particularly the profile of the surface exposed to flow—the magnitude of these forces can be effectively reduced. Incorporating sharper edges can limit the area over which the pressure distribution acts, thereby decreasing the effect of flow forces on compensator. Such geometric refinements improve the valve's ability to maintain a consistent flow rate under varying pressure conditions.

(a) (b)

Figure 4.6: (a) Design changes of compensator, (b) Performance curves corresponding to two different compensator designs.

5. CONCLUSION

A comprehensive methodology has been developed for predicting the performance of a pressure-compensated flow control valve. The approach enables accurate estimation of pressure–flow characteristics and internal forces under different operating conditions. The predicted results have been validated against experimental measurements, showing good agreement and demonstrating the reliability of the developed simulation methodology. Using this validated model, the influence of key design parameters—such as the main orifice geometry, spring characteristics, and compensator land dimensions—has been systematically investigated. The study highlights how each parameter governs the valve's set pressure and compensating behaviour. The findings emphasize the importance of proper selection and optimization of these design parameters to achieve desired performance and ensure consistent pressure compensation across the operating range.

Fluid Solutions Innovative and sustainable hydraulic fluid concepts

Wolfgang Bock, Romina Ambrosi, Gerit Dornacher

Fuchs Lubricants Germany GmbH

Abstract.

Hydraulic fluids are an important design element in stationary and mobile hydraulic equipment. Based on different sustainable base oil concept, FUCHS has developed new hydraulic fluid concepts which in addition to offering "hydraulic performance" have a low carbon footprint value. The product carbon footprint (PCF) of the relevant ACT (Advanced Circular Technology) fluids is significantly lower than vigor oils. Additionally, the C02 footprint of different fluid concepts during the application phase of hydraulic fluids will be discussed, based on a life cycle assessment (LCA) study. This presentation will provide an overview of the latest developments in hydraulic fluid technology. Energy-saving potential, lifetime aspects and performance levels will also be discussed.

1. INTRODUCTION

Hydraulic fluids are a significant group of lubricants in Germany. The fluid group includes in general mineral oil based hydraulic fluids, fire resistant, biodegradable, food-grade and multigrade hydraulic fluids as well as other specialties. The diagram shows the total market development of hydraulic fluids in Germany. Mineral based hydraulic fluids can be classified according to API base oil groups: Group 1, Group II and Group III. Conventional hydraulic fluids are based on Group I base oils, also known as solvent neutral (SN) base oils. New innovative hydraulic fluids are based on Group II/Group III, hydrotreated or hydrocracked which have a lot of technical and sustainable advantages (high lifetime, no aromatics, low sulphur content, etc.).

All Open Access articles are peer-reviewed, distributed under the Creative Commons Attribution-Non Commercial 4.0 International

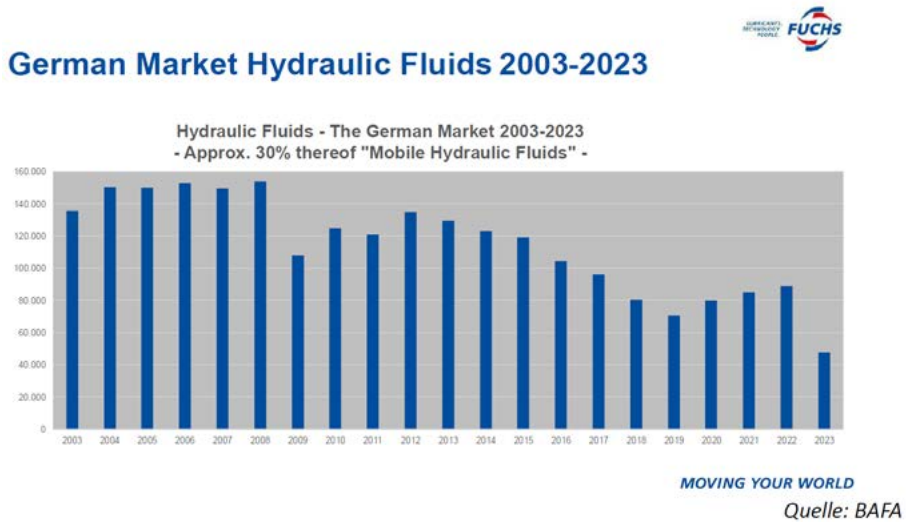

Figure 1.1. German Market Hydraulic Fluids 2003-2023

2. NEW INNOVATIVE MINERAL OIL BASED HYDRAULIC FLUIDS

Today, more than approximately 30% of mineral oil based hydraulic fluids are based on hydraulic fluids made from hydrotreated, hydrocracked Group II/ Group Ill. These high-performance fluids have a very long service life (2-3 times longer than comparable conventional fluids based on Group I), a low sulphur content, no aromatics, and a slightly higher viscosity index.

They also have low/ no varnish potential due to their extremely high oxidation stability. The hydrotreated fluids of the new generation of base oils are also increasingly important worldwide for industrial lubricants (e.g. Asia, America, Europe).

Diagram 2.1. shows the extended service life of these high-performance fluids.

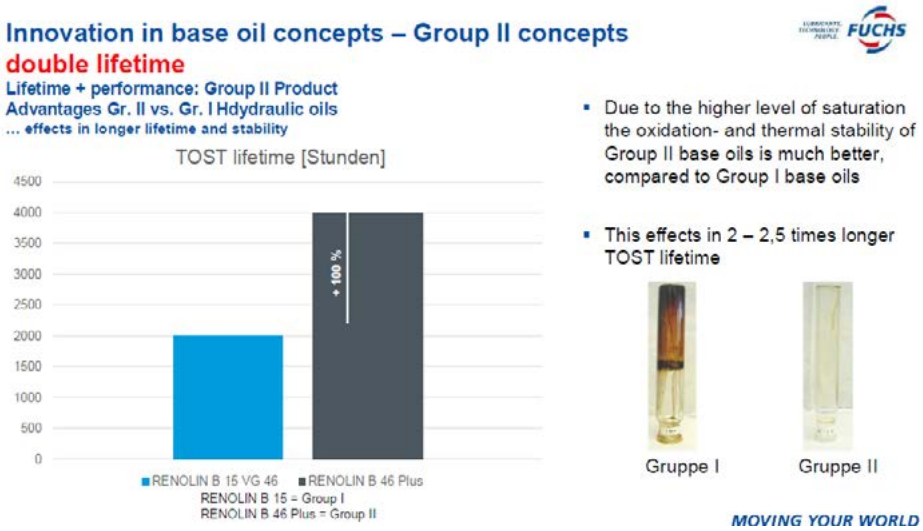

Diagram 2.1. Innovation in base oil concepts – Group II concepts

3. SUSTAINABILITY ASPECTS PCF VALUES, TRENDS

In general, sustainability, energy-saving and additive labeling aspects must be considered when formulating hydraulic fluids.

In addition, new fluid types must also meet economic criteria.

An important sustainability value is the Product Carbon Footprint (PCF) of hydraulic fluids, the PCF value. FUCHS evaluates the PCF value of the products within the cradle-to-gate boundaries.

Through the targeted use of sustainable base oils (e.g. re-refined base oils: Group I, Group II and Group III), the PCF value of sustainable products can be specifically reduced significantly (PCF reduction of up to 70%).

Diagram 3.1. shows different PCF values of virgin and sustainable base oil based hydraulic fluids.

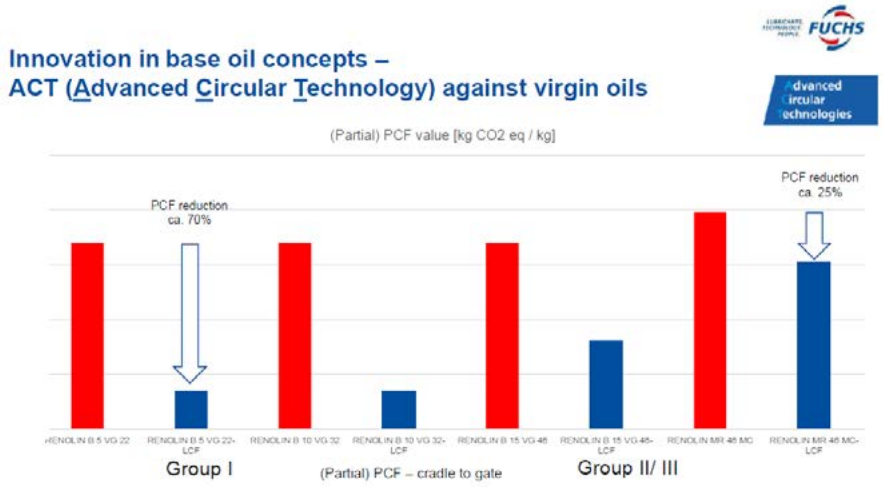

Diagram 3.1. Innovation in base oil concepts – ACT against virgin oils

4. SUSTAINABILITY PERFORMANCE PARAMETER, LIFETIME, ENERGY SAVING, LCA-STUDY, CUSTOMER STUDY

The sustainability of fluids can be assessed from various perspectives. The specific PCF of a product/ (per year of use) fluid, the overall lifespan, the use of re-refined base oi ls (RRBO), the use of renewable raw materials (for bio hydraulic fluids with the EU eco-label, > 25%), and additive systems that are not labelled acc. To CLP regulation.

In addition, life cycle assessment studies (LCA) - (comparison of mono- to multigrade hydraulic fluids) can provide information on the CO2 footprint of the products used during the application phase.

Figures 4.1. to 4.3. show the different aspects of sustainability in hydraulic fluids and the results of a LCA study.

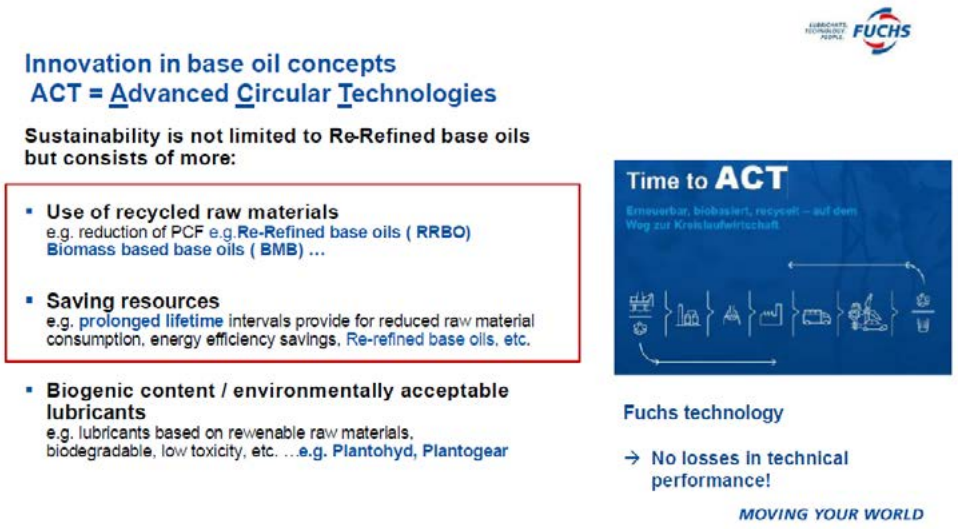

Figure 4.1. Innovation in base oil concepts

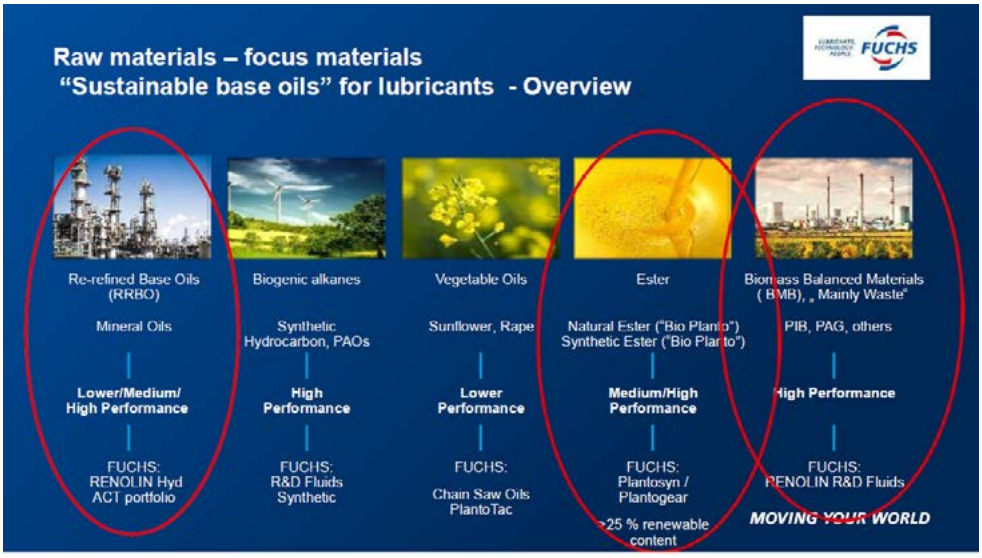

Figure 4.2. Raw materials – focus materials

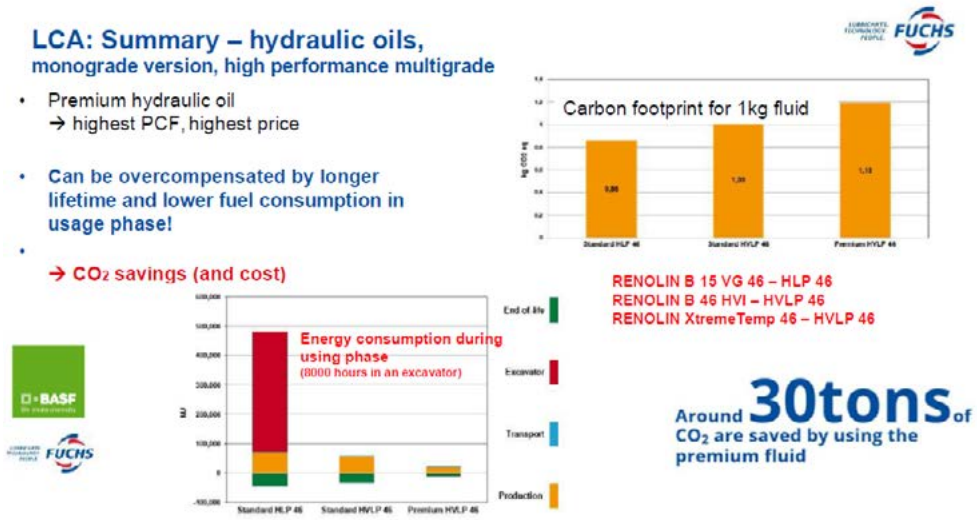

Figure 4.3. LCA: Summary – hydraulic oils, monograde version, high performance multigrade

5. CONCLUSION

Sustainability aspects should be considered when selecting hydraulic fluids. The product carbon footprint value (cradle to gate) is a meaningful parameter for assessing the carbon footprint of a product.

Other aspects such as energy efficiency, flu id lifetime, LCA considerations, and the labeling of additives must be considered and will become very important for products and users of fluids in the future.

Rating Hydraulic Fluids for Performance and Sustainability: Bosch Rexroth's Approach

Klaus Ellenrieder[1]*, Karl-Heinz Blum[2]

[1]Bosch Rexroth AG, Glockeraustraße 2, 89275 Elchingen, Germany

Abstract

The increasing power density of hydraulic systems and growing demands for environmental compatibility, resource conservation, and energy efficiency are putting traditional mineral oil-based hydraulic fluids under increasing pressure. This encourages the development of new fluid types such as zinc- and ash-free formulations, biodegradable and bio-based hydraulic fluids, and re-refined base oils (RRBO). In view of this development, Bosch Rexroth has expanded its "Fluid Rating 90235" [1], established in 2015, which originally focused on wear behaviour and component lifespan. Since 2026, the rating includes a practical oil aging test for precise evaluation of fluid lifetime. In the future, the Fluid Rating will be supplemented by a comprehensive sustainability block, integrating criteria such as energy efficiency, environmental compatibility, and aspects of circular economy, including life cycle assessments (LCA) and product carbon footprints (PCF). This expanded assessment approach enables a standardized and transparent evaluation of hydraulic fluids, considering modern technical and regulatory requirements, and supports the transformation towards more sustainable fluid solutions.

Keywords. Fluid Rating, sustainability, energy efficiency, oil aging, performance, regulatory requirements

1. INTRODUCTION

In recent years, the performance of hydraulic systems has once again significantly increased. Consequently, the demands on the hydraulic fluids used are also rising steadily, as they can, for example, decisively influence the wear properties of hydraulic components. Relevant standards only define minimum requirements for hydraulic fluids. They do not reflect technical advancements and do not allow for differentiation between fluids. Bosch Rexroth offers lubricant and additive manufacturers a standardized evaluation procedure based on scientific findings, which takes these aspects into account and tests hydraulic fluids for suitability under realistic operating conditions.

All Open Access articles are peer-reviewed, distributed under the Creative Commons Attribution-Non-Commercial 4.0 International

The increasing power density, growing demands for environmental compatibility, resource conservation, energy efficiency, occupational safety, and rising regulatory requirements from countries and authorities pose new challenges for the development of hydraulic fluids. Traditional mineral oil-based fluids, which currently make up the majority of the market, are increasingly under pressure as the mentioned aspects become crucial criteria (Figure 1).

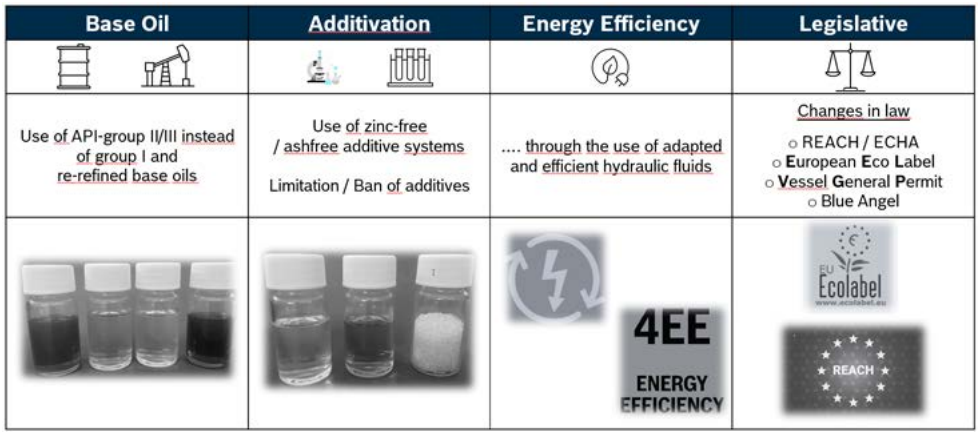

Figure 1: Challenges for future high performance hydraulic fluids

This development promotes the emergence and use of new fluid types, including zinc- and ash-free formulations, biodegradable hydraulic fluids, bio-based products, re-refined base oils (RRBO), and fire-resistant fluids. This change is no longer driven solely by environmental awareness but significantly by stricter regulations, the pursuit of carbon neutrality, and technical innovations. For example, biodegradable lubricants are increasingly used in environmentally sensitive areas such as transport, marine, food processing, and forestry and agriculture.

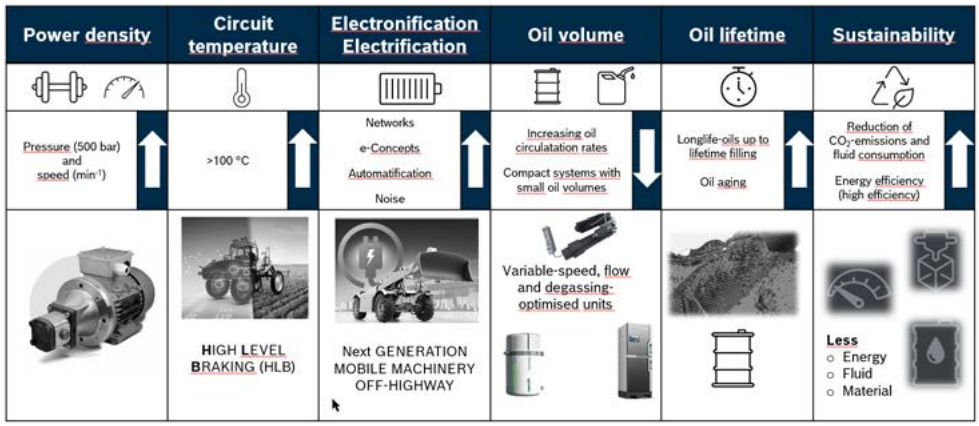

Figure 2: Changes and trends in hydraulic systems and components

At the same time, hydraulic applications are also being further developed through electronification and electrification. The replacement of internal combustion engine-driven systems by electric drives, power-on-demand systems with electrically controlled pumps,

and decentralized hydraulic systems with small oil volumes and high-power density require correspondingly adapted fluid properties (Figure 2).

2. STATE OF THE ART AND TRENDS

Hydraulic fluids based on mineral oils are the most used group, accounting for approximately 85%. About 15% of the market share is accounted for by synthetic base oils, such as esters, polyalphaolefins (PAO), and polyalkylene glycols (PAG). Among mineral oil-based base oils, the trend is moving away from paraffinic API (American Petroleum Institute) Group I towards hydrotreated paraffins of API Group II (hydrotreated) and Group III (hydrocracked) (Figure 3).

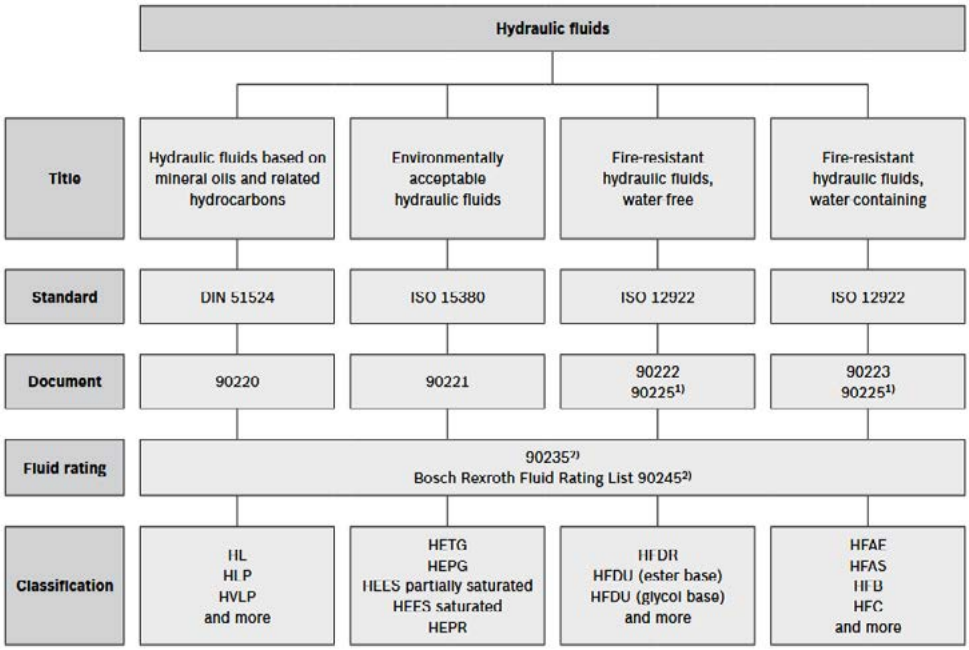

Figure 3: Overview of classification and relevant standards for hydraulic fluids [1]

To address this development, Bosch Rexroth has already established a standardized rating procedure for hydraulic fluids – the Bosch Rexroth Fluid Rating 90235 (Figure 4) [1]. Since then, this has become a recognized industry standard and is used by many fluid and additive manufacturers for the development of fluid formulations and hydraulic fluids. The primary focus has been and continues to be mainly on the wear behaviour and lifetime of hydraulic components.

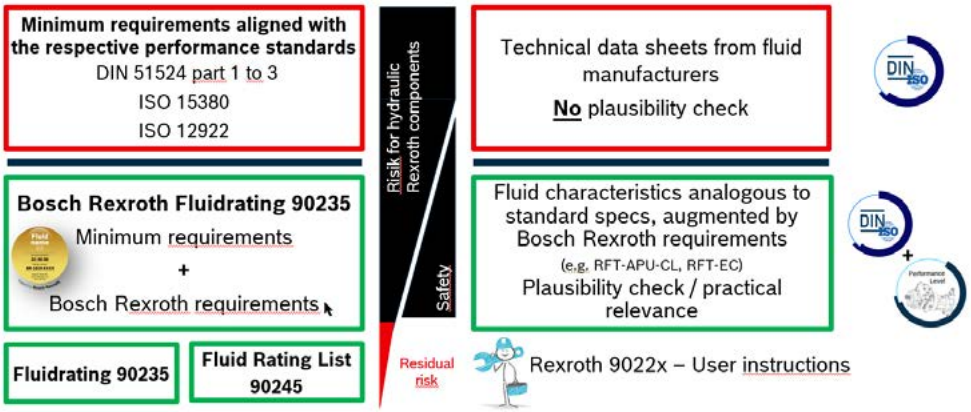

Figure 4: Bosch Rexroth Fluidrating: actual structure

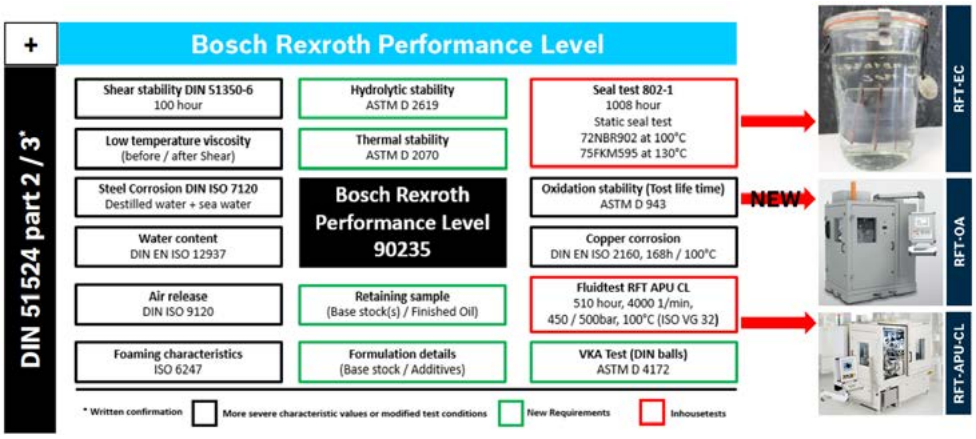
The central part of the Fluid Rating, in addition to stricter requirements based on relevant performance standards and a seal and oil aging test, is a comprehensive fluid test based on the use of hydraulic components such as swash plate axial piston pumps and bent axis axial piston motors (Figure 5).



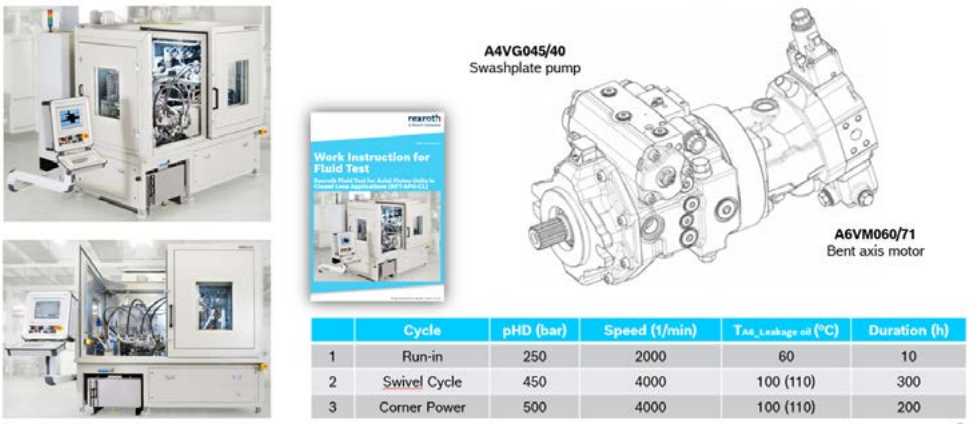


Figure 5: Bosch Rexroth Performance Level for mineral oils H(V)LP

These units simulate a typical hydrostatic drive in a closed circuit and, due to their high-performance parameters (pressure, speed, temperature), also cover the requirements of units in open circuits regarding wear behaviour and material compatibility. The drive components used are subject to strict quality control, are precisely measured and documented to minimize influences from test specimens. Such a fluid test lasts a total of 510 hours and includes phases such as run-in, swivel cycle, and corner power operation (Figure 6). After the test run, a detailed evaluation of the relevant components is carried out.

To reduce resources, the test units for the fluid tests are not completely replaced by new ones but reconditioned, and only relevant components, such as the rotary group and seals, are replaced – already a corresponding contribution to the sustainability claim.

	Cycle	pHD (bar)	Speed (1/min)	$T_{A6_Leakage\ oil}$ (°C)	Duration (h)
1	Run-in	250	2000	60	10
2	Swivel Cycle	450	4000	100 (110)	300
3	Corner Power	500	4000	100 (110)	200

Figure 6: Bosch Rexroth Fluid Test RFT-APU-CL (Rexroth Fluid Test Axial Piston Unit Closed Loop)

The Fluid Rating currently covers the different fluid categories: mineral oils, environmentally acceptable hydraulic fluids, UTTO oils, and hydraulic fluids based on re-refined base oils (RRBO).

3. OBJECTIVE AND APPROACH

Given the necessity to transparently rate new fluids (e.g., RRBO, biodegradable fluids, fire-resistant fluids) and the associated requirements regarding environmental compatibility, efficiency, and resource conservation, an expansion of the rating to include a comprehensive sustainability block is sought.Criteria such as fluid lifetime, energy efficiency, environmental compatibility in the context of the entire lifespan, and the CO2 footprint are to be integrated into the Fluid Rating in the future (Figure 7).

A first step for this is the recently implemented inclusion of an oil aging test, to assess the lifetime of hydraulic fluids more practically than the TOST TEST (Total Oxidation Stability Test) currently required in standardization. This will be described in more detail in Section 4.1.

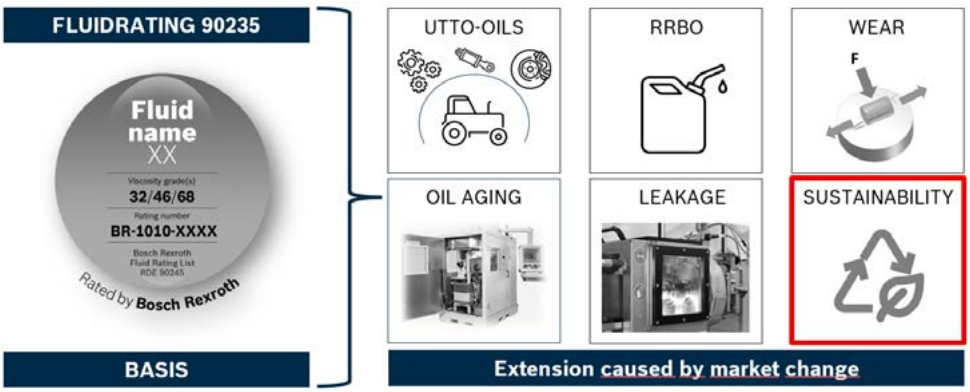

Figure 7: Extension of the fluid rating due to market change

The new requirements, in addition to the lifetime of hydraulic components which serves as the basis, are now to be integrated into the Fluid Rating as follows:
The primary objective is the development of a standardized and transparent evaluation procedure for additional sustainability aspects of hydraulic fluids. This essentially includes the following criteria (Figure 8):

- **Fluid Lifetime:** (Expanded in 2026 by an oil aging test)
- **Energy Efficiency:** Evaluation of the hydraulic fluid's influence on the system's energy consumption.
- **Environmental Compatibility:** Evaluation of ecological impacts, including biodegradability, toxicity, and water hazard class.
- **Circular Economy** (Life Cycle Assessment, LCA) **and CO2 Footprint** (Product Carbon Footprint, PCF): Evaluation of environmental impacts throughout the fluid's entire life cycle, from raw material extraction to disposal/recycling.

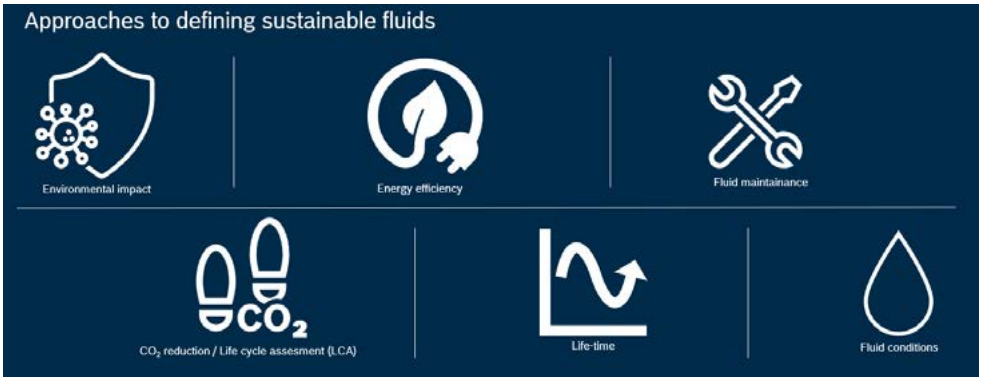

Figure 8: Sustainability aspects for hydraulic fluids

The approach envisages offering this expanded evaluation block successively in several expansion stages as a further module to the existing Fluid Rating. This requires the development of new test methods, the identification of relevant fluid parameters, and the creation of a transparent rating system that enables the comparison and classification of fluids regarding their sustainability performance (Figure 9).

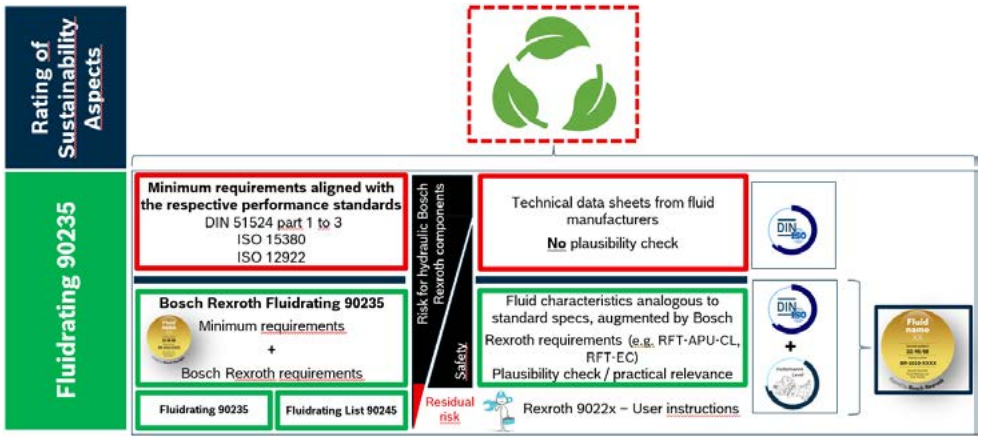

Figure 9: Sustainability aspects as a further rating block on top of the existing Bosch Rexroth Fluidrating

4. CURRENT STATUS AND ACHIEVED RESULTS

The expansion of the Fluid Rating is being carried out through targeted research and development efforts in the following areas:

4.1. Lifetime of Hydraulic Fluids

The determination and evaluation of the hydraulic fluid's lifetime are carried out using a specially developed oil aging test rig.

This fully automated test rig subjects the fluid to accelerated aging for over 300 hours at 90 °C with the addition of a copper catalyst and air. Automatically taken oil samples are regularly analyzed to comprehensively record and evaluate the aging behaviour (Figure 10). This test closes the gap for a practically relevant aging assessment that was not covered by the conventional TOST (Total Oxidation Stability Test).

Figure 10: Bosch Rexroth Oil Aging Test [2]

In preparation for inclusion in the Fluid Rating, tests were carried out with a reference oil (mineral oil HLP containing zinc), and the aging behaviour was determined over time based on NMR analyses (nuclear magnetic resonance analysis) and FTIR spectroscopy (Fourier-Transform Infrared Spectroscopy) and documented under different test parameters (speed, pressure, temperature).

4.2. Energy Efficiency (Development of a Systematic Approach)

The influence of hydraulic fluids on the energy efficiency of hydraulic systems is often underestimated. Currently, a uniform and standardized rating procedure is lacking. Bosch Rexroth plans, in cooperation with industrial partners and institutes, to identify relevant fluid parameters that influence the efficiency of various hydraulic components. Based on experimental data, a systematic approach will be developed and integrated into the Fluid Rating. This will enable a comparison and evaluation of hydraulic fluids regarding their contribution to energy efficiency in different applications. In the long term, this could include the development of a dedicated energy efficiency test rig and a standardized evaluation procedure to validly assess energy efficiency in various applications.

4.3. Environmental Compatibility (Integration of Labels and Criteria)

The environmental compatibility of hydraulic fluids is determined by their chemical composition, their behaviour in case of leaks, and their disposal. The assessment includes biodegradability, toxicity, and water hazard class. Transparent representation is achieved by integrating existing environmental labels and certifications such as the Blue Angel, VGP (Vessel General Permit), or the EU Ecolabel. These labels certify compliance with relevant environmental requirements. Additionally, ISO (International Organization for Standardization) certifications and manufacturer specifications, as well as fluid monitoring concepts, can be used to minimize environmental impact.

4.4. Circular Economy and CO2 Footprint (LCA/PCF Assessment)

For the evaluation of circular economy, the analysis includes the proportion of recycled or bio-based raw materials, the avoidance of scarce or poorly degradable raw materials, environmental impacts during raw material extraction and processing, reprocessability and recyclability, as well as corresponding service concepts and condition monitoring. The assessment of the CO2 footprint considers emissions from raw material extraction and production, behaviour during the use phase (energy efficiency, oil lifetime, leaks), and end-of-life management (emissions and energy consumption during transport, reprocessing, and disposal). For a neutral and comparable assessment, life cycle assessments (LCA) according to recognized standards are used, possibly in cooperation with independent institutions.

5. SUMMARY AND OUTLOOK

The increasing power density in hydraulic applications and global sustainability goals necessitate a fundamental adaptation of fluid formulations. The Bosch Rexroth Fluid Rating, a proven tool for rating the performance of hydraulic fluids, is being consistently expanded to meet these new requirements. By integrating aspects such as energy efficiency, oil aging, environmental compatibility, and holistic life cycle analyses (LCA/PCF), we are creating a comprehensive rating platform.

Achieved Results:

- Component lifetime is already established.
- The existing Fluid Rating has been supplemented since the beginning of the year by a practical oil aging test, which precisely evaluates the lifetime of fluids.
- The foundations for integrating energy efficiency parameters have been laid to make the influence of fluids on system efficiency measurable.
- A framework for evaluating environmental compatibility based on existing labels and other criteria is being established.
- The need for a comprehensive LCA/PCF assessment has been recognized, and the steps for implementation have been defined.

Outlook:
Bosch Rexroth will continue to actively support the transformation of the fluid industry. In the next steps, the detailed methodology for evaluating energy efficiency, environmental compatibility, and LCA/PCF aspects will be finalized and integrated into the Fluid Rating. This will be carried out gradually in several expansion stages.
Furthermore, we see potential for more intensive cooperation with the fluid industry to jointly develop sustainable hydraulic fluids that meet both the highest performance requirements and strict sustainability criteria. The possibility of offering fluid monitoring concepts in conjunction with the expanded rating criteria will also be evaluated. The goal is to provide users with transparent and reliable information for selecting the optimal fluid for their specific needs while promoting the sustainable development of hydraulic technology.

RWTH Aachen University - Institute for Fluid Power Drives and Systems (ifas), sebastian.deuster@ifas.rwth-aachen.de

Abstract.

This paper aims to describe the influence of synthetic fluids from Group 5 on various system boundaries and components of hydraulic systems, and to compare them with conventional hydraulic mineral oil. The focus is on evaluating the fluid mechanical properties. For this purpose, losses in pumps and pipes, as well as in valves, are analysed. Initially, these components are investigated and modelled mathematically to obtain a fundamental understanding. Experimental tests were conducted on a real hydraulic system of a mobile working machine using two different types of hydraulic fluids. These fluids include a mineral oil-based HLP (Group 2), a synthetic ester HEES (Group 5). The fluids are compared based on system boundaries losses in hydraulic systems components. The influence of their different chemical and physical properties is discussed.
The paper concludes with an analysis of the influence of the different losses when using alternative hydraulic fluids compared to mineral oils in hydraulic systems and potential future research activities in this field.

Keywords. Alternative hydraulic fluids, loss mechanism, energy efficiency, mobile machinery.

1. INTRODUCTION

In addition to the mechanical components of a hydraulic system, the hydraulic fluid is a key component that plays a crucial role in the efficiency and operating behavior of hydraulic machines. Hydraulic fluids consist mainly of a base oil and a small proportion of additives. Different base oils can result in varying chemical and physical properties. Base oils are classified according to the American Petroleum Institute (API). The API classifies base oils into five groups. Groups 1 to 3 include mineral oils of varying purity. Groups 4 and 5 comprise fully synthetic base oils. Most lubricants are based on mineral oils from Groups 1 to 3. Their market share is approximately 85%, with synthetic base oils accounting for 15 % [1]. Synthetic base oils, such as esters or polyalphaolefins, offer, for example, the advantage

All Open Access articles are peer-reviewed, distributed under the Creative Commons Attribution-Non Commercial 4.0 International

of adapting physical properties, including viscosity-temperature behavior, to the respective conditions of the hydraulic system during operation. Due to higher acquisition costs and the lack of suitable application tools for designing hydraulic systems tailored to a specific system, market sales are low compared to conventional mineral oils.

However, the use of hydraulic fluids based on API group 4 to 5 base oils has increased significantly in recent years [2]. These synthetic base oils provide physical and chemical properties that differ significantly, in some cases, from those of conventional mineral oils (Group 2). Using these oils in hydraulic systems results in distinct fluid mechanical and thermodynamic properties during their operation.

Previous research focused on the performance characteristics of synthetic hydraulic fluids in hydraulic displacement units [3, 4], which showed that the use of synthetic hydraulic fluids results in different efficiency levels than those achieved with conventional mineral oils. The tribological behaviour of synthetic esters was investigated in greater depth in comparison with mineral oils by [5, 6]. It was found that friction losses and wear are higher when synthetic esters are used. Jakobs [7] demonstrated in his work that the use of synthetic esters results in differentiated switching behaviour compared to mineral oils.

Previous work by us [8] showed high deviations in the overall efficiency of a mobile machine when using water-based hydraulic fluids instead of mineral oils.

This paper aims to expand on this work by identifying the causes of efficiency differences and balancing energy losses in the components of the hydraulic system. Unlike previous work, the focus here is on comparing mineral oils and synthetic esters.

The work is structured as follows: First, the fluid properties of the hydraulic fluid under investigation, mineral oil and synthetic esters, are presented in a comparative manner. This is followed by a presentation of the mathematical principles relating to the loss mechanisms that occur during the operation of a mobile machine. Particular attention is paid to the influence of different physical properties between mineral oils and synthetic esters. This is followed by validation of the mathematical assumptions using experimental data from a test excavator. The system is divided into different boundaries. Furthermore, the total losses during a dig and dump cycle of the machine, operating with different hydraulic fluids, are presented. Finally, a summary is provided in which the question should be answered: Which losses in the system are responsible for the different energy requirements associated with the use of different fluids in a mobile working machine?

2. FLUID PROPERTIES

The use of alternative lubricants results in variations in physical properties, which affect their operating behaviour when used in components and machines. Compared to conventional hydraulic fluids based on mineral oils, it is primarily the chemical structure of the base fluids that is responsible for differences in physical properties such as viscosity behaviour or density. Additives for hydraulic applications are used in nearly all base oil groups, featuring similar chemical components. These correlations can only be used qualitatively in the development of lubricants in the form of predictions and cannot be applied in a targeted manner by now.

The hydraulic fluids considered for the experimental investigations in this work differ fundamentally in their base fluid structure. This chapter examines the chemical structure of various base oils and explains the resulting physical properties.

2.1. Rheology and chemical structure

Viscosity generally describes the thickness of a fluid. It is used as a measure of a liquid's internal friction. This internal friction arises between the molecules of a flowing medium [9]. Physically, viscosity can be derived using the relationships shown in **Figure 2.1**. A fluid element located between a wall and a plate parallel to it is displaced by a force F applied on the plate. This creates a velocity gradient $d\dot{x}$ to the fluid between the moving plate and the stationary wall. The resulting shear stress τ depends on the area A of the moving plate.

The dynamic viscosity η is defined for Newtonian fluids as the proportionality constant between the shear rate $\dot{\gamma}$ and the shear stress τ acting on the fluid.

Figure 2.1 b) shows the atomic relationships for the graphical representation of the viscosity of lubricants in general. Molecular chains of hydrocarbons slide over each other due to an initiating force. The positively charged nuclei of the molecules repel each other due to their identical charge. For molecules to move from a given location to a vacant space, they must overcome a potential barrier. This requires activation energy. The potential barrier described defines the viscosity of the fluid. Additionally, mechanical resistance is caused by the branching of molecular chains and by branching structures within the chains. [10]

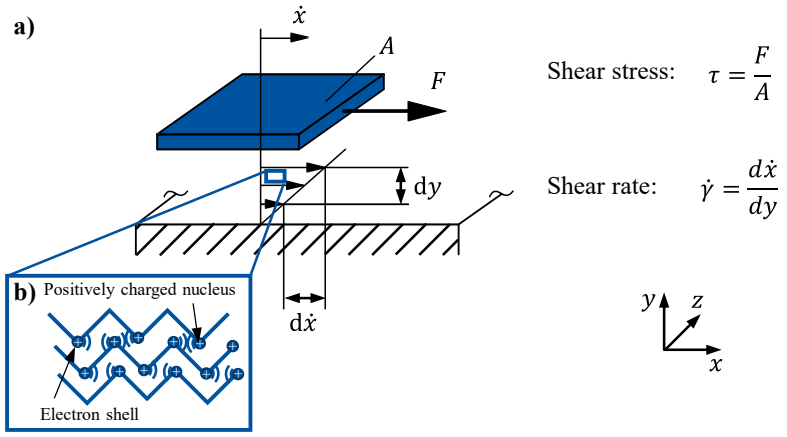

Figure 2.1. (a) Derivation of dynamic viscosity and (b) Intermolecular interactions between hydrocarbon chains in lubricants to illustrate viscosity at the atomic level

The base oils of the hydraulic fluids considered in this paper differ in their chemical structure. The differences in structure between mineral oils and esters primarily lie in the extent of branching and side chains. The chain length of the hydrocarbon chains, on the other hand, is similar for both types. Esters usually have long linear aliphatic molecular chains, whereas mineral oils have inflexible structural elements in the form of side chains. This difference in chemical structure influences the viscosity behavior of hydraulic fluids depending on temperature and pressure. Furthermore, this means that the carbon chains in ester oils are located nearer to each other, resulting in a higher packing capacity and thus a

higher density of ester oils compared to mineral oils. These relationships will be examined in more detail in the following chapters.

2.2. Temperature-viscosity behaviour

The viscosity of hydraulic fluids is highly dependent on temperature. As the temperature rises, the viscosity of the fluid decreases. At the microscopic level, this behavior can be explained as follows: Temperature affects the vibration and changing speeds of the atoms and molecules in the lubricant. The resulting vibration-energy reduces the activation energy required to overcome the potential barrier (see Figure 2.1). Corresponding mathematical descriptions of this behavior take the form of the Arrhenius equation [10]. Viscosity-temperature behavior depends on the chemical structure of the base fluid. Flexible, long linear molecular chains, such as esters, exhibit the lowest temperature dependence of viscosity. Inflexible structural elements, such as branches or sidechains, like in mineral oils, increase the dependence of viscosity on temperature accordingly [11]. Branching causes the hydrocarbon chains to separate further apart spatially, thereby reducing their influence compared to closely linked chains. The degree of dependence of viscosity on temperature is described using the viscosity index. As the viscosity index (VI) increases, the dependence of viscosity on temperature decreases. The calculation basis for determining the VI is described in DIN ISO 2909 [12]. While the VI of mineral oils is typically around 100, ester-based oils achieve values exceeding 180 [13].

2.3. Pressure-viscosity behaviour

The pressure-viscosity behavior is a fluid-specific characteristic that depends mainly on the composition of the base fluid. The addition of additives has a negligible influence. The pressure-viscosity behavior generally increases with the degree of branching, the number of cyclic structures, the presence of aromatic compounds, and the length of the side chains of the base oil (see **Fehler! Verweisquelle konnte nicht gefunden werden.**). Both naphthenic and paraffinic-based mineral oils have pronounced branched chain structures. These structures intertwine under increasing pressure, which in turn increases the internal friction within the fluid. Ester molecules have a significantly flatter structure with few side structures. This results in a lower pressure dependence on the viscosity. [14]

There are several approaches to calculating viscosity-pressure behavior. The first and still current approach is that, according to Barus (Eq. 2.1) [15]. Here, the dynamic viscosity η_0 at a specific pair of values for temperature and atmospheric pressure is the initial value. For a pressure p, the pressure-dependent dynamic viscosity $\eta(p)$ is determined. α_η is the pressure-viscosity coefficient, which is determined experimentally. The pressure-viscosity coefficient depends on the fluid and as described above, is largely determined by the chemical structure of the base oil. The coefficient for ester-based oils is therefore lower than for naphthenic mineral oils.

$$A_0 = \frac{\mu_0 \omega I_0}{4\pi} = 10^{-7} \omega I_0 \eta_0 \cdot e^{(\alpha_\eta \cdot p)} \quad (2.1)$$

Due to the exponential relationship, the pressure-viscosity coefficient (pV-Coefficient) and, thus, the use of different base oils have a significant influence on the viscosity of the lubricant in highly loaded tribological contacts. Studies in [16] show that the influence of the pressure-viscosity behavior is decisive for the formation of a load-bearing lubricating film and is only influenced to a small extent by the temperature-viscosity behavior.

2.4. Fluids investigated

The hydraulic fluids used in this study are a naphthenic mineral oil (HLP 46) and a synthetic ester (HEES 46) with a minimum content of 25 % renewable raw materials. It is a biobased lubricant in accordance with DIN 16807 [17]. Both fluids are commercially available hydraulic fluids containing additives. Table **2.1** shows the most important physical properties of the hydraulic fluids considered in this paper.

Table 2.1. Physical properties of the investigated hydraulic fluids

Fluid	Viscosity index	Density (15 °C) [kg/m³]	Spec. heat capacity [kJ/(kg·K)]	Therm. conductivity [W/(m·K)]	pV-coefficient [10^{-3}bar^{-1}]
HLP 46	113	858	2.0	0.135	2.0
HEES 46	184	944	2.3	0.14	1.5

3. MATHEMATICAL FUNDAMENTALS OF LOSS MECHANISMS IN HYDRAULIC SYSTEMS

This section presents a mathematical analysis of various common hydraulic components in terms of their losses resulting from fluid properties, which are eventually utilized for the examination of the experimental investigations.

3.1. Flow Friction

The hydrostatic and hydrodynamic pressure drops of the pipe and the orifice, as well as the tribological contacts in a pump, are investigated. Regarding the pipe, an advanced description of the relationship between laminar volumetric flow rate and pressure drop is provided by computing both steady-state and transient relations. The steady relation is determined by the Hagen-Poiseuille law:

$$\mathrm{A}_0 = \frac{\mu_0 \omega \mathrm{I}_0}{4\pi} = 10^{-7} \omega \mathrm{I}_0 \frac{\boldsymbol{\pi R^4}}{\boldsymbol{8\eta L}} \boldsymbol{\Delta p} = \frac{\boldsymbol{\Delta p}}{\boldsymbol{R_H}}, \qquad (3.1)$$

with the dynamic viscosity η, the pipe radius R, the pipe length L, and the hydraulic resistance R_H. The transient phenomena can be determined by incorporating the frequency-dependent wall shear stress as a convolutional integral:

$$\mathrm{A}_0 = \frac{\mu_0 \omega \mathrm{I}_0}{4\pi} = 10^{-7} \omega \mathrm{I}_0 \int_0^{t_n} W(\tau) \frac{\Delta p(t_n - \tau_n)}{R_H} d\tau_n, \qquad (3.2)$$

with $W(\tau)$ being a weight function in the form of $\sum_0^k m_k e^{-n_k t_n}$, $m_k \in [5.53, 1.05, 0.427, 0.23, 0.143]$, $n_k \in [5.78, 30.74, 74.9, 139, 222]$, the normalized time $t_n = \frac{v}{R^2} t$ with the kinematic viscosity v and the time t and the normalized integral dummy variable τ_n [18]. Extending this mathematical formula to consider fluid compressibility would introduce the dissipation number $D_n = \frac{vL}{R^2 a}$, which describes the relation of the time span of the axial propagation of pressure waves to the radial diffusion of axial momentum [19]. Regarding these compressibility phenomena, the effect on hydraulic loss is minor compared to the incompressible effects and is therefore not further examined. Investigating these equations reveals that the steady volumetric flow rate is inversely proportional to η, thus resulting in a decreased pressure drop for a lower dynamic viscosity while maintaining a constant flow rate. This translates to a lower hydraulic loss, which is determined by the

product of pressure and flow rate. Investigating the Reynolds number Re = $\frac{\rho Q D}{\eta A}$, with the pipe diameter D and the pipe area A, which relates inertial and viscous forces, reveals that Re increases for a lower viscosity, thus resulting in a flow that is more dominated by inertial forces than viscous forces. Until the tipping point of Re < 2300, the pipe flow remains laminar; however, for higher Re due to a further decrease of the viscosity, the flow reaches the non-laminar regime, which is characterized by eddies, vortices, and flow instabilities and results in a higher hydraulic loss, specifically a square-root dependency of the pressure with regard to the flow rate. Regarding the transient flow rate, the normalized time t_n increases with a higher kinematic viscosity, which results in a faster steady state and thus a higher value for the hydraulic loss for a given dynamic flow rate.

3.2. Orifice Losses

Another commonly installed component in hydraulic systems is the orifice, which determines the following pressure-volumetric flow rate relation:

$$\mathrm{A_0} = \frac{\mu_0 \omega \mathrm{I_0}}{4\pi} = 10^{-7} \omega \mathrm{I_0} \boldsymbol{\Delta p} = \boldsymbol{L}\frac{\boldsymbol{dQ}}{\boldsymbol{dt}} + \frac{\boldsymbol{\rho}}{\boldsymbol{2\alpha_D^2 A^2}} \boldsymbol{|Q|Q}, \qquad (3.3)$$

with the hydraulic inertance $L = \frac{l_{eq}\rho}{A^2}$ and the discharge coefficient α_D [20]. The hydraulic inertance accounts for fluid inertia and thus incorporates dynamic phenomena occurring in orifice flows. The second term of the equation represents the stationary flow rate.

In the case of dig and dump, a defined trajectory of the excavator bucket is followed. To do this, the piston length of the cylinders is controlled. To provide the required volume flow $Q(t)$, a pressure difference Δp at the orifice is necessary. For a defined movement this pressure difference is called Δp_{ref}. By changing the fluid properties of the used oil, the pressure difference must be adjusted to achieve an identical cylinder movement. According to Eq. 3.4, the adjusted pressure Δp_i, only depends on the oil's density ρ_i when the transient term is neglected.

$$\mathrm{A_0} = \frac{\mu_0 \omega \mathrm{I_0}}{4\pi} = 10^{-7} \omega \mathrm{I_0} \frac{\boldsymbol{\Delta p_i}}{\boldsymbol{\Delta p_{ref}}} = \frac{\boldsymbol{\rho_i}}{\boldsymbol{\rho_{ref}}}, \qquad (3.4)$$

While the volume flow $Q(t)$ remains constant for a defined cylinder movement, the pressure difference Δp required to perform this movement increases with higher density. Consequently, the energy $E_{p\to A,B\to T}$ required also increases.

$$\mathrm{A_0} = \frac{\mu_0 \omega \mathrm{I_0}}{4\pi} = 10^{-7} \omega \mathrm{I_0} \boldsymbol{E_{p\to A,B\to T}} = \int_0^{\boldsymbol{t_n}} \boldsymbol{Q(t)} \cdot \underbrace{\boldsymbol{\Delta p_{ref}} \frac{\boldsymbol{\rho_i}}{\boldsymbol{\rho_{ref}}}}_{\boldsymbol{\Delta p}} \boldsymbol{dt}, \qquad (3.5)$$

In addition to the losses described above, there is also leakage on the tank side of the valve, which must be considered within the efficiency calculation. By rearranging equation 3.3 to $Q(t)$, the classic orifice equation from Eq. 3.5 is obtained. Eq. 3.4 establishes a relationship between the pressure p_i and p_{ref}. The resulting equation corresponds to the reference state and thus, under the given assumptions, the leakage volume flow is independent of the density of the fluid (Eq. 3.5).

$$\mathrm{A_0} = \frac{\mu_0 \omega \mathrm{I_0}}{4\pi} = 10^{-7} \omega \mathrm{I_0} \boldsymbol{Q} = \boldsymbol{\alpha} \cdot \boldsymbol{A}\sqrt{\frac{\boldsymbol{2\Delta p_i}}{\boldsymbol{\rho_i}}} = \boldsymbol{\alpha} \cdot \boldsymbol{A}\sqrt{\frac{\boldsymbol{2\Delta p_{ref}}\frac{\boldsymbol{\rho_i}}{\boldsymbol{\rho_{ref}}}}{\boldsymbol{\rho_i}}} = \boldsymbol{\alpha} \cdot \boldsymbol{A}\sqrt{\frac{\boldsymbol{2\Delta p_{ref}}}{\boldsymbol{\rho_{ref}}}}, \quad (3.6)$$

Finally, the power losses due to leakage can then be calculated using equation (3.7).

$$A_0 = \frac{\mu_0 \omega I_0}{4\pi} = 10^{-7} \omega I_0 \boldsymbol{E_{p \to T}} = \int_0^{t_n} \boldsymbol{Q_{leak}(t)} \cdot \Delta \boldsymbol{p_{ref}} \frac{\boldsymbol{\rho_i}}{\boldsymbol{\rho_{ref}}} \boldsymbol{dt}, \quad (3.7)$$

The power loss due to leakage increases similarly to the losses due to cylinder movement as the density of the oil increases, even though the actual leakage volume flow remains constant for a defined movement on the cylinder. The losses are therefore attributable to the higher pressure required for oils with higher density.

3.3. Hydraulic Pump (Tribological Contact)

Further losses occur in the tribological contacts of the pump (piston/bushing, slipper/swash plate, cylinder block/valve plate). In axial piston pumps, the greatest losses can be attributed to friction and leakage between the slipper and swash plate. For this reason, the relevant parameter influencing this tribological system should be examined more closely under simplified assumptions. Especially, the influence of pressure- and temperature-dependent viscosity behavior, which differs significantly for mineral oils and class 4 oils, on quantities like the average gap heights $\bar{h}$ shall be addressed. To do this, the contact between the slipper and swash plate should be considered in simplified form, as shown in **Figure 3.1**.

The pressure force F_p acting on the slide shoe is compensated hydrostatically by the inner bore and hydrodynamically by the inclination that occurs during operation. Friction losses in the contact made up of hydrodynamic friction and solid body friction. For small to average gap heights $\bar{h}$, the proportion of solid friction increases disproportionately, which also increases the total friction in contact.

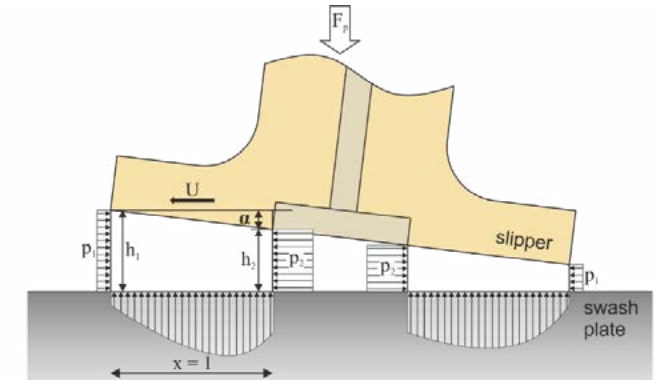

Figure 3.1. Schematic sketch of the slipper/swash plate contact

To estimate the qualitative influence of dynamic viscosity η on the average gap height $\bar{h}$, the Reynolds equation from Eq. 3.8 is used. The Reynolds equation describes the pressure distribution in small gaps for laminar flows and consists of the Couette term, the Poiseuille term, and a time-dependent term for pressure build-up. The relative movement U of the gap surfaces leads to a flow that is summarized in the Couette term. The flow driven by the pressure gradient $\partial p/\partial x$ is referred to as the Poiseuille term. Transient effects are represented in the unsteady case by the pressure build-up term.

$$\underbrace{\frac{\boldsymbol{U}}{\boldsymbol{2}} \frac{\boldsymbol{\partial}}{\boldsymbol{\partial x}} (\boldsymbol{\rho h})}_{\boldsymbol{Couette\ flow}} - \underbrace{\frac{\boldsymbol{1}}{\boldsymbol{12\eta}} \frac{\boldsymbol{\partial}}{\boldsymbol{\partial x}} \left(\boldsymbol{\rho h^3} \frac{\boldsymbol{\partial p}}{\boldsymbol{\partial x}} \right)}_{\boldsymbol{Poiseuille\ flow}} + \underbrace{\frac{\boldsymbol{\partial}}{\boldsymbol{\partial t}} (\boldsymbol{\rho h})}_{\boldsymbol{pressure\ build-up}} = \boldsymbol{0}, \quad (3.8)$$

The Reynolds equation can be solved analytically for the boundary conditions shown in **Figure 3.1** (p_1, p_2, h_1, h_2, U), assuming a constant inclination α and for the 1-dimensional steady-state case (Eq. 3.9).

$$\boldsymbol{p(x) = -\frac{6\eta U}{\alpha}\frac{1}{h(x)} - \frac{C_1}{2\alpha}\frac{1}{h(x)^2} + C_2}, \quad (3.9)$$

$$\boldsymbol{C_1 = \frac{12\eta U h_1 h_2 + 2(p_1 + p_2){h_1}^2{h_2}^2}{\alpha(h_1 + h_2)}}$$

$$\boldsymbol{C_2 = p_1 + \frac{6\eta U}{\alpha h_1} + \frac{C_1}{\alpha {h_1}^2}}$$

By integrating $p(x)$ with respect to x, a length-related force F_z is calculated, which depends on the average gap height $\bar{h}$, neglecting third order α terms $O(\alpha^3)$.

$$\boldsymbol{F_z = \int_0^1 p(x)\,dx} = \underbrace{\boldsymbol{\frac{p_1+p_1}{2} + \frac{\alpha}{4\bar{h}}(p_1 + p_1)}}_{\boldsymbol{Poiseuille\ fraction}} \underbrace{\boldsymbol{-\frac{\eta U \alpha}{2\bar{h}^3} + O(\alpha^3)}}_{\boldsymbol{Couette\ fraction}}, \quad (3.10)$$

The dynamic viscosity η is in the numerator of the Coutte fraction of the length-related force. If the viscosity decreases, this leads to a reduction in the force exerted on the slipper by the pressure field $p(x)$. To maintain a stable balance between the pressure field and F_p, the average gap height $\bar{h}$ decreases until a new equilibrium is reached. A reduction in the average gap height $\bar{h}$ simultaneously increases the proportion of solid contact and thus the friction between slipper and swash plate.

4. Experimental Investigation of the Loss Mechanisms During the Operation of a Mobile Working Machine

The experimental investigations were carried out on a test excavator. The crawler excavator belongs to the class of compact excavators, and it is driven by tracks. The hydraulic system of the test excavator is a closed-centre system with a downstream pressure compensator and a circulation valve in the form of a pressure relief valve. The displacement volume of the axial piston pump is controlled by a two-point controller, which swings back from full displacement to a minimum swing angle when a pressure of approx. 130 bar is reached. In addition to linear actuators, which are required for digging, there also are actuators for further operations which are not regarded in the investigations. The test excavator is controlled by electro-hydraulic pilot valves instead of the usually implemented hydraulic joysticks. Therefore, an automatic digging process can be performed by the control of the cylinder lengths over the cycle time to achieve identical output energy when using different fluids. For the investigations made a 90° dig and dump cycle (dig/swing/unload/swing) is performed. The excavated material is simulated due to a weight in the shovel of 25 kg. In **Figure 4.1** the bucket tip position is shown during the cycle for the two fluids investigated.

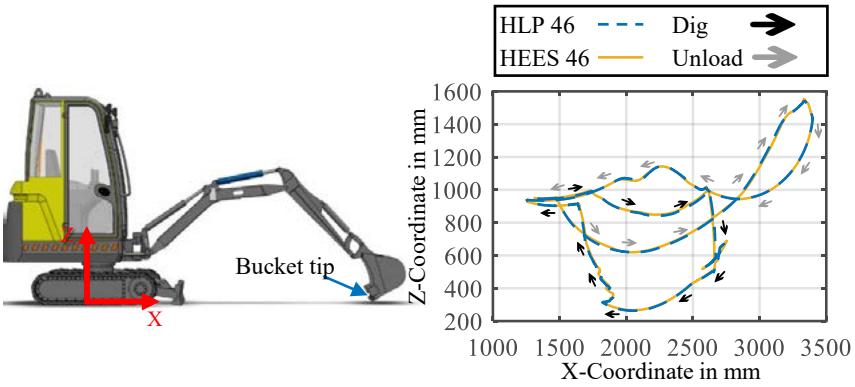

Figure 4.1. Position of the bucket tip during the dig and dump cycle at 40 °C tank temperature

The test operation is performed at three different tank temperature levels (25 °C, 40 °C and 50 °C). The allocation and assessment of losses is based on the mathematical principles set out in Chapter 3. To classify the losses, **Table 4.1** shows the dynamic viscosity of the hydraulic fluids investigated at the temperatures considered.

Table 4.1. Dynamic viscosity at investigated temperature stages

Hydraulic fluid	Dyn. Viscosity [mPas] (25 °C)	Dyn. Viscosity [mPas] (40 °C)	Dyn. Viscosity [mPas] (50 °C)
HLP 46	86.7	39.9	26.2
HEES 46	71.7	38.4	26.3

4.1. Flow Friction losses E_{Flow}

The flow friction losses $\boldsymbol{E_{Flow}}$ during the Dig and Dump cycle are calculated by integrating the power loss over cycle time t. The power loss caused by flow friction is determined by multiplying the pressure losses of a pipe section Δp by the volume flow Q_{Pump} (Eq.4.1).

Figure 4.2 shows the flow friction losses $\boldsymbol{E_{Flow}}$ of the hydraulic fluids considered at the three different temperature levels and the share of the losses on the total input energy. Both fluids investigated fit into the viscosity class of ISO VG 46 [21]. Due to the fact that the standard allows a deviation of ±10 % from the average kinematic viscosity (46 mm²/s), the kinematic viscosity of the same class can differ up to 20 %. This is the case with the examined: the HEES 46 has a viscosity of 41.4 mm²/s at 40 °C and the HLP 46 has a viscosity of 47.3 mm²/s. This means that the deviation in kinematic viscosity is approximately 12 %. This results in an intersection point of the dynamic viscosity of the two hydraulic oils at a temperature of 49 °C (Table **4.1**). Below this temperature, the dynamic viscosity of HEES 46 is lower than that of HLP 46. Due to the higher viscosity index, it lies above HLP 46 at higher temperature after the intersection point. The flow losses caused by friction are proportional to the dynamic viscosity according to Eq. 3.1.

$$E_{Flow} = \int_0^{t=end} Q_{Pump}(t) \cdot \Delta p \, dt, \qquad (4.1)$$

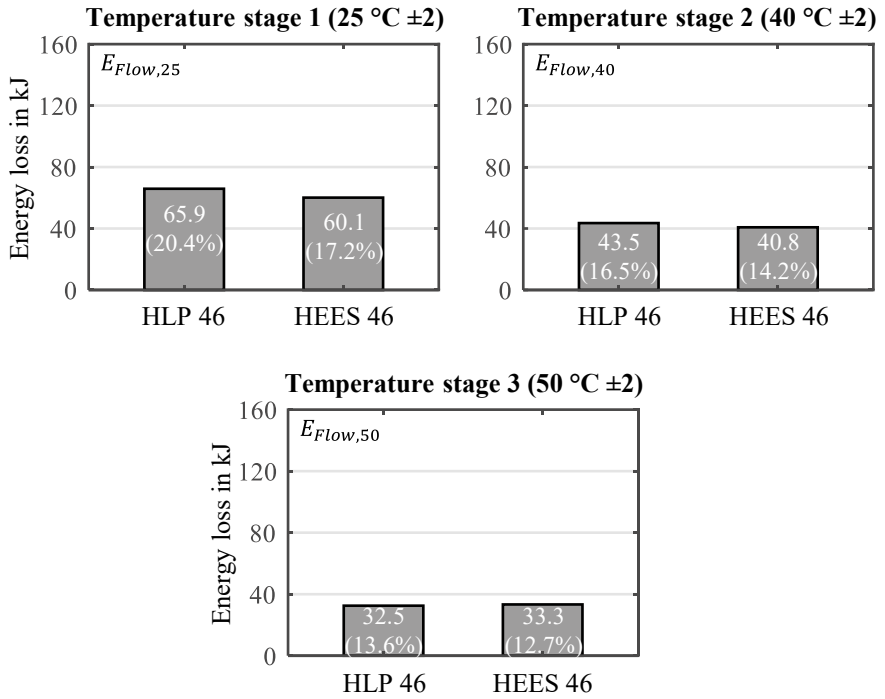

Figure 4.2. Flow friction energy losses $\boldsymbol{E_{Flow}}$ and their share on the input energy during dig and dump cycle dependent on tank temperature

4.2. Pump losses E_{Pump}

The hydraulic pump (axial piston pump) converts the incoming mechanical energy into hydraulic energy. This results in hydraulic-mechanical and volumetric losses. The total energy loss $\boldsymbol{E_{Pump}}$ is calculated from the difference between the measured mechanical input energy $\boldsymbol{E_{In}}$ measured at the drive shaft of the pump and the hydraulic output energy $\boldsymbol{E_{Out}}$ of the pump. The hydraulic output energy is calculated by integrating the product of the measured variables pressure at pump outlet $\boldsymbol{p_{Pump}}$and volume flow $\boldsymbol{Q_{Pump}}$ over cycle time $\boldsymbol{t}$ (**Eq. 4.2**).

$$E_{Pump} = E_{In} - E_{Out} = E_{In} - \int_0^{t=end} Q_{Pump}(t) \cdot p_{Pump}(t)\, dt, \qquad (4.2)$$

The comparison of the energy losses caused by the pump when using the two different hydraulic fluids at the different temperatures is shown in **Figure 4.3**. The pump losses are inversely proportional to the overall efficiency of the hydraulic pump. As the temperature rises, energy losses generally decrease. Except for HLP 46 between temperature stage 2 and 3. It can be assumed that the minimum proposed viscosity of the pump is reached at temperature stage 3. Due to the higher viscosity index of HEES 46 the behaviour of the energy losses is different. The overall efficiency is composed of the volumetric and hydraulic-mechanical efficiency. Volumetric losses are largely dependent on the dynamic viscosity of the fluid (Eq. 3.1). At higher dynamic viscosity, losses are minimized accordingly. Hydraulic mechanical efficiency, on the other hand, describes losses due to friction in the pump. Since the density of HEES 46 is higher than that of HLP 46, it can be assumed that the volumetric losses are higher. Since the total pump losses are higher when

using HEES 46, it can be expected that the hydraulic-mechanical losses and thus the friction losses are significantly higher. This assumption was confirmed in preliminary investigations and was attributed to the pressure-viscosity behaviour [5]. The influence of friction behavior in tribological contacts of pumps is described in detail in Chapter 3.3.

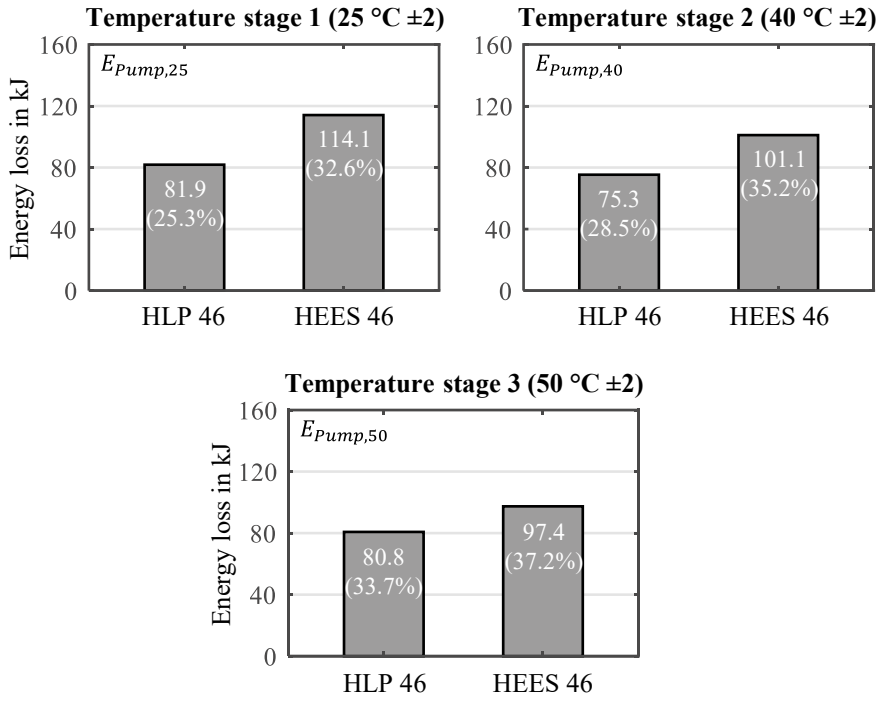

Figure 4.3. Energy losses caused by the pump $\boldsymbol{E_{Pump}}$ and their share on the input energy during dig and dump cycle dependent on tank temperature

4.3. System losses E_{Sys}

System losses $\boldsymbol{E_{Sys}}$ depend on the functionality and architecture of the hydraulic system. The excavator system under consideration is a closed-center system with a downstream pressure balance. The excess volume flow that is not used to fulfil the movement of the actuators is throttled back to the tank via a circulation valve. For this purpose, the volume flow requested by the activated consumer $\boldsymbol{Q_{Act}}$ is subtracted from the total volume flow provided by the pump $\boldsymbol{Q_{Pump}}$ and multiplied by the pump pressure $\boldsymbol{p_{Pump}}$. To calculate the energy loss $\boldsymbol{E_{Sys}}$, the measured values are integrated over the cycle time $\boldsymbol{t}$ (**Eq. 4.3**).

$$E_{Sys} = \int_0^{t=end} p_{Pump}(t) \cdot \left(Q_{Pump}(t) - \sum_{i=1}^{n} Q_{Act,i}(t)\right)\, dt, \quad (4.3)$$

When looking at the results of the system losses during the dig and dump cycle (**Figure 4.4**), only minor differences can be identified. The losses are almost identical, especially for the first two temperature levels (0.9%/0.38%). At the third temperature level, the difference is higher (4.8%).

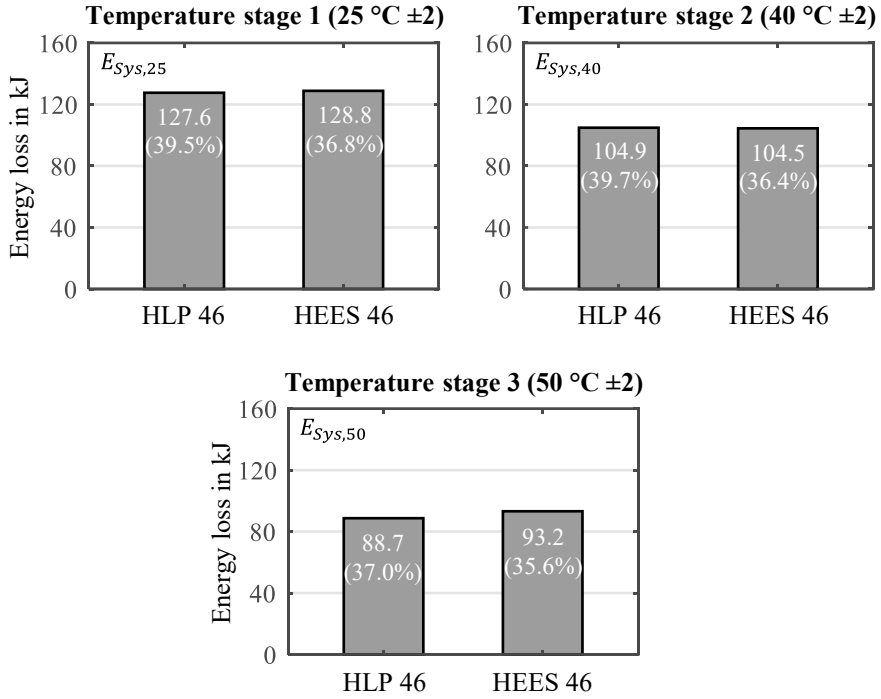

Figure 4.4. Energy losses caused by the system $\boldsymbol{E_{Sys}}$ and their share on the input energy during dig and dump cycle dependent on tank temperature

4.4. Valve losses E_{MCV}

When fluid passes through valves, several types of losses occur in varying magnitudes. The flow resistance depends on the type of closing element and the channel configuration. Furthermore, the geometric conditions depend on the opening position of the closing element. In case of the investigated excavator the valve sections for cylinders and swivel motor consist of spool valves combined into a main control valve. In spool valves, orifice losses and, to a lesser extent, throttling losses occur predominantly. The flow resistance of a valve is determined by the orifice area and the flow velocity. **Eq. 4.4** is used to determine the energy losses caused by the flow through the valves during the dig and dump cycle. This involves integrating the valve-related hydraulic power loss over cycle time $\boldsymbol{t}$. The power loss is determined by multiplying the pressure loss between the excavator´s pressure line near the pump $\boldsymbol{p_{Pump}}$ and the pressure right after the respective valve $\boldsymbol{p_{Act,MCV}}$ with the corresponding volume flow requested by the respective actuator $\boldsymbol{Q_{Act}}$. Losses in the valve due to leakage are not taken into account in this calculation.

$$E_{MCV} = \int_0^{t=end} \left(p_{Pump}(t) - p_{Act,MCV,i}(t)\right) \cdot Q_{Act,i}(t)\ dt, \quad (4.4)$$

Figure 4.5 shows the energy losses during the dig and dump cycle by operation with the different oils. The losses generated by the flow paths of the Main Control Valve (MCV) $\boldsymbol{E_{MCV}}$ generally show smaller differences between the various hydraulic fluids than the types of losses described before. This can be explained by the fact that the losses occurring at the valve can mainly be described as orifice-type resistance. This means that the losses are

largely independent of viscosity (see Eq. 3.3). Minor differences can be explained by the different densities of the fluids and sections with throttle losses of the inlet and outlet pipeline of the valves. Furthermore, the cross-section area can differ by using different fluids, while the cylinder lengths are regulated.

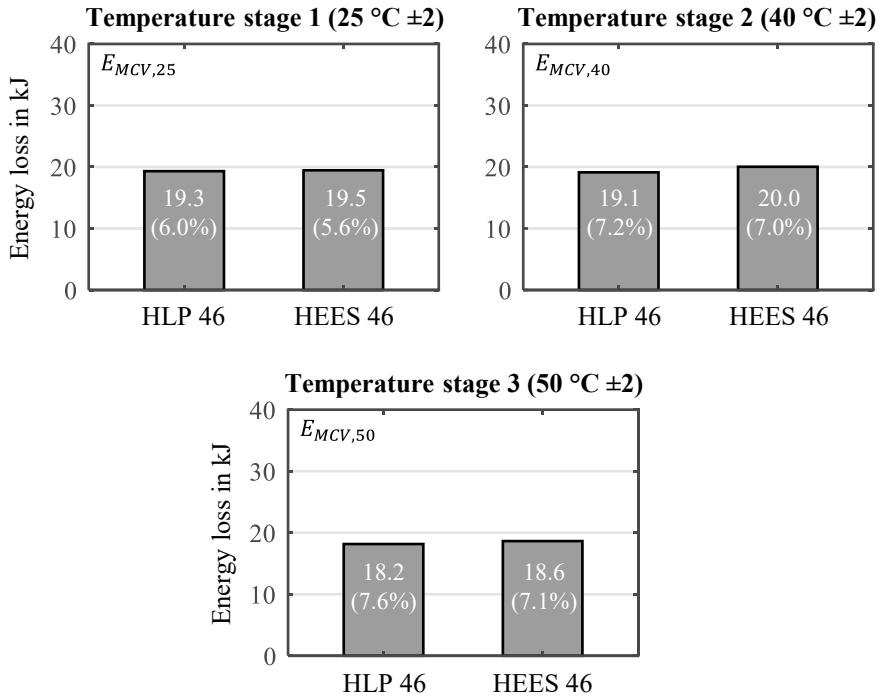

Figure 4.5. Energy losses caused by the main control valve $\boldsymbol{E_{MCV}}$ and their share on the input energy during dig and dump cycle dependent on tank temperature

5. DISCUSSION AND CONCLUSION

The individual losses described in previous chapters of course have an impact on the overall efficiency of the machine. **Figure 5.1** shows the energy requirement for the two hydraulic fluids over the tank temperature for the dig and dump cycle. The measured mechanical input energy E_{In} was integrated over the cycle time t. The highest measured energy requirement by the use the two fluids, which occurs at HEES 46 and 25 °C, serves as a reference. The losses when using HEES 46 are higher at all temperature stages than when performing the cycle with HLP 46. When considering the individual losses (Chapter 3), the higher losses caused by the hydraulic pump are mainly responsible for this. The further losses show only minor differences between the two hydraulic fluids investigated.

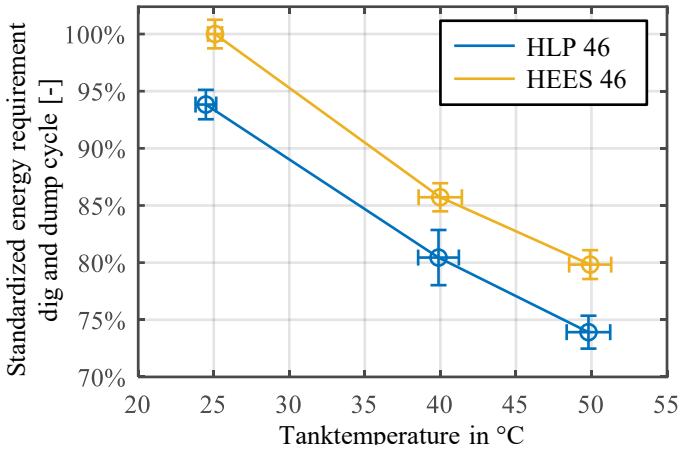

Figure 5.1. Standardized energy requirement on the highest measured energy consumption (HEES 46/25 °C) during dig and dump cycle

Since HLP 46 is one of the most used hydraulic fluids in the market, it was assumed that pump efficiency would be higher when using the mineral oil based fluid instead of HEES 46. In fact, the pumps and their tribological contacts were optimised based on the chemical and physical characteristics of HLP 46. In order to achieve comparable efficiencies with HEES 46, the geometry of the components needs to be adjusted by minimising the contact pressure. This can be achieved, for example, by increasing the hydrostatic relief in highly stressed tribological contacts. Furthermore, the research on ecological compatible additives for biobased lubricants, like extreme pressure (EP-) additives offer a high potential for further improvements of bio lubricants performance. These aspects offer further research potential for optimising both the resource efficiency and the ecological compatibility of hydraulic systems due to the use of biobased hydraulic fluids.

Advanced Hydraulic Fluids Make Mobile Machinery Not Only More Sustainable, but Also More Economical

Dmitriy Shakhvorostov, Michal Alibert, Thorsten Bartels, Rhishikesh Gokhale, Andreas Hees

Evonik Operations GmbH, Oil Additives, Presenting author: dmitriy.shakhvorostov@evonik.com

Abstract.

Europe is pursuing ambitious climate goals: by 2030, net greenhouse gas emissions are to be significantly reduced—by 65% in Germany compared to 1990. Globally, the pressure to cut emissions and promote sustainable technologies is also increasing. Mobile machinery such as excavators, wheel loaders, and other hydraulically operated equipment is coming into sharper focus, as these machines play a central role in construction, agriculture, and industry.

This technical study explores how advanced hydraulic fluids can contribute to achieving these goals. By using shear-stable viscosity index improvers based on polyalkylmethacrylates, fluids can be formulated to maintain high efficiency across a wide temperature range. This not only leads to energy savings of up to 20%, but also to a measurable reduction in CO_2 emissions.

In addition to the environmental impact, the economic perspective is also examined: despite higher initial costs, these fluids offer a positive long-term return on investment—through reduced energy consumption, extended component life, and lower maintenance costs.

The study is based on Evonik's many years of experience in developing and testing such high-performance fluids. Using technical data and case studies, it demonstrates how modern fluid technology can contribute to the sustainable transformation of mobile hydraulics.

1. INTRODUCTION

All Open Access articles are peer-reviewed, distributed under the Creative Commons Attribution-Non Commercial 4.0 International

In mobile hydraulic machinery, the total cost of ownership has become one of the most critical competitive factors. For machine owners and operators, fuel or energy costs and maintenance requirements play a decisive role in daily operations.

Rising fuel prices, stricter emissions requirements, and uncertainties in the supply of energy and raw materials have intensified the pressure to reduce energy losses in hydraulic systems. As a result, hydraulic efficiency and fluid performance are no longer secondary topics — they directly determine operating cost, machine uptime, and competitive positioning in the mobile equipment market.

At the same time, mobile machinery contributes significantly to global energy consumption and CO_2 emissions. Even incremental improvements in hydraulic efficiency, fluid formulation, and component durability can therefore offer substantial potential for reducing operating costs and environmental impact across large fleets.

The reasons for this are high fuel and energy cost and uncertainties in the supply of energy [1, 2] and raw materials (Figure 1.1).

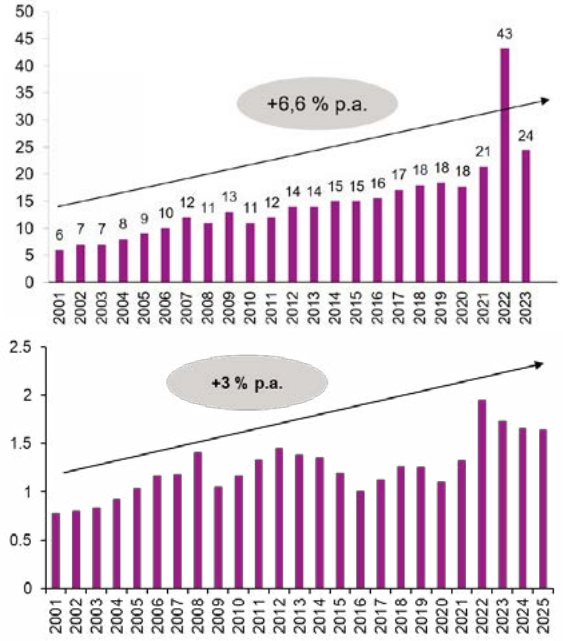

Figure 1.1. Electric energy price in €cent/kWh over time in the 21st century [3,4] and diesel retail price in €/l [5] in Germany.

Efficiency improvement potentials have been repeatedly demonstrated in the mobile machinery and industrial sector [6,7]. However, the implementation of energy efficiency measures is often slow, and several hurdles need to be overcome. The low acceptance, despite economic advantages, is attributed to a number of obstacles, which have been

investigated by numerous studies [8]. A well-known obstacle mentioned in several surveys is the lack of resources, time, and educated staff. Additionally, the effort required for the planning and implementation of energy efficiency measures represents a further barrier.

The optimization of construction sites in terms of up time process efficiency is not only a business requirement, but also a decisive step on the way to a climate-neutral society. A bundle of measures is available, which differ significantly in terms of investment costs and complexity [8]. A simple measure to achieve both, cost and emission reduction, is to increase the energy efficiency of the hydraulic system by choosing a suitable hydraulic lubricant. This approach does not require hardware design modifications and can therefore be easily applied to existing hydraulic driven machines. Since hydraulic oils are changed regularly anyway, the associated effort is also low.

2. HYDRAULIC OILS IN MOBILE MACHINES

Hydraulic fluids are widely used in industry. Their properties result from the choice of base oils and the selection and combination of suitable additives. Viscosity has a great influence. In principle, it is possible to reduce hydromechanical losses by using low-viscosity fluids and thus (theoretically) increase the efficiency of the machine, unless volumetric losses in hydraulic systems increase too much as a result of this measure. With very low viscosities there is a risk that no sufficient lubricating film will be formed in contact points that are subject to high temperatures leading to increase of mixed friction and increase of wear. This risk is avoided by reducing the temperature dependence of the viscosity of the lubricant – i.e. increasing the viscosity index (VI) – by using suitable VI improvers and/or base oils with high VI. An additional risk of simply lowering the viscosity is to increase the chance of an external leakage in older machines at elevated temperatures where fluids with low viscosity index will have dramatically reduced viscosity.

For hydraulic applications, it has been shown that both, viscosity index and shear stability of the fluid are decisive for the level of efficiency [6,7]. Figure 2.1 demonstrates the opposing characteristics of mechanical and volumetric efficiency in hydraulic equipment [6,7]. A low viscosity reduces internal friction and has a positive effect on the mechanical. The opposite is true for volumetric efficiency, which decreases as viscosity decreases. Overall efficiency is the combination of both efficiencies.

The aim is to minimize both, the "Total Cost of Ownership" (TCO) and the “GreenHouse Gas” (GHG) emissions, two parameters that are linked via the lifetime, reliability, and efficiency of equipment.

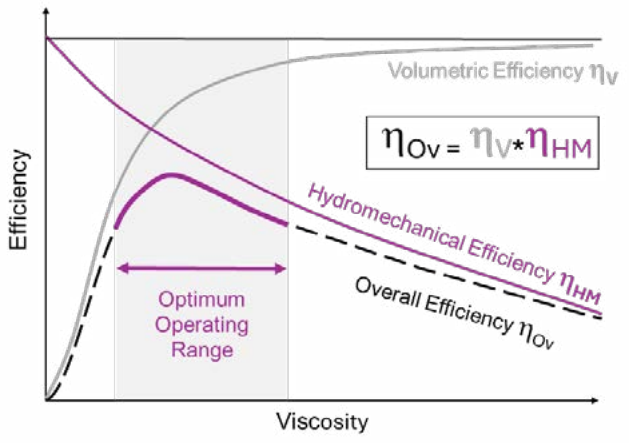

Figure 2.2. Correlation of efficiency and viscosity in a hydraulic pump [6,7]

3. VALIDATION OF FUEL AND ENERGY SAVINGS

Figure 2.1 describes a step-by-step approach to validate effects of an oil changes in hydraulic systems. An oil change can be an easy way to reduce overall cost in terms of savings on maintenance, energy consumption, and GHG emissions. The procedure to realize oil changes in mobile and stationary hydraulics was investigated and demonstrated for various systems (excavators, wheel loader, skid steer loader, tractor).

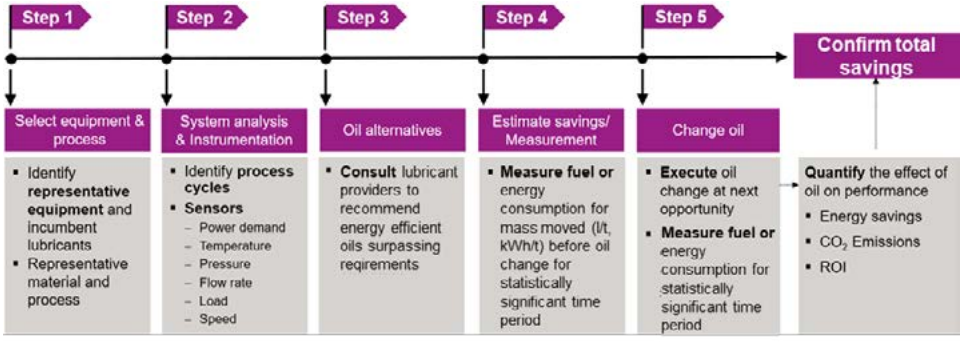

Figure 2.3. Universal step by step approach to execute oil changes and confirm fuel or energy savings.

In this article, the authors present an overview of observed effects depending on the fluid rheological properties and describe in more detail the effects of fluid in an excavator operation.

The field trial employed a medium-class hydraulic crawler excavator representative of machines in the 23–26 ton operating-weight range. According to published technical data for machines of this class, such excavators typically exhibit an operating weight between 23,400 and 26,050 kg and are powered by a diesel engine rated at approximately 129 kW (≈175 HP). The excavator used in the study incorporates a conventional hydraulic architecture consisting of three hydraulic cylinders controlling the boom, a single cylinder for the stick (arm), and an additional single cylinder for bucket articulation. Interchangeable digging buckets with nominal capacities of 0.75 t, 1.25 t, and 1.75 t were utilized to assess loading behavior and cycle efficiency under varying tool masses. This configuration is representative of typical quarry-class loading equipment.

To support the excavation cycles and evaluate downstream productivity effects, the test setup also employed a 25-ton class dump truck for material hauling and a wheeled loader for auxiliary material handling and site servicing. The integration of these machines enabled a controlled assessment of how changes in hydraulic fluid formulation influence the excavator's energy efficiency, loading dynamics, and overall productivity across a complete loading–hauling cycle.

The trial was conducted in a stone quarry environment in Gimbsheim, Germany, where conditions allowed repeatable and consistent measurement. An on-site truck scale facilitated accurate mass determinations for each truckload, enabling quantification of fill mass, bucket productivity, and cycle uniformity. The test material consisted of gravel stone with an approximate particle size of 1 inch, providing a homogeneous granular medium suitable for comparing hydraulic performance under realistic working conditions.

This instrumentation framework ensured a controlled, measurable, and representative evaluation of hydraulic system behavior in real-world quarry operations.

The experimental program consisted of seven test oils including reference fluid, each subjected to 31 operational test cycles per day, executed in three independent replicates to ensure statistical robustness. A reference oil was incorporated systematically throughout the campaign—at the beginning, midpoint, and end of each daily sequence—to monitor drift and establish baseline repeatability. Additional reference runs were scheduled immediately after the first test oil, after the machine's return to site, and at the conclusion of the final oil evaluation, providing a continuous calibration framework across the multi-day campaign. The order of oils was selected pragmatically to accommodate site logistics and thermal behavior, recognizing that operational temperatures naturally increased over the day, typically rising from 50 °C to 70 °C. Hydraulic oil temperature control was further refined by enforcing 100% cooling-fan duty via CAN-bus command, complemented by a deliberate reduction of the cold-air suction-hose cross-section, enabling tighter regulation of thermal boundary conditions during each test run.

Each oil was evaluated over a four-day operational block, followed by a dedicated operator test on day five, after which the machine underwent a one-day flushing and refilling procedure before transitioning to the next fluid. Two operators participated in the study, with both operators performing tests each day to reduce operator-specific bias. Operator sequencing was predefined and maintained consistently, applying the same order on days 1 and 3 as on days 2 and 4. For each oil, 16 test sequences per operator were executed, ensuring balanced exposure of each hydraulic fluid to varying operational styles and workloads. The 16 test sequences were distributed between moving, truck loading and digging cycles.

A stringent oil-flushing procedure was implemented between fluids to prevent cross-contamination. This process comprised four complete flushing cycles, performed with the excavator's boom and arm fully extended to maximize hydraulic-volume exchange, followed by one full refill of fresh test oil. The viscosity of the filled oil was measured at both the beginning and end of each test period to document potential degradation or shear-related viscosity loss over the operational interval. Collectively, this methodology provided a highly controlled and repeatable framework for quantifying the influence of hydraulic-fluid formulation on excavator performance, thermal stability, and cycle efficiency.

4. TESTED FLUIDS

The hydraulic fluids evaluated in this study consisted of formulations built on a standard hydraulic fluid anti-wear/oxidation inhibitor (DI) additive package, combined with base oils spanning API Group II, Group III, and Group IV quality levels. The product matrix was intentionally designed to see if the influence of base-oil quality and viscosity-index (VI) performance on hydraulic efficiency, including fluids blended with second-tier high-VI Group III stocks as well as maximum-VI formulations relying on Group IV (PAO) components can be elaborated. The set included conventional mono-grade fluids (ISO VG 46 and ISO VG 68) with moderate viscosity indices (VI 105 and VI 98, respectively), as well as a series of high-VI multigrade formulations engineered to deliver enhanced viscometric stability: VG 32 VI 189, VG 46 VI 112, VG 46 VI 155, VG 46 VI 167, and an ultra-high-VI VG 25 VI 285 fluid (see Figure 4.1). These exhibited viscosity indices ranging from 112 to 285, covering the practical performance envelope from improved cold-start viscosity control to advanced shear-stable elastomer-friendly multigrade behavior. Kinematic viscosities at 40 °C and 100 °C varied accordingly, from 26.0 to 71.2 cSt at 40 °C and 7.08 to 9.13 cSt at 100 °C, reflecting the tailored grade-dependent rheology. Shear stability, measured in a 40-minute ultra sonic test (ASTM D5621) viscosity loss, ranged from 0.45% in the mono-grade VG 68 to 15% in the ultra-high-VI VG 25, capturing differences in polymeric thickener architecture, treat rate, and mechanical shear sensitivity. Collectively, this hydraulic-fluid matrix provided a broad and controlled variation in base-oil structure, viscosity grade, and viscosity index improver properties, enabling systematic assessment of how fluid formulation influences excavator hydraulic efficiency, thermal behavior, and operational productivity.

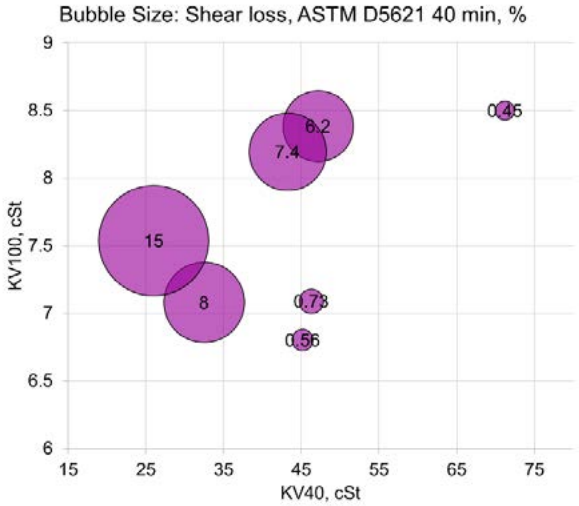

Figure 4.1. Overview of the rheological properties of seven tested fluids.

5. RESULTS

5.1. Performance Outcomes Across Viscosity Grades and Viscosity Indices

The weighted overall efficiency improvement (45% digging + 45% truck loading + 10% traveling) results (Figure 5.1) reveal a clear stratification of fluid performance driven primarily by viscosity grade (KV40) and viscosity index (VI). The reference monograde ISO VG 46 (KV40 = 45.16 cSt, VI = 105) establishes the 0% baseline. Deviations from this baseline strongly follow the expected physical mechanisms: reductions in viscosity grade paired with sufficiently high viscosity index produce substantial improvements in hydraulic efficiency, whereas increases in viscosity grade or insufficient VI lead to penalties. This is illustrated by the poorest-performing fluid, ISO VG 68 (KV40 = 71.2 cSt, VI = 98), which shows a −6.1% efficiency decrease due to elevated hydromechanical losses at higher viscosity. Conversely, the highest-performing fluids—ISO VG 22 with 285 VI and ISO VG 32 with 189 VI — demonstrate improvements of +13.6% and +10.7%, respectively, underscoring the strong advantage of pairing relatively low kinematic viscosity at 40°C with very high VI to minimize frictional losses while preserving pump leakage control at elevated temperatures.

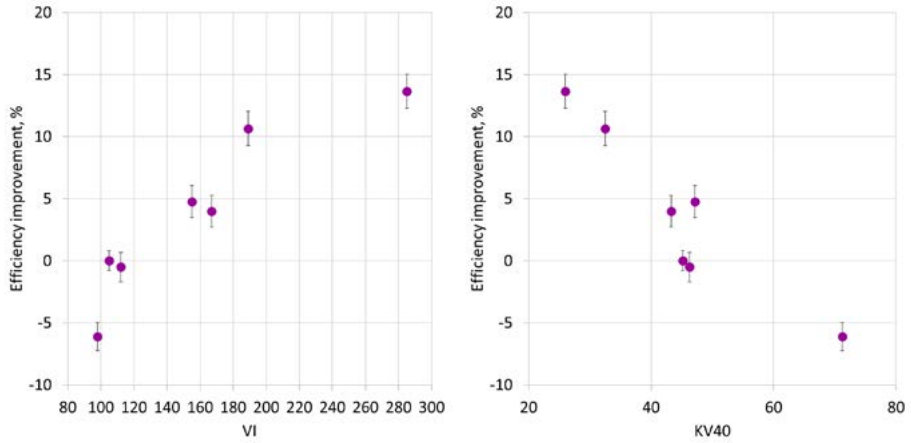

Figure 5.1. Efficiency improvement of test fluids with varying viscosity index (VI) and kinematic viscosity at 40°C (KV40) compared to the ISO VG 46 Monograde fluid in a combined cycle 45% digging + 45 % truck loading + 10 % traveling.

5.2. Influence of Viscosity Index (VI) on Efficiency

VI emerges as a decisive factor in the test results, exerting a strong positive influence on overall efficiency also when viscosity grade is held relatively constant. Among the ISO VG 46-based fluids, an increase in VI from 105-112 VI to 167 VI boosts efficiency from −0.5…0% baseline to +4.0…+5%, despite no significant differences in KV40. These results emphasize that VI governs the fluid's ability to maintain optimal viscosity as the temperature rises during operation. High-VI fluids prevent excessive thinning, thereby sustaining both lubrication, internal/external sealing effectiveness in pumps and actuators.

5.3. Effect of Viscosity Grade Reduction

The data strongly support viscosity-grade reduction—provided VI is sufficiently high. Fluids with markedly reduced KV40, such as 285 VI ISO VG22 (KV40 = 26 cSt) and 189 VI ISO VG 32 (KV40 = 32.5 cSt), consistently deliver the largest efficiency gains: +13.6% and +10.7%, respectively. These improvements are attributable to significantly lower hydrodynamic losses in pump, valve components and pipes, allowing hydraulic actuators to cycle faster and with reduced energy consumption. However, these gains only materialize because VI values are high (VI = 285 and VI = 189), preventing the fluid from becoming too thin during operation that it compromises volumetric efficiency or pump protection. In contrast, fluids with moderate KV40 but insufficient VI—such as 105…112 VI—experience efficiency losses or negligible gains due to poorer thermal viscosity retention.

5.4. Role of Shear Stability in Maintaining Volumetric Efficiency

Shear loss, measured via ultrasonic shear thinning (ASTM D5621, 40 min) for fluids, having the viscosity index improvers (VIIs) ranged from 6.2% to 15% across the fluids. This type

of shear loss correspond to the middle to high tier type of the VIIs used in hydraulic fluids. The results confirm that low to moderate shear loss supports efficient hydraulic operation by preventing excessive polymer breakdown and preserving the volumetric-efficiency advantage conferred by high VI. For example, 167 VI (shear loss = 7.4%) and 155_VI (6.2%) both maintain efficiency increases near 4–5%, however the fluid with 155 VI outperformes the fluid with 167 VI while even having slightly higher KV40, indicating that shear stability remains additional decisive factor to boost efficiency as already noted earlier [6]. The overall trend shows that lower shear loss helps sustain volumetric efficiency, in high-VI fluids where fluid temporary thinning or permanent breakdown would otherwise erode the sealing benefit.

6. IMPLICATIONS ON THE TOTAL COST OF OWNERSHIP AND AVOIDED EMISSIONS

Adopting a multigrade hydraulic fluid (ISO VG 46, VI 155) in place of a monograde ISO VG 46, VI 105 yields a measurable improvement in total cost of ownership and a material reduction in emissions over a single drain interval. Under the realistic assumption of a fleet of five machines, each consuming 26 L/h of diesel and filled with 900 L of hydraulic fluid, with a 2,500 h drain interval—the empirically observed 5% efficiency gain translates directly into lower fuel use during digging, loading, and travel. Priced at €1.60 per liter of diesel, the fleet-wide fuel saving over one interval amounts to €20,883. Against this benefit, the higher upfront cost of the multigrade—€4.50/L versus €2.00/L for the monograde—requires an additional €11,250 to fill the fleet (Δ€2.50/L × 900 L × 5 machines). Even after accounting for this premium, the upgrade produces €9,633 in net savings within the same service cycle. Typically high quality premium hydraulic fluids with high viscosity index bring an extended oil drain interval, which is not accounted for in the analysis here. Because fuel savings accrue with every operating hour, the investment reaches break-even well before the end of the interval—at roughly 1,350 operating hours per machine—after which all further savings are realized as pure financial gain. The environmental dividend is equally tangible: by avoiding the combustion of 13,050 L of diesel over the interval, the fleet prevents approximately 35 t of CO_2 emissions on a tank-to-wheel basis, contributing directly to Scope 1 reductions without any hardware changes or operational retraining. Mechanistically, these outcomes reflect the superior balance of mechanical and volumetric efficiency delivered by the higher-VI formulation: reduced viscous losses at operating temperature accelerate hydraulic cycles, while sufficient viscosity retention and controlled shear thinning preserve sealing and pump health. In practical terms, switching to ISO VG 46 VI 155 delivers a rapid-payback, low-risk pathway to lower operating costs and meaningful carbon abatement, realized entirely within a single drain interval.

7. BROADER FIELD EXPERIENCE AND GENERALIZATION OF RESULTS

The excavator study presented here represents only one example within a much broader body of long-term field evidence. Over more than 20 years of active field-trial work, Evonik has collaborated with equipment owners and OEM partners

to evaluate high-VI hydraulic fluids across a wide range of mobile machinery, operating environments, and hydraulic duty cycles. These long-duration studies—performed under real-world loading, digging, carrying, and travelling conditions—demonstrate that the qualitative efficiency- and productivity-enhancing mechanisms observed in the excavator trial are consistent, reproducible, and not machine-specific.

Across various equipment types—including skid steer loaders, compact and small-size excavators, mid-size excavators, and modern electronically controlled mid-size excavators—the introduction of high-VI, shear-stable multigrade fluids has resulted in clear operational gains. Depending on machine type and work mode, efficiency improvements have ranged from 6% up to 35%, and productivity improvements from 6% up to 25–35%. These effects have been observed under diverse hydraulic tasks: excavation, loading and carrying cycles, grading, travelling, and mixed operation. Importantly, the comparisons span a variety of baseline fluids—conventional ISO 46 HM monogrades, moderate-VI ISO 46 industrial fluids, and OEM 10W hydraulic formulations—demonstrating that the relative advantage of a higher-VI, thermally robust fluid holds regardless of the starting point.

A consistent pattern emerges from these long-term trials: fluids with higher viscosity index and carefully controlled shear stability maintain optimal viscosity under highly dynamic temperature and load conditions, thereby improving both mechanical and volumetric efficiency. This leads to faster hydraulic response, reduced pump losses, improved actuator speed, and more effective transmission of engine power into productive work. Crucially, these performance gains are achieved without any hardware modification. Machines require no changes to pumps, valves, filters, cooling systems, or control logic—operators continue to work exactly as before, while the hydraulic system benefits from the improved viscometric behaviour of the fluid alone.

Equipment type	Skid Steer Loader	Compact Excavator	Small-size Excavator	Mid-size Excavator	Modern Mid-size Excavator

* shear stable fluid
** very shear stable fluid

Improvement in Efficiency and Productivity obtained through high VI shear stable fluid and appropriate ISO grade in all trials

Figure 7.1. Generalized view on mobile equipment hydraulics field trial results at Evonik across the applications.

The combined evidence of two decades of field trials provides strong confirmation that the improved efficiency demonstrated in the excavator case study is representative of a broader principle: high-VI, shear-stable multigrade fluids enable both economically and environmentally superior operation of mobile hydraulic equipment, enhancing productivity while simultaneously reducing fuel consumption and emissions. This makes fluid-based efficiency improvement an immediately deployable, low-risk, and cost-effective lever for sustainable performance enhancement across the mobile hydraulics sector.

Abstract

The industrial hydraulics sector is undergoing a profound transformation driven by evolving customer expectations, commoditization, digital mindsets, automation pyramid restructuring, and demands for rapid time-to-benefit. This paper highlights five key trends and outlines strategic opportunities to address them, emphasizing a necessary shift from component-centric to system-oriented thinking. Analysis of recent conference topics reveals a progression from initial component digitalization to connectivity, data-based services, and finally to system integration, all converging to meet demands for sustainability, resilience, and increased automation. Three practical use cases – Digital Machine Engineering, Hydraulic Hub, and CytroConnect – exemplify proactive responses to these trends, showcasing how digital twins, accessible knowledge platforms, and predictive maintenance are being implemented. A core argument is advanced that effective cross-manufacturer collaboration, essential for navigating these complexities, critically depends on the adoption and active development of common standards. The Asset Administration Shell (AAS) is introduced as a pivotal enabler for seamless, vendor-independent interoperability. The paper concludes by stressing the imperative for industry-wide engagement in standardization initiatives (e.g., VDMA, IDTA, ZVEI) and proposes future advancements like the Asset Orchestration Platform (AOP), all built upon the foundational role of the AAS to ensure the continued competitiveness and innovation leadership of fluid power technology.

Keywords. Digitalization, Industry 4.0, Digital Twin, Asset Administration Shell (AAS), Standardization, Cross-Manufacturer Collaboration, System Thinking, Interoperability, Fluid Power Technology

1. INTRODUCTION AND OBJECTIVES

The industrial hydraulics sector is currently undergoing significant transformation, driven by several interconnected trends that present both challenges and substantial opportunities.

Firstly, we observe a shrinking pool of traditional hydraulic knowledge alongside the **unjustifiably declining reputation of hydraulics, which is perceived as a mature technology.** Furthermore, **rapidly evolving customer expectations** driven by B2C user

All Open Access articles are peer-reviewed, distributed under the Creative Commons Attribution-Non Commercial 4.0 International

experiences set the benchmark for B2B customer requirements. This trend opens an opportunity to innovate by developing user-friendly software solutions, we can simplify hydraulics. Furthermore, leveraging deep application knowledge and the expertise of internal system integrators, combined with insights from data-driven use cases in the consumer market, will be vital for future success.

Secondly, the industry faces increasing **commoditization, Hardware-as-a-Product (HaaP) models, and regulatory protectionism.** To counter the diminishing differentiation on component level, companies have the chance to provide solutions that offer added value across the entire product life cycle. By leveraging a leading market position, businesses can foster deep customer integration and commitment and actively shape the regulatory landscape through strong market presence and networks.

Thirdly, there's a clear emergence of an **increasingly digital mindset among customers.** A new generation of clients is entering the market with less traditional application knowledge but with distinct digital expectations. This shift creates an opportunity to learn from the success of data-driven business models prevalent in the consumer market. Moreover, monetizing hydraulic know-how and software (SW) solutions will be a key strategy for growth.

Fourthly, we are witnessing the **opening of horizontal layers within the automation pyramid.** By leveraging hydraulic know-how, it is possible to expand customer relationships within the ecosystem, independent of hardware and ecosystem. Proactively co-creating ecosystems with strategic partners and integrating vertically will be essential to capitalize on this trend.

Finally, there is an overarching **demand for fast time-to-benefit.** Shorter life cycles are becoming the norm, with the "China speed" benchmark dictating rapid development and deployment. The opportunity here lies in accelerating the digitization of internal processes to boost efficiency. Additionally, developing adaptable hardware platforms and shifting flexibility into software will be critical to meet the urgent need for quick results and innovation.

2. STATE OF WORK

The main topics of presentations at conferences in recent years reveal a clear trend. Around 2020, the primary focus was on component digitization – how can sensor data be acquired and initial digital functions implemented in valves or systems. In 2022, the discussion shifted towards connectivity and initial data-based services. The aim was to network components and generate initial added value from the acquired data, such as simple condition monitoring. Conferences around 2024 increasingly addressed system integration and efficiency improvements. The focus was on how networked components interact within a system to, for example, increase energy efficiency or improve overall equipment effectiveness (OEE). Today, we must converge these lines of development to address major industry trends: the call for greater sustainability (e.g., through decarbonization), the need for resilient systems, and the increased demand for automation driven by the shortage of skilled workers. This article uses three concrete use cases to demonstrate how these trends can be addressed and

derives from this the compelling need for industry-wide, standards-based cooperation. [1][2][3]

3. METHODOLOGY AND RESULTS

3.1. View of components

We provide three practical examples in this chapter, showcasing how we have proactively responded to and integrated the prevailing trends.

Use Case 1: Digital Machine Engineering – Efficiency from the Start
This approach drastically cuts development and commissioning times by enabling continuous digital development and simulation of entire machines, including hydraulics. A digital twin of the machine is assembled from component digital twins, allowing validation of system behavior and control logic before physical assembly. This significantly reduces errors, costs, and time-to-market, building on advances in component digitalization and system integration.

Use Case 2: Hydraulic Hub – Digitalizing and Accessing Knowledge
The Hydraulic Hub is an online platform offering 24/7 access to knowledge, data, and processes for hydraulic components for service technicians and maintenance personnel. It bridges the gap between the physical and digital world, allowing users to access data sheets, maintenance instructions, and spare parts lists via unique identifiers (e.g., QR codes). AI-powered "Smart Diagnostics" aid in rapid fault identification, addressing the skilled labor shortage and trend towards data-driven services by digitally preserving and applying expert knowledge.

Use Case 3: CytroConnect – From Reaction to Anticipation
CytroConnect is an IoT solution enabling condition monitoring and predictive analytics for hydraulic systems. By analyzing real-time operational data (pressure, temperature, oil condition), it prevents unplanned downtime and allows for proactive maintenance planning. Learning algorithms assess component health and predict remaining lifespan. CytroConnect exemplifies predictive maintenance and increased plant availability, responding to the demand for greater resilience and productivity

3.2. Necessity of system orientation

The necessity to shift from component-centric to system thinking arises primarily from the increasing complexity of modern engineering projects and organizational structures. While component-based approaches optimize individual parts, they often fail to account for how these components interact and influence the behavior of the larger system. This can lead to unforeseen consequences, suboptimal performance, and the creation of new problems while attempting to solve others.[4]

System thinking, in contrast, offers a holistic understanding by considering the interdependencies and relationships among various components, stakeholders, and the environment. [4] This broader perspective enables better decision-making, as engineers can identify underlying causes of issues rather than just addressing symptoms, anticipate unintended consequences, and align technical choices with overall strategic objectives. [4]

It fosters greater resilience, adaptability, and the ability to innovate more effectively by revealing critical connections and the "bigger picture," ultimately leading to more robust and sustainable solutions.[5]

3.3. Standards: Enabling Seamless Cross-Vendor Systems

In today's complex industrial landscape, cross-manufacturer collaboration has become indispensable, and its effectiveness is intrinsically tied to the adoption of standards. Without agreed-upon standards, collaborative efforts between different manufacturers would be severely hampered by issues of incompatibility and miscommunication.

Firstly, standards ensure interoperability. When multiple manufacturers contribute components or systems to a larger solution, standards provide a common language and set of rules for how these diverse elements should interact. This allows for seamless integration, preventing the need for costly and time-consuming custom adaptations between every new combination of products.

Secondly, standards enhance efficiency and consistency. By establishing common practices, protocols, and quality metrics, standards streamline workflows across different organizations. This reduces ambiguity, errors, and redundant efforts, leading to faster development cycles and higher quality outcomes for all collaborators.

Thirdly, standards foster trust and transparency. A shared understanding of expectations and requirements, facilitated by standards, builds confidence among collaborating parties. It clarifies responsibilities, simplifies quality control, and allows for greater accountability, strengthening the partnership. [6]

Finally, standards enable scalability and innovation. With a standardized framework, new partners can be integrated more easily, and new technologies can be developed and adopted without disrupting existing systems. This accelerates innovation by allowing manufacturers to build upon a stable, common foundation rather than reinventing core functionalities with each project. In essence, standards act as the crucial connective tissue, transforming disparate components from various manufacturers into a cohesive and functional system.

3.4. The Asset Administration Shell

The Asset Administration Shell (AAS) is a standardized digital representation, or digital twin, of a physical or virtual asset, playing a crucial role in Industry 4.0. It acts as a digital identity card, structuring and providing all relevant information and functionalities of an asset throughout its entire lifecycle.

The primary benefit of the AAS is to enable seamless integration and communication between machines, equipment, and IT systems, regardless of the manufacturer. This fosters true vendor-independent interoperability, breaking down data silos and facilitating efficient and secure data exchange across different systems and company boundaries. By providing a common, machine-readable database and standardized interfaces, the AAS supports real-time data transmission, advanced analytics, and the development of new business models,

ultimately leading to optimized processes, increased efficiency, and greater flexibility in industrial production. [7] [8]

4. BRIEF INTERIM SUMMARY AND APPEAL

The preceding chapters underscore the critical necessity of collaboration to effectively navigate and address emerging industry trends. This collaborative imperative inherently dictates the joint development of common standards. Organizations must actively engage in standardization efforts within relevant industry associations. For instance, contributing to bodies like the VDMA, which considers standardization a core task for corporate management and promotes the competitiveness of the mechanical engineering industry , or the IDTA, which focuses on maintaining data protection standards and facilitating secure international data transfers Similarly, participation in the ZVEI, which sees standardization as an essential integrative task for bringing together stakeholders and accelerating the digital and green transformation , is crucial. Furthermore, formalizing commitment through signing a Letter of Intent (LoI) with organizations like the ZVEI further solidifies the dedication to such shared standardization goals. Active involvement in these and similar initiatives is not merely beneficial but essential for ensuring interoperability, fostering trust, enhancing efficiency, and ultimately driving innovation across the industry. [9] [10]

5. OUTLOOK - ORCHESTRATION OF ASSETS WITH THE AAS

For the Asset Administration Shell to reach its full potential, tools must make its use simple and efficient for a multitude of use-cases. One such tool is the Asset Orchestration Platform (AOP). This platform leverages the Asset Administration Shells (AAS) provided by component suppliers to radically simplify the integration (or "onboarding") of components into systems and the coupling of systems with each other, e.g., in a production process. Instead of manually sifting through data sheets and individually integrating a proprietary protocol, the AOP reads a component's data and capabilities directly from its AAS and orchestrates its interaction within the system – a "plug-and-produce" approach for industrial applications.

6. SUMMARY

Fluid power technology demonstrates its innovative strength through the consistent development of digital solutions. Systematic monitoring of trends and their driving factors (like in chapter 1 described) is essential to serve as a basis for deriving necessary strategic measures. The path to a successful future is clearly defined and based on three inseparable pillars:

Defining the standard together: With AAS, driven by IDTA and Fluid 4.0, the standard for the digital twin has been defined.

Consistently using the standard: Use cases such as Digital Machine Engineering and solutions like the Hydraulic Hub and CytroConnect, supported by tools like AOP, translate the standard into practice.

Collaboration: Industry-wide cooperation to establish these standards ensures the competitiveness and innovation leadership of the entire sector.

By embarking on this path together, fluid power technology is ideally equipped for a successful and profitable future.

Abstract.

This paper presents a deployable and interpretable framework for the health monitoring of high - power electro-mechanical actuators (EMAs) used in non-road mobile machinery (NRMM), turning standard sensor data into compact predictors, a health index, and finally a fused ensemble that tracks degradation for real-time maintenance.

Using experimental run-to-life data, four correlation-based coefficients identified in a previous study are computed to capture cross-sensor dynamics. An early-life baseline is established, and a bounded, monotone health index is derived using Mahalanobis distance-based deviation, persistence gating, and outlier-robust accumulation. Several machine learning regression models are trained and compared; three complementary models—Gaussian process regression, a bagged-tree ensemble, and a compact multilayer perceptron are selected for further process.

The models are then deployed in Simulink where raw sensor signals are transformed into correlation-based coefficients, which feed three trained regressors. The outputs of these individual regressors are fused via a performance-weighted scheme and smoothed with a rolling-window average to produce a bounded health index. In a separate 200-cycle dataset withheld from all training, the Simulink implementation tracks degradation accurately and suppresses transients. After an initial overshoot due to a shorter adaptive window, the HI remains close to 0.4 on a scale of 0 to 1, which is within the expected range for the withheld data from the HI map of the training data. The fused HI remains interpretable, monotonic in expectation, robust to brief operational disturbances, and consistent with training behaviour, and providing a practical basis for real-time maintenance decisions for high-power EMAs used in NRMM.

1. INTRODUCTION

Electro-mechanical actuators (EMAs) are rapidly being proposed for adoption in non-road mobile machinery (NRMM) due to their combination of high energy efficiency, precise motion control, and compatibility with the broader trend toward the electrification of heavy machinery. Unlike hydraulic systems, EMAs convert electrical energy directly into mechanical motion without the need for pressurised fluid, reducing energy losses and eliminating the complexity of pumps, valves, and hoses. This not only improves system level efficiency but also simplifies integration with modern, software-based control architectures that are increasingly prevalent in NRMM [1].

Despite these advantages, EMAs in NRMM operate under harsh and variable conditions that can accelerate component degradation. High mechanical loads, impact forces, and repetitive duty cycles impose wear on mechanical components, such as screw drives, bearings, and gears. Moreover, exposure to dust, moisture, and temperature extremes can degrade lubrication, increase friction, and cause corrosion. The electric motor and power electronics are also subject to thermal stress, insulation breakdown, and electrical component aging. Importantly, the majority of these degradation processes are not immediately apparent in the output of the actuator until a critical threshold is crossed, leading to sudden and unexpected failures. In contrast to hydraulic systems where issues, such as leaks or pressure drops, often provide an early warning, EMA faults can progress silently, making them more difficult to detect without continuous monitoring.

Research into health monitoring and prognostics for EMAs has grown steadily over the last few years for NRMM, with interest driven largely by aerospace applications and the broader adoption of more-electric systems. Early work in this area focused primarily on fault detection and isolation (FDI), aiming to identify actuator malfunctions as they occur rather than tracking gradual degradation. For example, a comprehensive prognostics and health management (PHM) framework for EMAs is developed by [2] by integrating model-based

fault detection with a data-driven prognosis. Their system was validated on aerospace representative actuators, demonstrating accurate isolation of injected faults, such as motor winding failures and gear jams. However, as with much of the early PHM research, this work relied heavily on simulated fault scenarios and laboratory testbeds operating under simplified duty cycles, limiting its applicability to the variable, high-load operating environments found in NRMM. Subsequent studies extended EMA health monitoring by incorporating mechanical degradation mechanisms into the analysis. For example, the work on screw backlash and fatigue estimation examined the evolution of mechanical wear in transmission components, particularly in ball-screw assemblies [3]. The aforementioned study modelled wear progression and fatigue using analytical relationships and parameter estimation techniques, sometimes coupled with laboratory experiments under controlled loading. While they provided important insight into mechanical degradation pathways, they typically did not operate under the diverse and harsh conditions typical of NRMM service. A recurring theme across the literature is the use of synthetic or fault-injection data in place of genuine run – to - failure datasets.

A test rig has been developed for the experimental evaluation of a flight control EMA, with the ultimate goal of developing health monitoring algorithms in [4]. However, the actuator used in this study has a nominal load capacity of 300N. Furthermore, to generate the test data, the test rig has been subjected to axial loads up to 70% higher than nominal in order to accelerate degradation. The same research group proposes a general health monitoring approach for EMAs based on statistical process control methods using electric motor currents in [5]. In that study, the actuator does not reach failure, but testing was stopped at an event frequency of 60%. Another paper proposes a change detection algorithm for health monitoring of the same small EMA [6]. This algorithm compares the statistical features of the current experiment with past ones in batches, rather than providing an online estimation. Hence, the algorithm assumes that the external conditions on the EMA remain the same each time it is tested, which limits its application for real-time health monitoring. Two points stand out in the last three studies mentioned: first, the size of the EMA, with a nominal load capacity of 300 N, which is significantly low for any work function of NRMM; second, the assumption that external conditions (i.e., load, disturbances) remain the same during all test sessions, which is highly unlikely for any NRMM. The recent study by [7] notes that many approaches to actuator health assessment rely on artificially induced faults, such as deliberate increases in backlash or step changes in motor parameters, to generate degradation data for algorithm testing. While useful for algorithm development, these data often represent abrupt failures rather than the gradual degradation experienced in the real-life operating conditions. Furthermore, artificially induced faults can bias algorithms toward detecting the specific fault types injected, reducing generalizability.

In terms of sensing and feature extraction, multiple studies have explored multivariate feature spaces derived from actuator signals. These include time-domain statistics (i.e., mean, RMS, skewness, and kurtosis), frequency-domain parameters from vibration or current spectra, and residuals from physics-based models. For instance, [8] investigates condition monitoring through multiple sensor channels, applying statistical analysis to extract discriminative features. Similarly, the work in [9] discusses combining motor current signature analysis (MCSA) with vibration and temperature data to detect early anomalies. These approaches underscore the potential of feature fusion for more reliable health estimation. Feature extraction and multi-model fusion have been used for condition

monitoring of an EMA in a train transmission in [10]. The study employs correlation-based feature selection and, through a Multimodal Fusion Improved Transformer Network, achieves better accuracy compared to traditional models. However, the study uses a 1:2 scaled-down experimental setup, and faults are induced manually rather than through natural degradation. That said, in most cases, the outcome is an anomaly score or classification label, not a continuous, interpretable health score.

The use of advanced machine learning (ML) methods for EMA health monitoring has also been investigated. Supervised learning techniques are applied in [11] to predict the actuator condition from sensor features. While these methods demonstrate strong offline performance, they are often computationally intensive, involving high-dimensional feature vectors and complex nonlinear models. Such complexity poses challenges for embedded real-time deployment, especially in NRMM applications where on-board computational resources may be limited. Moreover, many ML-based approaches in the literature are trained and validated on datasets that do not represent the full life cycle of the actuator, making them less robust to long-term drift and variability in operating conditions.

Another limitation is the focus on small to medium-sized EMAs, especially in aerospace and robotics contexts. In contrast, high-power EMA of the type used in heavy construction, mining, and agricultural machinery exhibit different thermal, mechanical, and electrical behaviours due to their larger components, higher load levels, and more severe environmental exposure. This gap is particularly significant given that high-power EMAs are now being deployed more frequently in NRMM applications, where predictive maintenance is essential.

This highlights a clear research gap where work on the health monitoring of high-power EMA working on duty cycles of NRMM is lacking so far.

This work directly addresses this gap by developing a health index for a high-power EMA using exclusively experimental degradation data from a long-term run-to-failure test. The method fuses multiple statistical features into a single normalised scale, enabling continuous tracking of actuator health. This work proposes a framework for constructing and predicting a health index for high-power EMAs operating under realistic duty cycles using experimental data. The starting point for this study is our previous research, in which a systematic feature selection procedure identified four statistical parameters from multi-sensor EMA data that exhibit consistent and monotonic degradation trends across the life cycle of the actuator [12]. Derived from load force, actuator velocity, and electric motor torque, these features form the basis for the HI construction.

A key challenge in this study is the absence of a clearly observed zero-health failure point. During the experiments, the actuator had an unexpected mechanical failure which is not directly related to the gradual degradation [12], which prevents the direct mapping of sensor data to a complete health trajectory from 1 (perfect condition) to 0 (end of life). To address this, the current study employs the Mahalanobis distance method [13, 14], which has been widely adopted in condition monitoring for combining multiple correlated features into a single metric that quantifies deviation from the healthy baseline. MD is advantageous in this context because it is scale-invariant, accounts for feature correlations, and produces a monotonic measure of degradation when applied to well-chosen features. The HI is then

obtained by mapping MD values to a normalised scale where '1' corresponds to the healthy state and '0' to the end of life.

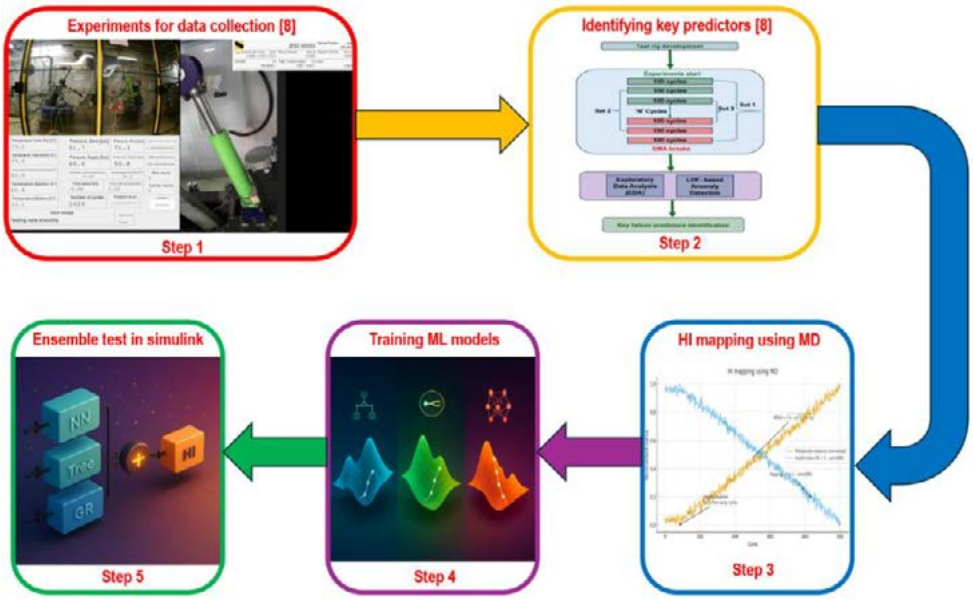

Figure 1. Overview of the study methodology

Figure 1 shows the overall process used for the study. In the above figure, Step 1 and Step 2 are covered in detail in our earlier study [12], which outlines the test rig, experiments, and the identification of key predictors of degradation. The current study carries forward the results from Step 2 and converts the key predictors from Step 2 into a score for HI using the MD. In Step 4, using MATLAB, several ML regression models are evaluated, and finally, the three best performing models in terms of the accuracy and size of the model are selected. These are a tri-layer feedforward neural network, a Gaussian process regression, and a bagged ensemble of decision trees. Each model is trained on the majority of the dataset, with a small, randomly selected segment of 200 cycles withheld for independent validation. Finally, in Step 5, the selected models are integrated into a Simulink-based ensemble, where their predictions are combined through a weighted moving average. The moving window length adapts over time (2, 10, 50, and 100 cycles), enabling early predictions with limited data and improving the stability as more observations become available. This adaptive windowing ensures that actionable health estimates can be generated immediately after startup, without waiting for extended operating histories. Finally, the ensembled model is tested in Simulink using the withheld 200-cycle experimental dataset, representing data that the models have never encountered during training.

The remainder of the paper is structured as follows. The next section of the paper introduces the test rig, the experimentation, and the key predictors of degradation identified in the previous study. Section 3 provides a detailed description of the data labelling process for the health index using MD. Section 4 then presents the training of machine learning regression models. Section 5 elaborates on the formation of the ensemble and its implementation in

Simulink as well as the testing of the framework on randomly excluded data. Finally, Section 6 concludes the paper with remarks and outlines potential future research directions.

2. TEST RIG, EXPERIMENTS, AND KEY PREDICTORS OF DEGRADATION

The long run-to-failure test was conducted on a purpose-built, seesaw-type test bench at Tampere University. The EMA under test is a ball-screw linear actuator driven by a servomotor and loaded by a hydraulic cylinder whose chamber pressures are regulated by electronically controlled pressure-relief valves (PRVs). In combination with anti-cavitation valves, the PRVs let the hydraulic load act as a passive brake in both motion directions: as the EMA moves, pressure builds in the opposing chamber until it exceeds the PRV cracking pressure, producing a controllable, bi-directional resistive force. The test rig with control and monitoring UI is shown in Figure 2 [12].

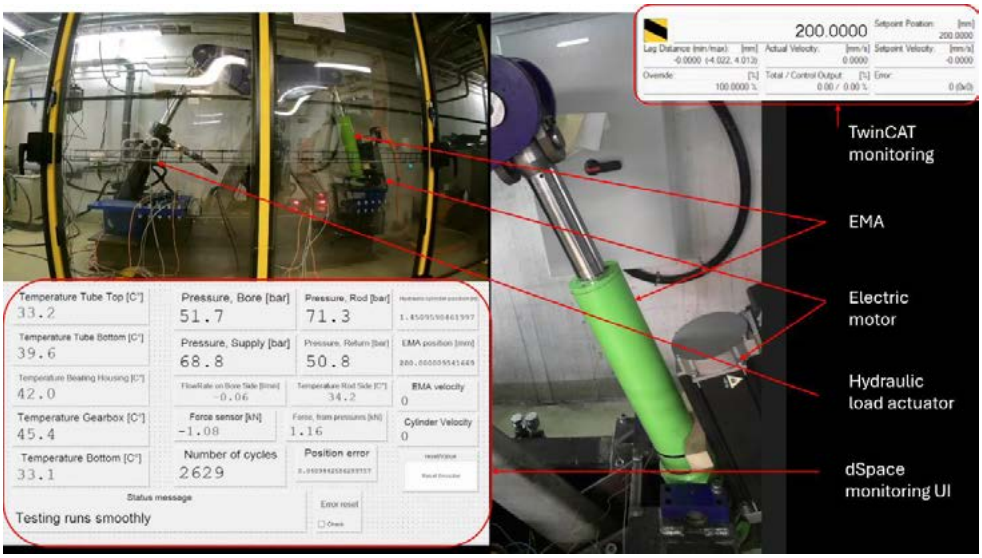

Figure 2. Test rig with monitoring UI [12]

A dedicated 20-bar PRV in the tank line maintains sufficient backpressure to overcome pressure drops across the anti-cavitation valves, and additional passive PRVs protect the circuit against fault-induced over-pressurisation which is important for safe unattended operation. The tested EMA has a 500mm stroke and is powered by an electric motor of 11.62 kW, and a nominal torque rating of 37 Nm at 3000 rpm. Whereas the hydraulic cylinder for loading is 150/80-550 mm and is controlled by an electronic PRV with a maximum operating pressure of 350 bar and maximum flow of 120 L/min.

The test rig has been fitted with numerous sensors on both sides, the hydraulic loading side and tested EMA side. On the tested EMA side, five temperature sensors are placed on different locations on the EMA, and the electric drive is used to measure the position and speed of the EMA as well as the torque and speed of the electric motor. On the hydraulic side, both the chamber pressures are measured, and a 250kN bi-directional load cell records the external force; the calculated cylinder force from these pressures is used to cross-validate

the load-cell readings. The hydraulic cylinder position is monitored using a draw-wire position sensor and used as a safety interlock against drifting to stroke limits by comparing it with EMA position readings. Data collection and the control are split between a dSPACE MicroLab Box (hydraulic load control and centralised logging) and Beckhoff TwinCAT (electric motor control), with dSPACE recording all signals. The test rig was built to operate unsupervised and work 24/7 and hence fitted with numerous safety features against any accidents and failures.

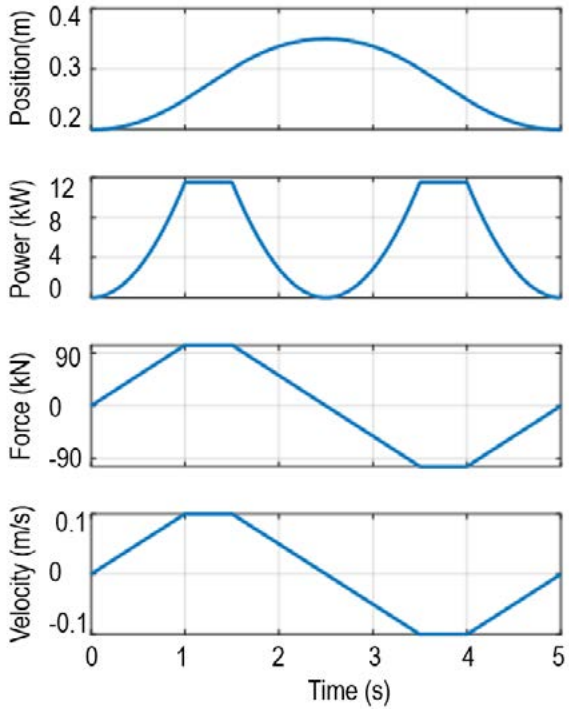

Figure 3. Utilized duty cycle for testing

One cycle for the tested duty cycles is shown in Figure 3. The duty cycle, designed with industrial partners, is an aggressive push-pull sequence: the actuator is driven at its maximum 100 mm/s within a mid-stroke window under a targeted load of 95kN. The bench is capable of regenerative energy via a proportional valve, but regeneration was not used in the current tests. As there is no active cooling, a 20-second pause follows each cycle to allow heat to conduct from internal interfaces (e.g., the screw nut) to the monitored surfaces; automated interlocks pause operation above safe temperature limits and resume once conditions normalise.

2.1. Key predictors of degradation

To quantify how degradation emerges in statistics rather than in any single raw channel, our previous study [12] compared early-life versus late-life operation using three matched pairs of datasets: (i) first 100 cycles versus last 100 cycles; (ii) second 100 cycles versus second-to-last 100 cycles; and (iii) third 100 cycles versus third-to-last 100 cycles. A sliding window was applied within each dataset to compute the summary features-mean, standard deviation

(STD), and skewness on the principal signals of load force, motor torque, and EMA velocity. Correlations among these windowed features were then evaluated, emphasising changes from the beginning to the end of life.

The exploratory data analysis (EDA) revealed consistent weakening of several cross-signal relationships as the actuator wore. Specifically, correlations that were strong and positive early on diminished markedly by the end of life. Complementing EDA, we performed local outlier factor (LOF) anomaly detection directly on the raw signal pairs (load - torque) and (load- velocity) which showed that late-life data occupies regions farther from the "healthy" cluster, with heavier distribution tails toward high anomaly scores [12].

From nine candidate correlation metrics (i.e., combinations of feature types across signals), four emerged as key predictors of degradation because they changed monotonically and consistently across all three dataset pairs:

1. **Correlation of the STD of load force with the STD of motor torque (C1)**
2. **Correlation of the STD of load force with the STD of actuator velocity (C2)**
3. **Correlation of the skewness of load force with the skewness of actuator velocity (C3)**
4. **Correlation of the mean of load force with the mean of actuator velocity (C4)**

In the present study, these four correlations are employed as key predictor signals to map the actuator's health index and to train the ML regression models.

A more detailed description of the test rig, experiments, and the procedure used to obtain the four signals lies outside the scope of the present study, as the primary objective here is to develop a health monitoring framework based on the results of our previous work. For comprehensive details regarding the test rig, experimental procedures, and signal acquisition process, the reader is kindly referred to our earlier study [12].

3. HEALTH INDEX AND DATA LABELLING

This section describes the construction of a scalar health index utilised to label data for supervised ML regression. The procedure operates on cycle-segmented signals and the four correlation-based predictors defined in Section 2, converting their windowed behaviour into (a) a multivariate deviation from a healthy baseline, (b) a smooth exceedance measure with persistence control, (c) a cumulative damage variable with outlier-robust scaling, and (d) a bounded HI suitable for training and evaluation.

The three signals of load force, actuator velocity, and electric motor torque are segmented into cycles using motion and reversal logic; cycles with insufficient samples are discarded to maintain statistical reliability (minimum sample count specified in Table 1). Low-activity cycles are filtered by an activity threshold defined as a fraction of a healthy reference quantile, ensuring that correlation estimates are not biased toward zero by quiescent operation. Within a rolling window of fixed length (see Table 1), it computes Spearman rank correlations for the predictor pairs defined in Section 2.

For distinct ranks, the coefficient ρ is

$$\rho = 1 - \frac{6\sum_{i=1}^{n} d_i^2}{n(n^2-1)}, \quad (1)$$

Here d_i is the rank difference and n is the number of observations in the window.

To quantify degradation, the Mahalanobis distance was employed to measure deviations from baseline correlations:

$$MD = \sqrt{(X - \mu)^T \sum^{-1} (X - \mu)}, \quad (2)$$

Here X is the current correlation vector, μ is the baseline mean, and $\sum$ is the covariance matrix. MD was transformed into an exceedance score using a sigmoid function:

$$e = \frac{1}{1 + e^{-\frac{MD - z0}{k}}}, \quad (3)$$

Here *Z0* sets the sensitivity threshold, and k controls the sigmoid steepness. Persistence gating was applied requiring exceedances in at least 4 of the last 7 cycles to reduce false alarms.

Damage D accumulation used an exponential relation:

$$D = \sum e^{\beta(MD - z0)}, \quad (4)$$

Here β regulates the exponential rate, ensuring smooth, monotonic accumulation. Damage was capped at the 95th percentile to avoid extreme outliers, Finally Health Index is:

$$HI = 1 - \frac{D}{D_{95\%}} (1 - h_{min}), \quad (5)$$

Here, h_{min} denotes the minimum allowed HI.

Table 1 summarises the notation and hyperparameters used in this study. While the equation coefficients *(e.g., ρ and MD*) are computed dynamically from the data, the hyperparameters (e.g., *β, z0 and k)* were optimised through a grid search in MATLAB and cross-validation within literature-based ranges. The final selected values are reported in Table 1.

Table 1. Hyperparameters used to calculate HI

Parameter	Description	Value
MinSample	Minimum data samples per cycles to eliminate bad cycle data	500
Z0	Exceedance sensitivity threshold	3
k	Sigmoid Scaling	0.25
β	Damage exponential factor	1.2
h_{min}	Minimum HI	0.20

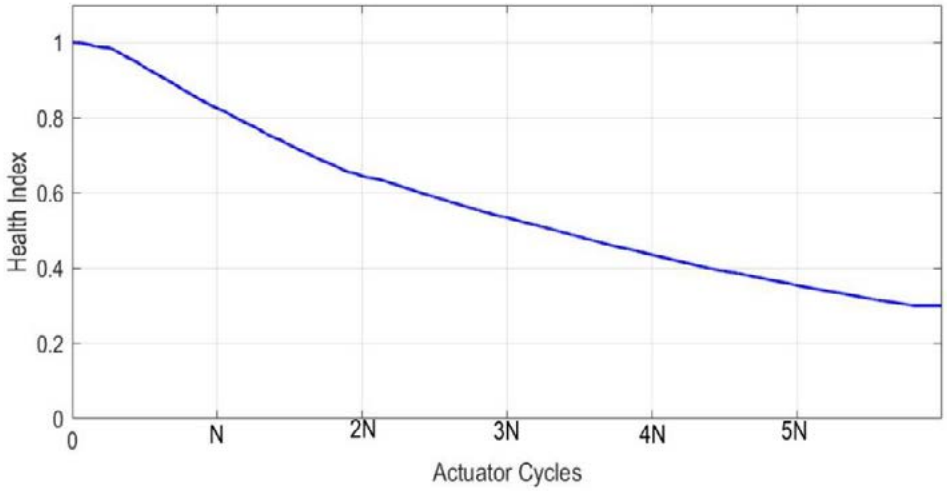

Figure 4. Health index mapping with actuator cycles

Applying the above pipeline to our full run-to-failure dataset gives a strictly non-increasing HI trajectory. The HI values remain near unity during early operation, decline gradually with time without collapsing to zero. This trajectory is presented in Figure 4, where the final HI is mapped with the number of cycles of the actuator. To respect the confidentiality constraints of the manufacturer of the tested EMA, the abscissa is de-identified: the numerical cycle count is replaced with a non-numeric value. The data of 200 cycles was withheld from the entire process to test the framework by deploying in Simulink at a later stage. The withheld data was from the dataset between the 4N and 5N points in Figure 4.

The monotonic decline of the HI demonstrates that the proposed methodology reliably captures progressive degradation of the actuator. Importantly, the absence of abrupt fluctuations indicates robustness against noise and transient effects in the sensor data. The gradual convergence towards a lower bound further confirms the stability introduced by the chosen hyperparameters and strategy. These characteristics collectively ensure that the HI provides an interpretable and reproducible representation of actuator health over its lifecycle.

It shall be noted that the proposed method, the selected hyperparameters, and the resulting HI trajectory are only for the present dataset and experimental conditions. We do not claim this representation to be a universal standard, as the actual health evolution of other actuators may differ. The results shown here are derived from a single run-to-failure experiment and therefore should be interpreted as an illustrative case study rather than a generalised benchmark. Neither this should be interpreted as the actual HI of the tested actuator, since the actuator failure was not directly linked to the gradual degradation, as explained earlier in Section 1.

4. TRAINING OF MACHINE LEARNING REGRESSION MODELS

The data and the HI prepared in Section 3 is used for the training of the ML regression models to estimate the HI directly from the four correlation-based predictors (Section 2).

The training data is divided into 90% for training in a 5-fold cross-validation and 10% for testing. Here, it is worth noting that this 10% testing data is different from the 200 cycles kept exclusively and randomly outside from the dataset for final testing in Simulink at later stages. Several model families were explored, and the three best performers were selected for complementary strengths are selected finally. These models are a Gaussian process regression, bagged decision tree ensemble, and feed-forward neural network.

Gaussian Process Regression (GPR): This provides flexible, non-parametric modelling with built-in uncertainty quantification which means it predicts behaviour while also estimating confidence in the prediction. The trained model has a zero-mean basis and an isotropic exponential kernel. Kernel scale and signal variance were determined by marginal-likelihood optimisation in the MATLAB regression learner app. The optimised sigma value is 1.7054e-4 which is obtained by the Bayesian optimiser of the MALTAB. The model achieved a test **RMSE** of **0.0254**, the lowest error among all candidates. The parity plot shown in Figure 5(A) shows tight adherence to the identity across the full health range with a minimal bias at the extremes, indicating an accurate and smoothly varying fit.

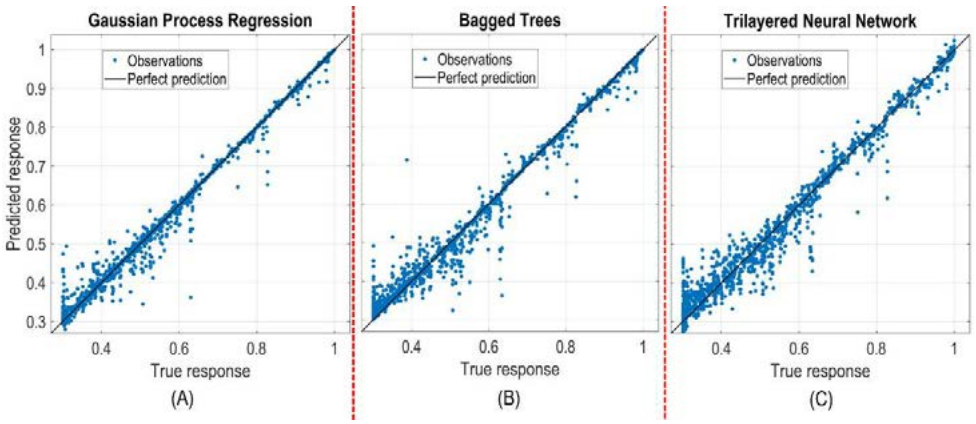

Figure 5. Regression models and predicted versus true response

Bagged Decision Tree Ensemble: An ensemble of 50 bootstrap-aggregated regression trees was fitted, with all predictors available at each split and a minimum leaf size of 1. No input standardisation was required. Bagging reduces the estimator variance by averaging high-variance trees, yielding a robust predictor that captures local nonlinearities without strong parametric assumptions. On the test set the ensemble delivered an **RMSE** of **0.0342**, the second best among the three used models. The parity plot shown in Figure 5(B) exhibits near-linear alignment with a modest dispersion in the mid-range.

Feed-Forward Neural Network (MLP): The last selected and trained model was a compact multilayer perceptron with three fully connected layers (sizes 60–300–50) and ReLU activations. Inputs for this were standardised, and a regularisation strength (Lemda) of 8e-5 was applied. Training used a maximum of 2000 iterations with cross-validation guiding early stopping and hyperparameter choice. The network provides a sufficient capacity to model smooth nonlinearities while remaining small enough to generalise from a modest feature set. On the test set, it achieved an **RMSE** of **0.0378**. The parity plot in Figure 5 (C) shows accurate tracking the near high and low ends of the HI with slightly conservative

predictions in the lower-mid range. Owing to its compact size, the MLP offers very high inference throughput and a small model size, which are attractive for embedded deployment and closed-loop evaluation.

5. ENSEMBLE AND IMPLEMENTATION

The three regressors developed in Section 4 were deployed in Simulink as a real-time estimation chain that converts raw measurements into an operational HI. The architecture shown in Figure 6 implements three independently trained regression models as parallel branches in a Simulink environment. The same cycle segmentation, activity gating, and rolling-window settings used during labelling are embedded in this feature block to avoid a train–test mismatch. An upstream feature-extraction block processes the raw sensor signals of load force, actuator velocity and motor torque to compute the four correlation coefficients (C1–C4) described in Section 3. Once computed, the four features are fed concurrently into the three trained regression models explained in the previous section. Each branch is encapsulated as a standalone block with the exact hyperparameters learned during offline training; the blocks run synchronously on the same time steps, ensuring that all model outputs correspond to the same cycle. The modular design also simplifies diagnostic logging and makes it straightforward to replace or update individual regressors without affecting the rest of the system. Collectively, the three models provide redundant health estimates derived from complementary inductive biases, nonparametric kernel regression, variance-reduced ensemble partitioning, and parametric deep learning, thus meeting reliability requirements for critical machinery.

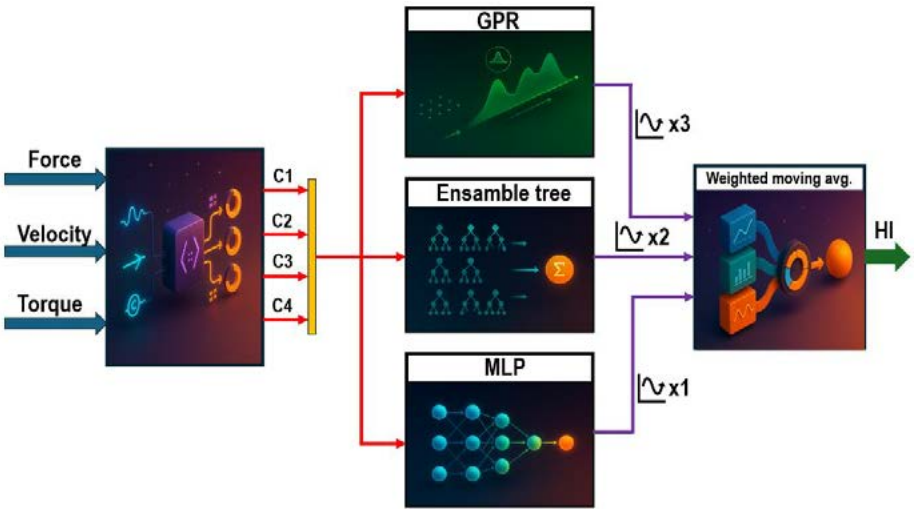

Figure 6. Simulink-implemented ensemble architecture

All three regressors are retained to exploit complementary inductive biases, i.e., kernel smoothing (GPR), partition-based nonlinearity (trees), and universal function approximation (MLP), so that the fused estimator is more robust to regime shifts and single-model failure modes than any constituent alone. Each model returns an instantaneous HI estimate at every cycle as shown in Figure 7. The GPR is the most accurate and stable across the range; the tree ensemble is competitive but slightly more variable in the mid-range; and the MLP reacts

fastest but exhibits significant transients during the first few cycles, including a brief overshoot above the nominal upper bound of 1. As the operation proceeds, all three models converge toward consistent estimates in the mid-range. Although the MLP (neural network) exhibits transient overshoot at the beginning, its high sensitivity to rapid nonlinear changes increases ensemble diversity and early-change detectability, while the performance- and interpretability-weighted fusion prevents it from dominating, yielding a more resilient and stable estimate overall, as explained next in the section.

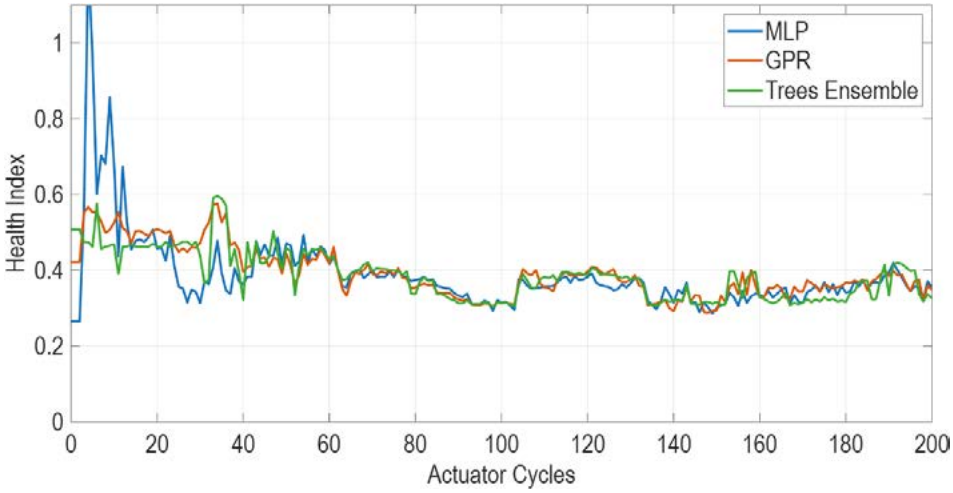

Figure 7. Individual output of instantaneous HI of regression models

The next step assigns fixed model weights to combine the three instantaneous estimates into a single operational HI on a rolling weighted average window. Weights were chosen using two principles. The first is predictive performance in the training stage in Section 4, where the GPR achieved the lowest RMSE, followed by the bagged trees, and finally the MLP. The second is model transparency at the global level, which is operationally valuable during deployment and auditing: GPR provides a principled predictive variance that can be surfaced as a confidence indicator; the tree ensembles support aggregated importance diagnostics and split-wise summaries; and the MLP, while fast, is less transparent as commonly called a black-box model [15]. Balancing these considerations, the fusion uses weights of 3:2:1 for GPR, trees, and MLP, respectively. This choice privileges the most accurate and interpretable models while retaining the responsiveness of the MLP as a minority voice that can nudge the fused estimate when rapid, genuine changes occur.

Since health evolves slowly while measurements and model outputs exhibit short-term variability, the fused weighted signal is smoothed by an adaptive moving-average window whose length increases as operational data accumulates. Immediately after start-up, only a handful of cycles are available; a 2-cycle window is therefore used to produce actionable estimates with minimal latency. This window maximises responsiveness but carries the largest variance, so it is used only long enough to cover the very early regime. Once sufficient data have accumulated, the window expands to 10 cycles, which reduces variance while still allowing the estimate to follow any real operating-regime transitions. After further operation, the window grows to 50 cycles, where the estimator begins to align with the slow time scale of mechanical wear rather than with short-term fluctuations. Finally, it settles at

100 cycles for steady operation, providing strong suppression of residual noise and model idiosyncrasies and enforcing temporal coherence consistent with gradual degradation. Transitions occur only when the next window can be fully populated with sufficient cycle count. Importantly, this adaptive smoothing acts after the instantaneous, weight-based fusion: the correlation windowing used for label construction in Section 3 is kept fixed and separate, ensuring methodological consistency while giving the online estimator the flexibility to manage its own bias–variance trade-off as evidence accumulates.

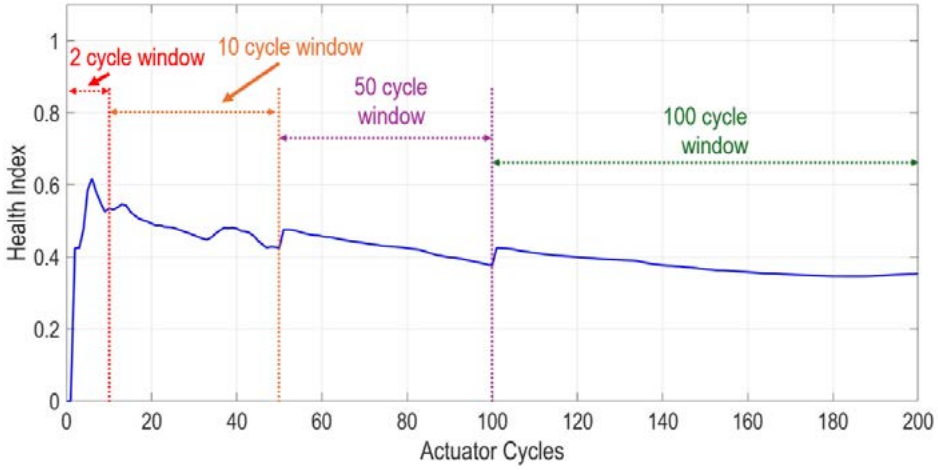

Figure 8. Final weighted average HI with varying window

Figure 8 presents the final HI after the fusion of three independent model estimations over the rolling window average. Vertical markers in the figure indicate the scheduled transitions of the adaptive window (i.e., 2→10, 10→50, and 50→100 cycles). Small, short-lived impulses appear at these markers due to a reweighting toward longer-horizon averages; they are not indicative of mechanical self-healing. Apart from these controlled adjustments, the fused curve is smooth, monotone in expectation, and bounded within the operational range. Here it should be noted that all results use a contiguous 200-cycle segment from the middle of the dataset that was randomly withheld from training and cross-validation; none of the models had prior exposure to these data. The response in Figure 8 remains within the interval expected from the held-out data shown in Figure 4. To protect the industry partner's confidentiality, the exact numerical range is intentionally omitted in Figure 4; however, the 200-cycle segment analysed here lies between the 4N and 5N markers in that figure, which corroborates the HI produced by the Simulink-deployed ensemble of Figure 8. At start-up, when the rolling window is short the fused HI is slightly elevated, driven by the initial peaks of the MLP visible in Figure 7. As the window length increases and more cycles are incorporated, the estimate stabilises and settles squarely within the 4N–5N interval, i.e., the region to which the test segment belongs.

Taken together, the Simulink ensemble provides a timely and stable HI estimate that generalises to previously unseen operating segments, reconciling early responsiveness with long-horizon coherence. These results validate the end-to-end pipeline—from feature extraction through weighted fusion with adaptive averaging, as a practical basis for real-time monitoring and maintenance decision support for high power EMAs.

6. CONCLUSION

This paper presented an end-to-end framework for the health monitoring of a high-power electro-mechanical actuator, from experiment design to real-time deployment. Building on correlation-based predictors established in our previous study, we defined a scalar health index that maps windowed feature relationships to a bounded health scale via an activity-gated, Mahalanobis-distance pipeline with persistence and damage accumulation.

Using the HI label and predictors, the ML regression models are trained, and the three best performing models are selected for their complimentary advantages. The selected regression models are a Gaussian process regression, a bagged-tree ensemble, and a tri-layered neural network. The three models were then imported into Simulink and fused by a weighted moving average that emphasises accuracy and transparency. An adaptive temporal window (i.e., 2→10→50→100 cycles) provided immediate estimates at start-up and increasing stability as more data accumulated. On a contiguous 200-cycle segment drawn randomly from the dataset and withheld from all training and validation, the fused output tracked the expected gradual degradation while suppressing early overshoot; brief impulses coincided with scheduled window transitions rather than physical recovery. Overall, the study provides a reproducible and deployable framework from raw measurements to robust health estimation.

7. ACKNOWLEDGEMENTS AND DECLARATION

This research is part of the Business Finland project EMMA-2 (2471/31/2021). The authors gratefully acknowledge this funding and support by Business Finland.

The authors gratefully acknowledge the contribution of Ville Raunio, Zakhar Afansev, Matias Alenius, and Toni Haapakoski from the Faculty of Engineering and Natural Sciences of Tampere University, for their contribution in building the test rig and carrying out experiments.

At the time of submission of this study, the first author, Dr. Vinay Partap Singh, was employed at Danfoss Power Solutions, Denmark; however, this study and all the experiments were solely carried out at the IHA lab of the Faculty of Engineering and Natural Sciences of Tampere University, Finland.

OpenAI's ChatGPT was used to generate some graphics used in Figure 1 and Figure 6; this does not affect or reflect the methodology or results of the study. The authors take full responsibility for these graphics and for the content of the paper.

Abstract.

Tracking energy losses and global warming potential (GWP) in mobile hydraulic machines and individual components is of growing importance due to an increase in regulations limiting the total GWP of operations and products. Based on data from a wheel loader performing a Y-cycle load operation, this paper computes the energy flow within the hydraulic system using a combination of measurements and system simulation. The energy flow can be used for system optimization. The calculated energy losses and GWP are shared with actors along the value chain using the Asset Administration Shell.

Keywords. Digitalization, simulation, asset administration shell, global warming potential, mobile hydraulics.

1. INTRODUCTION

The EU directive on the energy performance of buildings requires member states to set limits on the total global warming potential (GWP) of new buildings from 2030. The total life cycle GWP include emissions emitted during the construction phase of a building [1]. Already since July 2025, the Danish building regulations (BR18) include mandatory GWP limits for the combined emissions during transportation to and from a construction site (phase A4) and during construction and assembly (phase A5) [2]. BR18 requires the measurement and reporting of consumed energy for vehicles heavier than 1 ton, motivating the live monitoring of energy usage and energy optimization of construction equipment.

Using a wheel loader as an example vehicle, this paper shows how a static simulation model can be used to augment standard measurements to enable component level energy consumption calculations. The aggregated data can be used to fulfill regulations like BR18 while the individual data can be used for system efficiency optimization. This individual energy data can be shared using standardized interfaces like the Asset Administration Shell (AAS) [3] as tested in the research project Fluid 4.0 [4].

In the next section the wheel loader and the load cycle are introduced. A wheel loader enables the analysis of two common hydraulic functions: propel and cylinder-based work functions. Next the simulation model is introduced. It is based on quasistatic analysis of the individual components. Section 4 discusses the energy losses of individual components and highlights potential savings. Section 5 presents how the results of section 4 can be

postprocessed to fulfill regulations and outlines how these values can be shared effectively using the AAS. Lastly, the results are evaluated and future steps discussed.

2. WHEEL LOADER DEMONSTRATOR

The test vehicle is a mid-sized wheel loader shown in **Figure 2.1**. It is equipped with sensors for pressures, rotational speeds, positions, control currents, temperature, and flows. However, not all measurements are required for the energy flow calculations. Notably the flow measurements which are not provided in standard applications are not required. During a Y-cycle, four hydraulic functions were investigated: the hydrostatic drivetrain, articulated steering, lifting of the boom through two parallel cylinders and tilting of the bucket.

Figure 2.1: Wheel loader used for testing.

2.1. Wheel Loader

A modified Paus RL 8.7 wheel loader with a weight of 6.5 tons is the test vehicle. It has three hydraulic circuits of which two are discussed in this paper. First, the hydrostatic drivetrain consists of a single motor and a single pump. Second, the work functions (WF) are driven by a single open circuit pump. The fan drive system is not discussed in this paper but also contributes to the load on the main engine.

The drivetrain consists of the variable displacement axial piston pump Danfoss H1P-078 and the variable bent-axis motor Danfoss H1B-110 connected to a Dana Spicer 367 gearbox. All measurements were collected in first gear. The investigation of this paper focuses on the hydraulic components. This means that losses in the gearbox and the engine are not considered. A simplified overview of the propel and work function hydraulic components can be seen in **Figure 2.2**. Load sensing, load holding, pilot, cooling and emergency functions are not shown and not considered in the simulation.

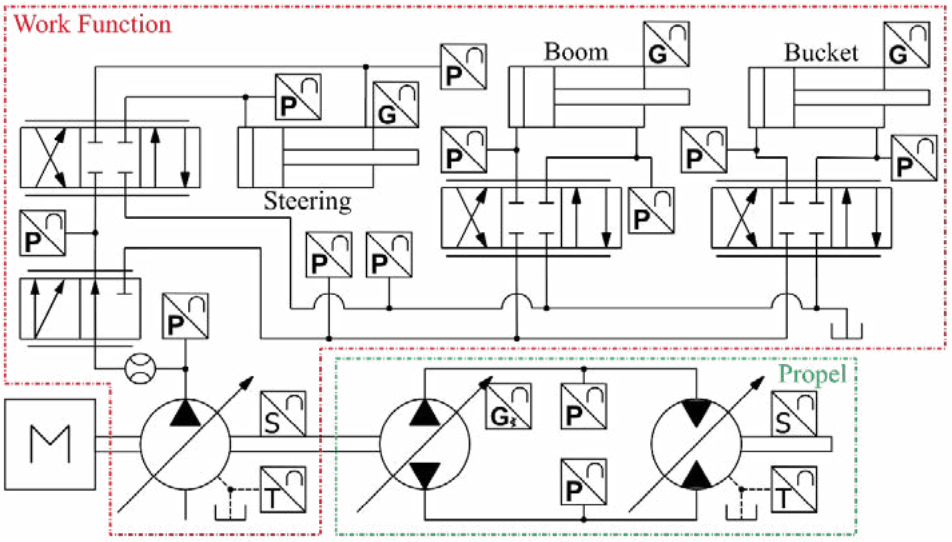

Figure 2.2: Overview of hydraulic circuit and measurements taken.

In the propel circuit the following quantities were measured: Pump and motor shaft speed, pump displacement angle, line pressures at motor and pump side, and motor drain temperature.

The open circuit hydraulics drives four work functions: articulated steering, boom lifting, bucket tilting, and auxiliary hydraulics. During testing, no auxiliary hydraulics were connected, leaving three hydraulic functions. All functions are driven by a single load sensing open circuit Danfoss S45-75 pump. The pump outflow is passed through a priority valve, giving priority to the steering function. A Danfoss OSPC250 steering unit controls the flow to the steering cylinder. Flow to the boom and bucket cylinders is controlled by two proportional Danfoss PVG valves. All returning flow from the steering unit and the proportional valves is filtered and cooled. The boom cylinders are equipped with a ride control unit. While the ride control unit was not actively used in any of the tests, the automatic system still precharged the accumulator for potential use.

Measurements were recorded with a sampling frequency of 500 Hz. The position of the cylinders was captured using draw-wire position sensors. Pressure was measured at the pump side of the steering unit and proportional valves, at both sides of all cylinders, and the pump outflow. The temperature was recorded in the pump case flow and after the cooler. Furthermore, the outflow of the open circuit pump, flow into the ride control unit and into the steering unit were measured.

2.2. Load Cycles

The Y-cycle was performed as shown in **Figure 2.3** on loose gravel. To start the cycle, the wheel loader is positioned with an empty bucket and raised boom at the drop-off pile on the right (1). Splitting the cycles at the drop-off ensures that the start and end states of the cycles are as similar as possible, because the boom is at a defined position. First, the wheel loader reverses and starts lowering the boom. The vehicle switches directions at point 2 and drives

to the left pile (3). When reaching point 2, the boom might not be fully lowered yet. At point 1 the bucket is filled and the boom raised while driving in reverse to the initial turning point (4). The cycle ends by dropping the gravel at point 1. In total 8 cycles were recorded.

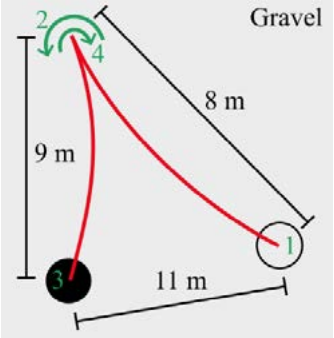

Figure 2.3: Wheel loader test cycle.

Figure 2.4 shows the vehicle speed and boom cylinder displacement with corresponding pressures during the test cycle. During the reverse driving from point 1 to 2, the propel delta pressure is negative during acceleration and positive while braking. After passing point 2 and driving forward, this relationship switches. Pressure during acceleration is now positive. While driving from 1 to 3, the boom is lowered. The boom pressure spikes when the wheel loader hits the gravel pile just before point 3. With a full shovel the boom pressure is higher and exhibits oscillation.

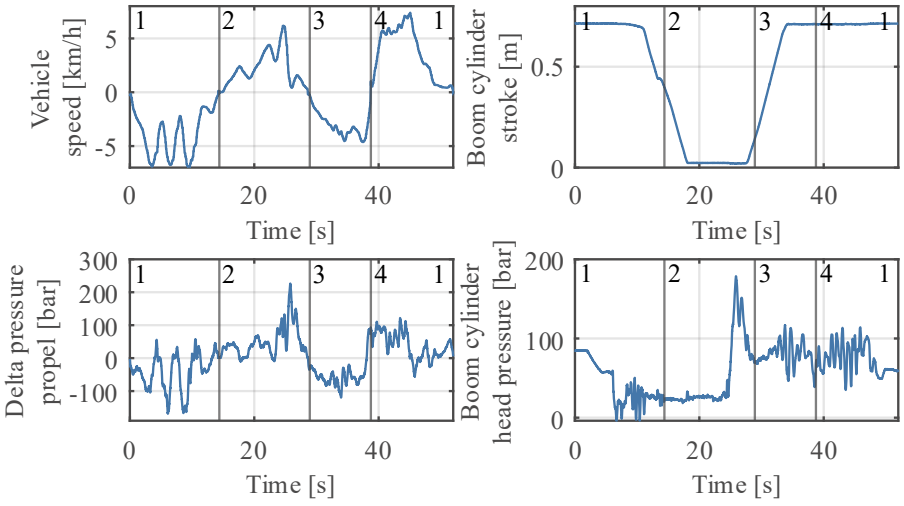

Figure 2.4: Measurement examples for test cycle.

3. SIMULATION MODEL

A quasistatic simulation is used to augment the measurement data and calculate the power flow through each component in every timestep. The simulation model is modular, allowing to swap measurements for simulation components and vice versa. Compared to an analysis only based on measurements, this approach allows replacing hard-to-measure hydraulic quantities like volumetric flow rates by simulation models. On the other hand, hard-to-simulate or unknown hydraulic components can be replaced with measurements. Compared to a full dynamic simulation, no complex environment needs to be simulated. In the following the overall simulation methodology as well as the component models and required external inputs are presented.

The main components of the hydrostatic system are modeled by a component model defining its hydraulic, mechanical, and electrical connections. Every component model defines linear and non-linear relationships between its connections. For example, a pressure relief valve model might define two equations:

1. The inflow is equal to the outflow as a linear equation.
2. The relationship between throughflow and pressure-drop as a non-linear equation through a look-up table.

If the relationship between throughflow and pressure drop is unknown, only the first equation can be defined. Instead of defining the second equation, pressure can be measured on both sides of the valve such that the system can still be solved.

To solve the complete system, the linear and non-linear equations of the individual component models are assembled into a system of linear and a system of non-linear equations using the hydraulic, mechanical, and electrical connections of the components. The system of linear equations is solved first and the solution substituted into the non-linear system. Next, the measurement values are substituted into the non-linear system, and the system is solved using a numerical solver. In postprocessing steps, the system solution is transferred to the individual component models and the power flow through each component is calculated. The modeling framework is implemented in MATLAB.

The level of detail of the component models depends on the available product knowledge and availability of measurement data. While a lot of information is known about the hydrostatic pumps and motor, less information is available for the valves and cylinders. In the following, first the models of the work function circuit and then of the propel circuit are presented.

The performance characteristics of the open circuit pump are known allowing a detailed model. The Polymod efficiency map based on [5] is used to define the non-linear relationship between pressure, shaft speed, displacement angle, temperature and flow. Due to the detailed model, no measurement of the displacement angle is necessary.

In contrast to the open circuit pump, the 4/3-valve performance characteristics are not known. The valves connections are modelled as generic pressure drops. Based on the valve control signal, flow continuity between the connected ports is ensured. Furthermore, the model ensures fluid flows from high to low pressure. The amount of fluid flow is determined by the connected cylinders.

Pressure and position measurements are available for all cylinders. The cylinder model is lossless. Speed, inflow, and outflow are calculated using the time derivative of the position. The cylinder force is computed using the differential cylinder area and the measured pressures.

The propel pump and motor are modelled analogous to the work function pump. Motor and pump shaft speed as well as both line pressures are measured. One more measurement is needed to specify the power flow through the drivetrain. As the control of the pump is equipped with an angle sensor, the displacement of the pump can be determined. Through the efficiency maps of pump and motor, the system flow and motor displacement are calculated by the model. As the flow through the system is based on the pump equations, the pump efficiency model and measurements specifying the evaluation point need to be accurate.

In summary, the simulation model calculates flow, torque and force based on pressure, control signals, pump angle, linear speed, and rotational speed measurements. In a postprocessing step power flow across the connections and power loss in each component are calculated. The presented model is not solvable for all measurement times. This is likely due to the violation of the quasistatic assumption of the simulation or errors in measurement as discussed in section 4.

To validate the simulation for the solvable states, the propel motor displacement and work function pump flow are used. Unlike in a real-world application, the flow rate of the work function pump was measured and is plotted along the simulation result on the right-hand side of **Figure 3.1**. The overall fit between measurement and simulation is good, but for certain time periods, for example around the 30 s mark, the simulation has an offset to the measured value.

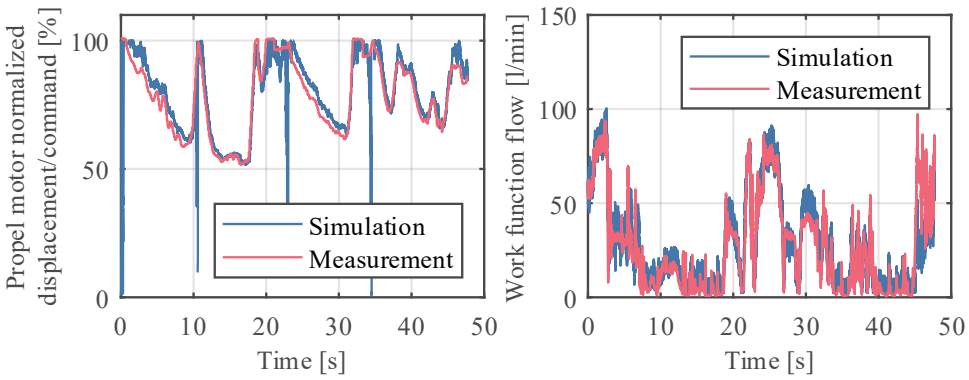

Figure 3.1: Comparison between simulation and measurement data.

No flow rate was measured in the propel hydraulic circuit. However, due to the mechanical feedback link in the motor control, the motor displacement correlates well to the motor control signal. Hence, the simulated normalized motor displacement is compared to the normalized motor displacement command on the left-hand side of Figure 3.1. Like in the work function circuit, the simulation matches the commanded value well most timesteps. However, around the times when the simulation is not solvable, the simulated displacement

drops sharply. As the simulation failures are of short duration, the impact on results concerning a complete Y-cycle is small.

4. RESULTS

This section presents the results derived from augmenting the measurement data with the simulation model and the subsequent energy calculations. The Y-cycle described in section 2.2 was performed 8 times by a non-professional driver. The power flow between components, during different operating phases and differences between cycles are discussed. The analysis focuses on the main power flow, neglecting control flows, cooling flows, and dynamic effects. As the sample size is small and the data was gathered in a test setup and not during regular operations, the results are only illustrative.

First, the power flow through the hydraulic system is discussed. The Sankey diagram shown in **Figure 4.1** shows the power flow between the components during one particular Y-cycle. Red arrows mark the useful work performed by the boom, bucket, steering unit, and wheel relative to the absolute engine output power. Roughly half of the energy provided by the engine is used for the work functions, the other half is used for the propel application. About a third of the energy provided by the engine is turned into useful work. In the median cycle 28 % are used at the wheel, 4 % at the boom, and about 1 % for steering and bucket tilting.

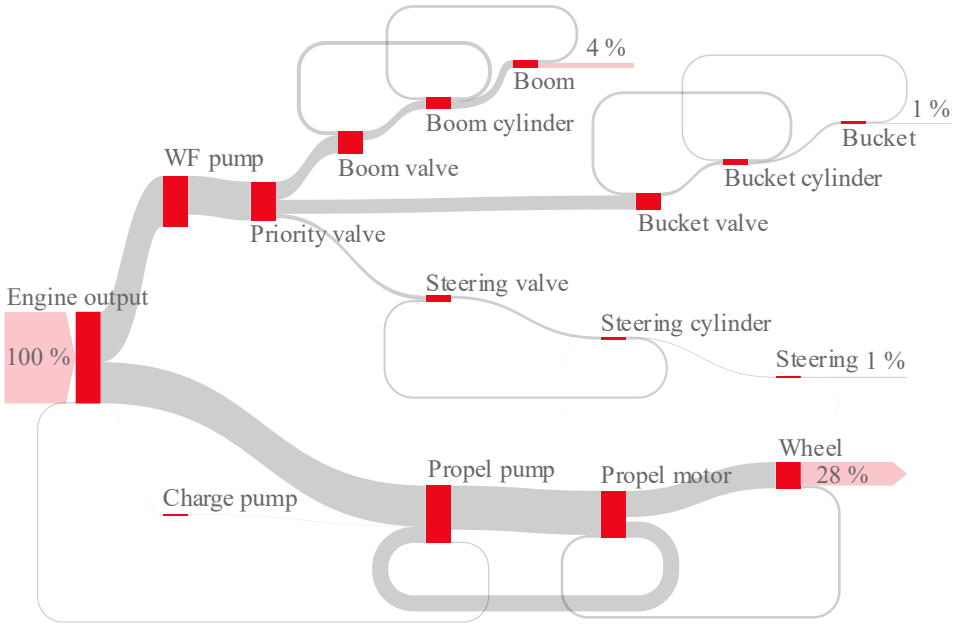

Figure 4.1: Energy flow during 1 Y-cycle. Red arrows mark hydraulic system energy inflow and outflow.

In the work function system, the priority valve splits the work function flow between the cylinders and the steering function. The losses in the priority valve are minor. The highest relative losses are in the throttling valves to the cylinders. As Figure 4.1 shows the energy

flow across a complete cycle, it includes raising and lowering of the boom. During raising unnecessary losses occur in the valve as the pressure level between the cylinders differ. While lowering, all potential energy from boom and bucket is converted to heat. A hydraulic circuit which allows for energy recovery, could recover energy during lowering. Roughly 42 to 76 % of the energy required to move the bucket and 26 to 36 % for the boom are provided back at the cylinders during cylinder retraction. The large spread in recoverable energy for the bucket highlights the influence of vehicle operation on energy saving potential.

The propel system has a median efficiency of roughly 64 % engine to wheel. Only about 8 % of the energy provided to the wheel is returned to the motor during braking. The rest of the energy is lost to friction, especially due to the loose gravel ground. A comparatively large energy flow from the propel motor to the propel pump can be observed due to the low pressure return flow at around 22 bar.

All results are based on measurements with a sampling rate of 500 Hz. All calculations have been repeated with lower sampling rates. With the 500 Hz computations as a baseline, the relative error stays below 1 % for sampling rates up to 20 Hz. For the same sampling rate, the relative error in the work function components is larger than for the propel components. This means, sensors capturing the work function hydraulics need to have higher sampling rates to achieve the same accuracy level.

For a few timesteps, no solution within the physical limits of the components could be found. In these cases adjacent solutions were linearly interpolated. The most common cause for unsolvable system states is the propel motor on maximum displacement not being able to consume all flow produced by the pump. Likely reasons for the surplus of flow on motor side are the neglect of control losses for the propel motor, violation of the quasistatic assumption and measurement errors. The issues might be alleviated by smoothing the measurements before processing in the simulation model.

Figure 4.2 gives an overview of the energy outflow of the system while the same Y-cycle was performed 8 times. The top 4 energy sinks (red borders in Figure 4.2) are the useful work performed for the steering, bucket, boom and propel function. All other items are losses in the hydraulic circuit. While the energy provided by the engine to the work function and propel circuit is similar (see. Figure 4.1), more work is being done by the propel circuit. This is caused by the efficiency of the propel circuit being larger than that of the work function circuit. While the efficiency of the rotating units is larger than the efficiency of the valves, the absolute energy loss is comparable, because the rotating units handle a larger energy flow.

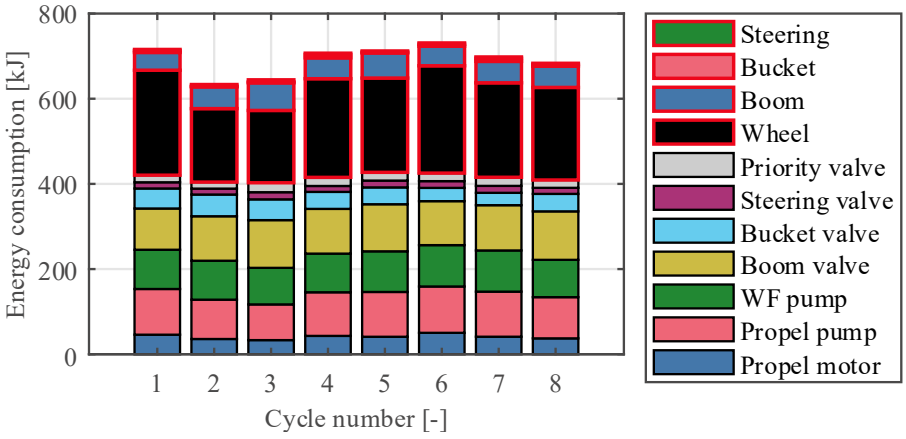

Figure 4.2: Work performed (red border) and energy loss of individual components.

The median energy used in a single Y-cycle is 700 kJ. In all cycles the same work was performed by the same operator. The large spread of total energy consumed, 14 % of the median, highlights the importance of repeated field measurements. To acquire exact energy consumption and emission values, measurements as presented in this paper are required. Accurate knowledge of energy consumption is the basis for GWP calculations in the next section. Furthermore, the energy data can be shared directly via the AAS as demonstrated in the Fluid 4.0 research project and explained in the next section.

5. EMISSION CALCULATION AND SHARING

The energy flow data presented in section 4 is the basis for computing key climate emission indicators. An overall GWP value for the wheel loader is calculated based on the total energy output of the engine and then attributed to the components of the hydraulic system. The total GWP potential can be used to fulfill building regulations like BR18. Individual GWP of the components can be used to calculate the lifetime GWP of individual products. To share the GWP information along the value chain, the standardized interface of the AAS is used. This facilitates the further automatic processing of the emission information into Life Cycle Assessments (LCAs) and other documents required to meet regulations.

Building regulations like BR18 not only stipulate overall emission limits for materials and the use phase of a building, but also specific limits for transportation to and from a construction site (phase A4) and during construction and assembly (phase A5). While the calculations for phase A4 can be performed based on the distance driven by trucks, the energy consumed during construction and assembly needs to be measured directly. For diesel fueled machines, this can be achieved by measuring the fuel consumption or using the engine's specific fuel density and engine energy output calculated in section 4. By using time stamps, the latter approach can be used to assign emissions to the corresponding projects, when a construction machine is performing work for multiple projects on one tank filling. By multiplying the engines' specific fuel consumption of 221 g/kWh and the GWP (including life-cycle emissions) of diesel of 4.13 $kgCO_2e/kg$ [2] with the engine's power output, the median GWP for one Y-cycle is calculated to 178 gCO_2e. Note that the GWP of

diesel varies with the calculation scope determined by the regulation. The value provided by BR18 not only includes the direct effects of diesel combustion, but also emissions generated during sourcing and transportation.

Following the same calculations, the GWP for individual components may be calculated. The GWP for individual components may be used as a data point in the components LCAs. Due to the versatility in use of hydraulic components and the strong impact on energy losses, only real-world measurements can provide an accurate value for the GWP of a component in a specific system. If, for example, the same valve is used in a work function system with accumulator and energy recovery, less energy loss in the valves during lowering is expected. While the proposed method provides an accurate GWP value for a component in a specific system and use case, it is difficult to compare it with the GWP of other products without testing them under the same conditions. On the other hand, a GWP value based on testing defined operating points does not represent the real GWP value of a component, but it ensures that GWP values between similar products are easily comparable.

The calculated emission data is needed by a variety of parties along the value chain. In the example of a rented wheel loader working on a building, the raw emission data might be used by the construction site management, the rental company, vehicle manufacturer, and hydraulic component manufacturers. While the construction site management and rental company are primarily interested in aggregated vehicle level data, the vehicle and component manufacturers have an interest in emissions of particular components. Field data for components ensures that emission reporting is based on real life and thus actual emissions are tracked and can be reduced over time.

To facilitate the sharing of emission data with the different parties in varying granularity, a standardized exchange format is needed. A digital machine-readable format is preferred, because the emission data needs to be aggregated and processed at the different parties before being ready for reporting. One exchange format which is gaining traction in the fluid power industry is the AAS [6]. The AAS framework specifies the technical aspects of data exchange and the data content on a semantic and structural level. The content level structure is described in submodules. For example, a submodule “Energy Monitoring”, facilitating sharing of component level energy data, is currently developed in the research project Fluid 4.0 [4]. The prototype of the submodule Energy Monitoring was used to provide the energy data of this paper in a standardized format to the Fluid 4.0 project partners.

Multiple submodules holding carbon footprint data are already released or under review. The submodel Carbon Footprint can be used to share carbon footprints which were calculated according to ISO 14067 or similar standards [7]. However, two further submodules related to product emission data are in review by the IDTA: Digital Battery Passport – Part 3: Product Carbon Footprint and Product Related Environmental Data [8]. Multiple submodules holding the same or similar data hinders efficient automatic processing of the information within. Ideally every piece of information would have a well-defined unique place inside the AAS. In the future, it is important to consolidate overlapping submodules to create submodules which are general enough to apply to a wide range of assets while providing a unique place for specific information.

6. CONCLUSION AND OUTLOOK

Using a wheel loader as a test machine, this paper demonstrates how standard measurement data can be augmented using a static simulation model to analyze energy flow within a hydraulic system and compute global warming potential (GWP) of vehicle operation to fulfill emission regulations of construction sites. The information about energy flow between components is helpful for system optimization and emission reporting of individual components. Furthermore, the energy and emission information can be shared with parties along the value chain using the Asset Administration Shell (AAS) as a standardized format.

The energy loss of hydraulic components and thus the overall system efficiency is strongly dependent on the load cycle for each component. The individual load cycles depend not only on the machine load cycle, but also on the operator. This makes energy calculation based purely on system simulation difficult, as defining realistic load conditions is challenging. On the other hand, measuring all flow and pressure quantities in a real hydraulic system to determine energy losses, is costly and time consuming. The methodology outlined in this paper reduces the need for a complex sensor setup by augmenting the test data using static simulation models for the individual components. The resulting energy flows show large variations of 14 % in energy consumption between cycles of the same task, highlighting the need for real world measurements to achieve accurate results. Accurate live data is required to fulfill emission limits targeting the use phase of a machine like the Danish building regulation BR18. For planning purposes, it needs to be investigated if the GWP results can be generalized to different drivers, cycles or even machines of different sizes using a larger data set.

To facilitate accurate emission reporting for all stakeholders, emission data needs to be communicated along the value chain. An AAS allows standardized machine-readable communication of the emission data to various parties. Next to emission data, per component energy data can be shared to facilitate system optimization and lifetime load calculations.

Moritz Neltner received a bachelor's degree in mechanical engineering in 2020 and a master's degree in theoretical mechanical engineering in 2022 from Hamburg University of Technology. He received a master's degree in technology management from the Northern Institute of Technology Management in 2023. Since 2023 he works at Danfoss Power Solutions as a simulation engineer focusing on system simulation, data automation, control, and condition monitoring for mobile hydraulics.

Dr. Robert Rahmfeld is the Senior Director Engineering for Hydrostatics at Danfoss Power Solutions, being technically responsible for hydrostatic axial piston units. He is with Danfoss over 20 years, holds several patents, and is author or co-author of more than 60 scientific journal and conference papers. Dr. Rahmfeld completed his PhD on new displacement controlled hydraulic linear actuators at the Technical University of Hamburg-Harburg in 2002 under supervision of Professor Monika Ivantysynova, and his MSc in mechanical engineering at Duisburg University in 1996. He was also holding a postdoc position in fluid power for 2 years at the Technical University of Hamburg-Harburg and Purdue University, Indiana, USA. Dr. Rahmfeld represents Danfoss within the VDMA fluid power board and is also the chairman of the corresponding fluid power research fund with more than 60 member companies. He was awarded in 2024 by Purdue University with the *Monika Ivantysynova Medal* for technology advancements of hydrostatic units and their controls, and for leadership in fostering industry - academic initiatives to promote fluid power.

Senior Director **Dr. Andreas Schumacher** is responsible for Sustainability and Product Compliance for the complete Danfoss Power Solutions segment. He joined Danfoss in 2007 as a simulation engineer after his PhD on mobile machinery tire and driving dynamics simulations at the Technical University of Braunschweig under the supervision of Professor H.-H. Harms. The career development over the nearly 20 years in Danfoss increased his responsibilities and also changed from Engineering to the current role. Dr. Schumacher is also author and co-author of over 30 journal and conference papers as well as presentations. As part of his current role, he is representing Danfoss Power Solutions externally in the field of mainly Sustainability in regulatory, scientific/research and business contexts and further publications like publicly available podcasts (e.g. on Spotify).

Predicting leakage and operating conditions in axial piston pumps using vibration-based machine learning

Simon Knoll, Svenja Horn and Jürgen Weber

Institute of Mechatronic Engineering, Technische Universität Dresden,

E-mail: simon.knoll@mailbox.tu-dresden.de, fluidtronik@mailbox.tu-dresden.de

Abstract.

Condition monitoring for axial piston pumps is often hindered by high sensor and infrastructure costs. This paper presents the groundwork for a low-cost, edge-computing "virtual sensor" that uses vibration-based machine learning (ML) to predict pump operating conditions (OCs) and leakage. Using data from a test rig with multiple artificially generated fault types, ML models (XGBoost and Multilayer Perceptron) were evaluated.

Results show that direct leakage prediction from vibration data is accurate for known faults ($R^2 \geq 0.97$) but fails to generalize to unknown faults ($R^2 > 0.50$). This prediction for unknown faults improves significantly (e.g., $R^2 \approx 0.80$) when OCs are provided as features. It is shown that these OCs (pressure, speed, and stroke) can be accurately predicted ($R^2 > 0.96$) from the same vibration signal. This high accuracy, however, is critically dependent on a robust training dataset that includes various fault types.

Finally, edge-computing feasibility is confirmed by deploying a Multilayer Perceptron model to an ESP32-S3 microcontroller starting at less than 10 €. This work validates the key data requirements for developing a cascaded, low-cost smart sensor.

Keywords. Economic fault detection, condition monitoring, machine learning, Edge-Computing.

1. INTRODUCTION

Condition Monitoring (CM) for fluid power systems, particularly axial piston pumps, is a subject of growing importance. These pumps are critical components in many industrial settings, such as steel mills, where they can be difficult to access for maintenance. Traditional maintenance relies on fixed replacement intervals, which is often costly and does not prevent spontaneous, expensive failures. Predictive Maintenance (PM) offers a needs-based alternative, but its implementation in existing systems faces significant hurdles.

Integrating new sensors into established industrial plants is often complicated and cost intensive. Furthermore, many applications involve sensitive process data, making cloud-based monitoring solutions undesirable due to data security concerns. These practical and economic constraints point toward the need for low-cost, stand-alone retrofit solutions that perform calculations locally. This "Edge-Computing" approach, using low-power microcontrollers, has become increasingly viable. While much recent research focuses on high-performance Deep Learning algorithms, this paper targets a robust, low-hardware solution by focusing on predicting leakage flow, a highly interpretable health index for axial piston pumps.

All Open Access articles are peer-reviewed, distributed under the Creative Commons Attribution-Non Commercial 4.0 International

To achieve this without an expensive flow meter, a "virtual sensor" concept is proposed. This paper demonstrates the ground work for a cascaded regression method where vibration data from a single, low-cost accelerometer—identified in previous work as a highly promising sensor for ML-based monitoring [1]—is first used to predict the pump's operating conditions (pressure, speed, and stroke). This predicted operating condition information is then, in a second step, used to improve prediction of the pump's leakage flow.

This paper is structured as follows: Chapter 2 provides an overview of the existing work in fault detection for Axial Piston Units (APU). Chapter 3 introduces the artificially generated faults, the test rig, the installed sensors, and the machine learning (ML) methods. Chapter 4 presents the results of the ML algorithms including the proof-of-concept implementation and performance of this approach on a low-cost microcontroller for edge deployment.

2. STATE OF THE ART

Condition Monitoring (CM) and Predictive Maintenance (PM) are established fields for hydraulic systems, motivated by the high economic cost of unexpected failures and the growth of the Industrial Internet of Things (IIoT). A significant amount of research focuses specifically on axial piston units (APUs), developing CM systems for both mobile and stationary applications. While model-based fault detection exists [2, 3], data-driven methodologies using sensor data (e.g., pressure, acceleration) are gaining interest.

Most research employs Machine Learning (ML) for fault classification, utilizing algorithms like K-Nearest Neighbors [4], SVMs [5], or Deep Learning (DL) [6, 7] to identify the type of fault or a severity measure defined by multiple classes. Notably, Duensing [22] predicted wear progress in APU using data from actual degradation rather than artificial faults, identifying Multilayer Perceptrons and Random Forests as the most effective models. Keller et al. [4] identified specific acceleration and operating parameters as essential for classifying valve plate damage. Aligning with this, previous work [1] validated the triaxial acceleration sensor for ML tasks and demonstrated that higher sampling rates improve prediction quality, motivating the 16.4 kHz rate used here. Some approaches omit manual feature extraction using DL pipelines. For instance, Tang et al. [6] utilize wavelet transforms to convert signals into images for DL classification. While effective, this lacks an interpretable, continuous degradation measure necessary for maintenance planning. Additionally, data-driven models often struggle with small datasets, requiring transfer learning or simulated data [8, 9].

Addressing this, regression models enable continuous condition prediction. Schimke et al. [10] applied Random Forests and CNNs to predict damage severity. To simulate cavitation erosion holes are drilled in specific areas of the valve plate. The area of the drilled-out portion then functions as the regression target. Their use of 96 operating conditions highlights the importance of dataset diversity. They emphasize that inclusion or exclusion of damage types in the training dataset significantly influences prediction accuracy.

Other studies quantify degradation via abstract "Health Indices" (HIs) [11, 12]. However, unlike physical metrics such as leakage flow, HIs often lack the direct meaning required to set concrete maintenance thresholds. While Liu et al. [9] proposed a "virtual flow sensor" to predict leakage directly, their reliance on simulated data limits real-world relevance. Furthermore, high-performance architectures like PINNs [13], CNNs [10], and LSTMs [14, 15] demand computational resources often unavailable in low-cost, retrofit scenarios.

Walani et al. [16] argue for lightweight models on edge platforms to ensure real-time processing and low latency, though hardware limitations restrict model complexity.

Consequently, this review identifies a gap for an APU monitoring solution that is simultaneously: 1) Low-Cost & Edge-Deployable, avoiding heavy DL models; 2) Interpretable, by predicting physical metrics like leakage; and 3) Robust against variable conditions and unknown faults, a challenge for static classification models.

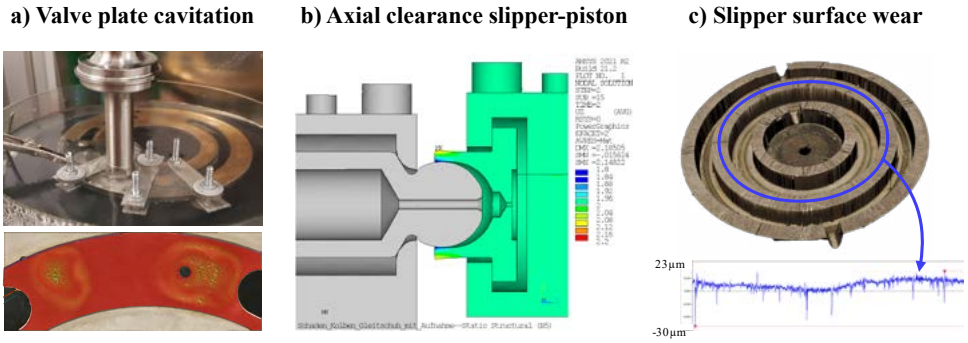
3. EXPERIMENTAL AND METHODICAL SET-UP

This section provides an overview of the artificially worn pump parts, the test rig and sensors, followed by a description of the measurement procedure and a brief introduction of the methodical approach for the implementation of ML algorithms. More details as well as the pump efficiencies for the different faults are presented in [17].

3.1. Artificially worn pump parts

Figure 3.1 illustrates three representative types of axial piston pump damage, each reproduced as realistically as possible. To identify the location and severity of a typical valve plate cavitation damage, simulations were conducted at elevated speeds, complemented by measurements at very low suction pressures. Real cavitation erosion at three different intensities (I, II, III) was induced locally in the transition zone between low and high pressure using a sonotrode, compare Figure 3.1 a).

Axial clearance between slipper and piston, a failure that can result in total pump breakdown, was implemented with a tensile testing machine. The required axial force was estimated via finite element analysis (FEA), as shown in Figure 3.1 b). All nine slipper-piston assemblies were then elongated until reaching a 179 µm clearance using a tensile testing machine, with a custom fixture to clamp both parts without damaging the sliding interfaces.



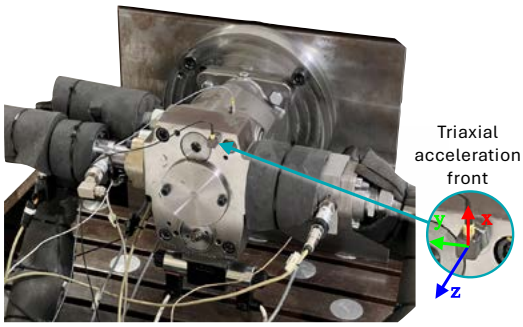


Figure 3.1 Artificially damaged pump parts, manufactured as realistically as possible (more details in [17])

Finally, slipper sealing lands were intentionally damaged using a file, and the achieved damage was quantified by profilometer measurements, as depicted in Figure 3.1 c).

3.2. Pump Test-Rig and Measurement Procedure

A standard test rig setup, designed for pump efficiency measurements, was equipped with high-frequency pressure and acceleration sensors. These were sampled at 16.4 kHz and

located at the pump's front plate and housing, compare Figure 3.2. The triaxial acceleration sensor at the front plate provided the most informative signals for machine learning applications. In this study, all three acceleration components were included in the predictive pipeline. Suction pressure was maintained at 1.8 bar to prevent cavitation throughout all operating conditions. Low-frequency pressure and temperature data were acquired to monitor and control the test environment. Measurements were conducted across the full operating range of the variable displacement APU, covering six pressure levels, four stroke values and four rotational speeds, resulting in 96 distinct operating conditions. Most faults resulted in minor efficiency losses, with the exception of severe valve plate cavitation III, as clearly shown by the leakage results (see Figure 4.1).

Property	Value
Sensor	MMF KS903.10
Sensor type	triaxial piezoelectric accelerometer
Mounting method	threaded stud
Upper frequency limit (3 dB)	11 kHz (X), 22 kHz (Y/Z)
Sampling Frequency	16.4 kHz

Figure 3.2 Mounting location and technical information for the triaxial acceleration sensor used in this work.

The study's findings are based on a representative subset of 28 operating conditions that are presented in Table 1. Each measurement lasted 10 seconds, sufficient to capture multiple pump rotations at each speed. Since temperature significantly affects leakage and vibration damping, the inlet temperature was controlled at 40°C ± 3°C. In practical applications, temperature variations can be measured cost-effectively and incorporated into the evaluation process.

Table 1: Overview of representative set of 28 operating conditions (OCs) grouped by stroke value relative to the maximum

100 % stroke		**75 % stroke**		**50 % stroke**		**25 % stroke**	
n/rpm	Δp/bar	n/rpm	Δp/bar	n/rpm	Δp/bar	n/rpm	Δp/bar
500	200	500	150	500	50	500	100
1000	100	500	250	1000	150	500	250
1000	250	1000	50	1000	300	500	300
1500	150	1000	200	1500	50	1000	150
1500	200	1500	100	1500	250	1500	50
2000	50	1500	300	2000	100	2000	200
2000	300	2000	150	2000	200	2000	250

Initially, a reference measurement was conducted under healthy conditions without any damaged parts (“new” condition). This data serves as a baseline for comparison with subsequent measurements involving damaged parts. Each defect was measured separately, without combining multiple defects.

3.3. Methodical approach for implementing machine learning

This section details the standardized methodology applied to all supervised machine learning tasks performed in this paper using Python (v3.12.3). As illustrated in Figure 3.3 the approach encompasses data acquisition, data preprocessing, feature engineering, model selection, hyperparameter optimization and final model evaluation. Additionally, a proof-of-concept edge deployment on an ESP32 micro controller is presented for one selected model.

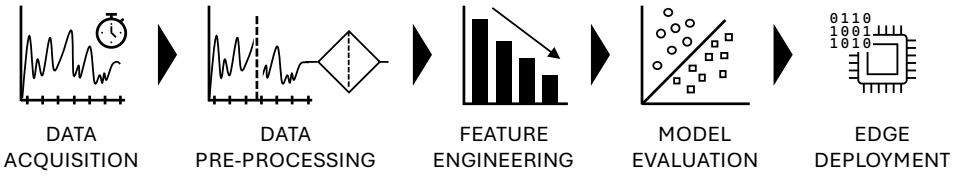

Figure 3.3 Methodical approach to implement machine learning algorithms.

3.3.1. Data segmentation and feature engineering

The raw acceleration signals exhibit cyclostationary behaviour, with patterns repeating for each pump revolution. To create a high volume of training samples, the data is split into smaller segments, each containing two full pump revolutions. Each segment underwent normalization (zero mean, unit variance) to emphasize signal shape over absolute amplitude across operating conditions. Feature extraction was performed using TSFresh (v0.20.2) [18], a Python library validated in prior studies [1, 17].

Table 2: Selected feature types ordered by count in the final top 700 (names matching the TSFresh implementation)

Feature Type	Amount in final selection	Feature Type	Amount in final selection
fft_coefficient	384	linear_trend	9
change_quantiles	126	number_cwt_peaks	6
agg_linear_trend	62	mean_abs_change	3
ar_coefficient	26	longest_strike_below_mean	3
autocorrelation	22	longest_strike_above_mean	3
partial_autocorrelation	21	count_above_mean	3
number_peaks	15	count_below_mean	3
fft_aggregated	11	abs_energy	3

From an initial candidate set of approximately 2,400 features, a preliminary reduction using univariate p-value analysis selected the top 16 feature types based on median ranking. This yielded 1,600 spectral and time-domain features, which essentially describe the shape and patterns of the signal. A second p-value analysis further reduced this selection to a final set of 700 features, detailed in Table 2. The most significant predictors included time-series autocorrelation, longest strikes above and below mean as well as spectral attributes (FFT coefficients, skewness, variance, kurtosis) up to 1.7 kHz equivalent frequency. Finally, the feature matrix was standard-scaled to ensure equal contribution during training. The regression label for each sample is represented by the unscaled mean leakage flow for the corresponding time segment.

3.3.2. Model selection

To balance performance with deployment feasibility, two regression models are employed. First, **XGBoost** (v2.0.3) [19], a decision-tree-based ensemble, serves as a robust benchmark due to its proven success in prior studies. Second, a **Multilayer Perceptron** (MLP) using Scikit-Learn (v1.5.0) [20] is selected specifically for its computational efficiency, making it ideal for resource-constrained edge deployment.

3.3.3. Hyperparameter optimization and training

Before the models are optimized and trained, 20 % of the entire dataset is separated as a final, untouched hold-out set for the calculation of performance metrics. The remaining 80 % of the data is used for hyperparameter optimization. The optimization for both models is conducted using the Optuna framework (v3.6.1), an automated, trial-based hyperparameter optimization tool [21]. This process employs a GroupKFold cross-validation strategy with 5 folds per trial. For this strategy, the data is grouped by the specific "damage kind" (e.g. valve plate cavitation II, slipper wear). This ensures that for each fold of the optimization process, the validation set contains data from at least one damage type that the model has not been exposed to during training in that fold. The objective of this approach is to develop final deployment models that are as robust as possible and generalize well to novel or unseen fault conditions. The hyperparameter search spaces for both models are represented in Table 3 in the appendix.

3.3.4. Final model evaluation

Performance results in the following sections are generated using the 20 % hold-out set that was segregated prior to hyperparameter optimization. The evaluation on this hold-out set is conducted using a KFold cross-validation strategy with 10 folds and random sampling aiming to represent the real-world deployment of pretrained models. In each iteration, a model is instantiated with the optimized hyperparameters, trained on 90% of the development set, and evaluated against the fixed hold-out set. This process is repeated 10 times, ensuring that varying samples in the original set are used for training. The aggregated results from these 10 folds provide a robust and comprehensive assessment of the model's final performance in a deployment setting.

4. PREDICTING PUMP LEAKAGE

4.1. Critical faults rise leakage flow

Leakage flow measurement is a widely used indicator of hydraulic pump condition, as increased leakage often signals wear and the need for replacement. However, clamp-on flow meters are expensive (beginning from 1000 €) and typically require a straight section of pipe or specific housing to ensure accurate readings, making them less practical for many installations. In-line flow meters, on the other hand, are difficult to implement in existing systems and can be prone to failures. For these reasons, the vibration signal should be used to predict the pump's leakage. In comparison to traditional fault analysis as for example the classification in "good" and "bad" or the use of a "health index" [12], operators that have a long-standing experience with their pumps and systems know the critical leakage values to decide whether the pump needs to be exchanged. As a further advantage, leakage has the potential to also work for different pump sizes if normalized. Not all pump faults - such as those involving the shaft or bearings - directly affect leakage, so relying solely on leakage measurements may miss some mechanical issues. Therefore, vibration analysis provides a more comprehensive assessment, allowing for better detection of both hydraulic and mechanical faults. In addition to predicting leakage, other models can monitor the vibration signal to detect fault types that do not measurably increase leakage, a capability demonstrated in previous fault classification work [1, 17].

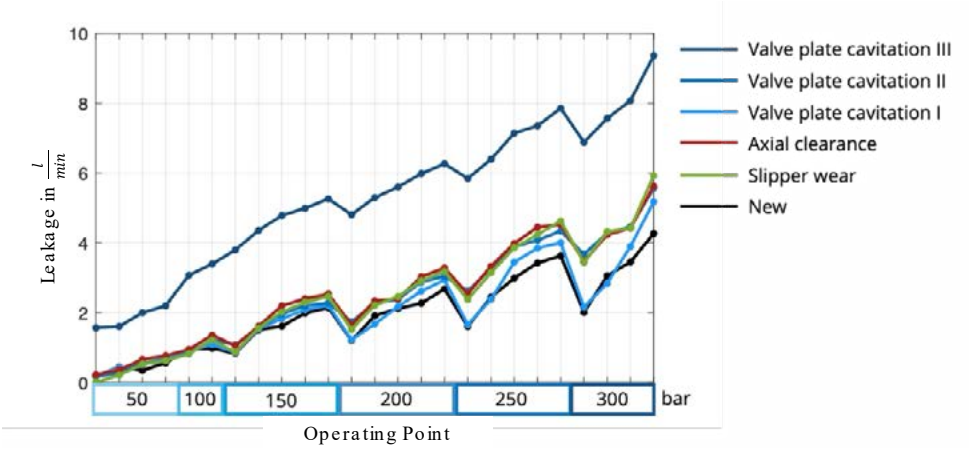

Figure 4.1 Leakage of the different faults over many operating conditions at maximum stroke (100 %) with rising speed for each pressure level

Figure 4.1 illustrates the measured leakage for the maximum stroke (100 %) for the different faults across a wide range of operating conditions, clustered by pressure levels and rising speeds for each pressure. Measurements were conducted using a VSE VS1 gear type flow rate sensor recording the total external leakage flow of the APU at a sampling frequency of 330 Hz. All faults are situated within the minor wear range, causing only slight increases in pump leakage, except for valve plate cavitation III, which shows a more pronounced effect. The figure demonstrates that higher pressures and speeds particularly accentuate leakage differences between fault types. Additionally, leakage is shown to be significantly dependent on operating conditions and temperature, supporting the hypothesis that machine learning

models could improve fault detection by incorporating additional variables such as speed and pressure.

4.2. Correlation between pump vibration and fault types

While leakage indicates severe faults (e.g., valve plate cavitation III), it shows only minor increases for defects like slipper wear (Figure 4.1). To capture a holistic view of pump health, a vibration-based ML approach is employed. The correlation between vibration and condition is analysed using heatmaps of the y-acceleration amplitude against the "pump order". Due to cyclostationary behaviour, spectral peaks occur at harmonics of the piston frequency f_p, where Z is the piston count and the n rotational speed. Unlike raw frequency, the pump order normalizes the signal frequency f against f_P, enabling comparisons across varying speeds:

$$pump\ order = \frac{f}{f_p} = \frac{f}{Z * n}$$

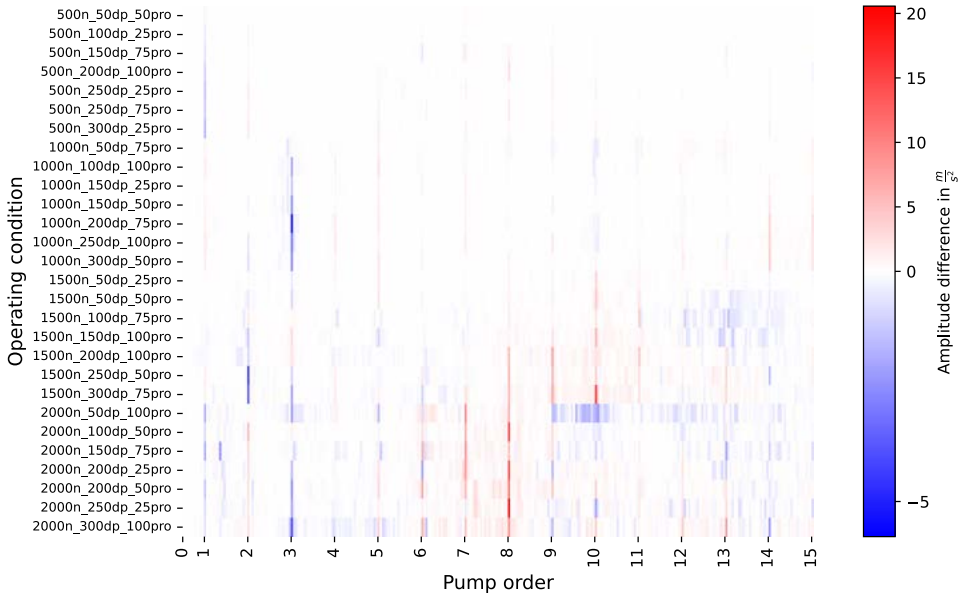

Figure 4.2 Differential amplitude spectrum of the y-acceleration signal highlighting changes from new pump condition to valve plate cavitation damage (stage III) across varying operating conditions.

Figure 4.2 illustrates the spectral difference between a healthy pump (new condition) and a pump exhibiting valve plate cavitation (stage III) as a function of pump order and operating condition. The difference spectrum directly reveals how the fault alters the acceleration amplitude at each harmonic order: blue regions indicate amplitude reductions relative to the healthy baseline, while red regions denote amplitude increases induced by the cavitation damage. Notably, certain orders, such as the 3rd harmonic, exhibit particularly pronounced differences, and the magnitude of these deviations varies significantly across operating conditions. This order-dependent and operating-point-sensitive behaviour confirms that

spectral analysis of the acceleration signal provides a robust means of detecting and characterizing condition changes in the pump.

4.3. Leakage flow prediction with supervised learning

The dataset of the 28 OCs (see Table 1) is used, including the data from the new condition, axial clearance, slipper wear, as well as valve plate cavitation I and III. The fault of valve plate cavitation II is not included, as it will be used to judge the model's ability to perform on unknown damages. When training deployment models, data may only be available for low and high fault intensity (e.g. valve plate cavitation I and III). During the deployment of the final model, actual faults are expected to lie in between these extremes as represented by valve plate cavitation II. The triaxial sensor is evaluated, whereby for this investigation all three axes x, y, and z are used at the full sampling rate of 16.4 kHz.

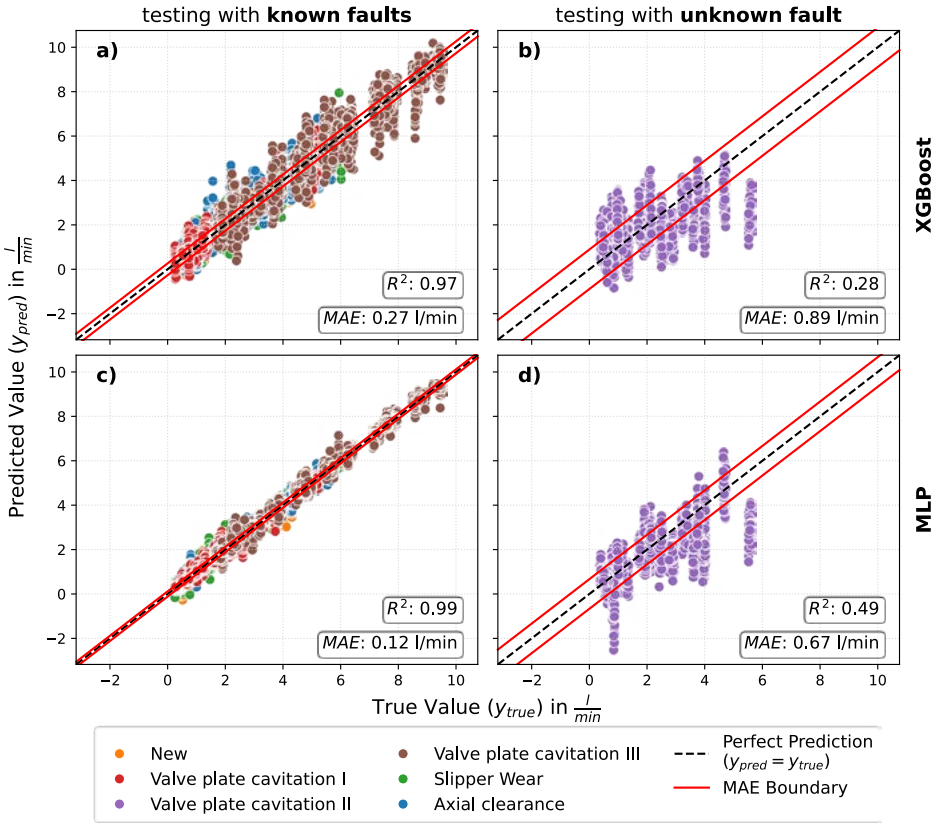

Figure 4.3 Comparison of leakage prediction with known pump conditions and unknown valve plate cavitation II damage not seen during training using XGBoost and MLP regression models.

Figure 4.3 a) shows the prediction result of the XGBoost regression model on known fault types. When predicting the leakage, it achieves a mean absolute error (MAE) of 0.27 l/min and a coefficient of determination (R^2) of 0.97. This high regression quality can be attributed to the fact that the same operating points and fault types were included in both the training

and test data. As a next step, the dataset valve plate cavitation II is used for prediction, as it is still completely unknown for the model. The prediction results are depicted in Figure 4.3 b) and show a larger variation and a MAE of 0.89 l/min with R^2 of 0.28. This lower performance is expected when predicting samples with an unknown fault type.

Figure 4.3 c) shows the same kind of scatter plot for predictions made using the Multilayer Perceptron model. Prediction quality improves across the board when compared to the previous XGBoost predictions reaching a MAE of 0.12 l/min when predicting for known fault types. Performance on the unknown valve plate cavitation II damage also improves to 0.67 l/min of mean absolute error in Figure 4.3 d). Judging by this first analysis the Multilayer Perceptron model shows a higher adaptability to the unknown fault type combined with better performance metrics on known damages than the XGBoost model.

For the valve plate cavitation II predictions (Figure 4.3 b) and d)), both models clearly reveal distinct operating conditions through the dispersion of the vertical lines. Since leakage flow strongly depends on these parameters (speed, pressure and stroke/displacement), the objective is to enhance the prediction of leakages under unknown faults by incorporating operating condition information as model features.

4.4. Leakage flow prediction with known operating condition

Up to this point all features used by the models are derived from acceleration time series data. For the following analysis, the operating parameters speed (revolutions per minute), pressure (bar) and stroke (% of maximum displacement) are added to the feature space. Using these features, models can now deduce that, for example high speed and stroke values lead to higher overall leakage across all fault types. As can be seen in Figure 4.4 the addition of operating parameters improves prediction quality for the unknown valve plate cavitation II fault and both models. The XGBoost Regression model show the biggest improvement for predictions on this fault type, increasing R^2 values from below 0.4 to above 0.8 and almost halving MAE to 0.47 l/min. The Multi-Layer-Perceptron shows smaller improvements for the unknown fault type with a higher variance of R^2 values between folds.

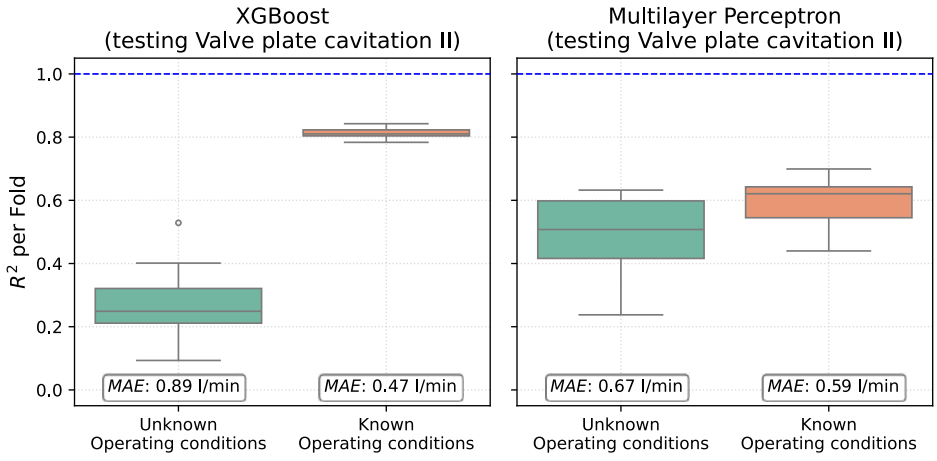

Figure 4.4 Improvement of leakage flow prediction when testing on unknown valve plate cavitation II fault and adding operating conditions to the feature space

4.5. Operating condition determination using vibration data

As demonstrated in the previous section, incorporating operating parameters (speed, pressure, and stroke) as features enhances the model's ability to predict leakage, especially for unknown fault types (Figure 4.4). However, this crucial information is often unavailable in retrofit scenarios, as dedicated sensors for pressure or stroke (i.e. swashplate angle sensors) may not exist or are unavailable to the CM system. The following analysis, therefore, investigates the feasibility of using the same high-frequency acceleration data to predict the operating conditions themselves.

Determining the operating condition from the vibration signal enables three key functions for a 'smart sensor'. First, it allows the recording of load history. By logging these conditions, load patterns become visible, which are important for assessing the system state. Second, it enables indirect monitoring. In applications without dedicated sensors, parameters like flow rate can be derived directly from the vibration data. Finally, it improves predictive maintenance. Analysing the connection between wear and load allows for a better prediction of potential pump failures. To achieve this, the following sections will test the ability of machine learning models to determine the operating condition (speed, pressure, and stroke value) using *only* the acceleration data, with the goal of realizing this functionality within a single sensor.

While the rotational speed can be analytically calculated from the frequency spectrum using spectral and order analysis, a similar analytical approach for pressure (e.g., correlating the amplitude of the first harmonic) was found to be unreliable. While a clear trend exists for the healthy pump, this correlation breaks down completely in the presence of faults, as the fault signatures interfere with the pressure-based amplitudes. This high complexity and variance, especially under fault conditions, lends itself to the application of machine learning models to predict speed and the remaining stroke parameter.

4.6. Operating condition prediction with ML-models

To predict the operating point from vibration data, both XGBoost and MLP regression models are employed. The feature space and the representative set of 28 operating conditions (Table 1) are identical to those used in the leakage prediction tasks.

A key challenge is that a deployed model will initially only be trained on data from a healthy pump. To simulate this, models are first trained exclusively on data from the undamaged pump (new) and then tested on data from the faulty components. As shown in Figure 4.5, this approach fails.

While the models achieve near-perfect accuracy on undamaged test data and XGBoost can still predict speed on faulty samples with $R^2 > 0.8$, the R^2 scores for pressure and stroke drop to negative values. This is attributed to the substantial impact of damage on the vibration spectra (see Section 4.2), which indicates the models have overfitted to the specific patterns of the healthy pump and cannot generalize to unknown fault conditions.

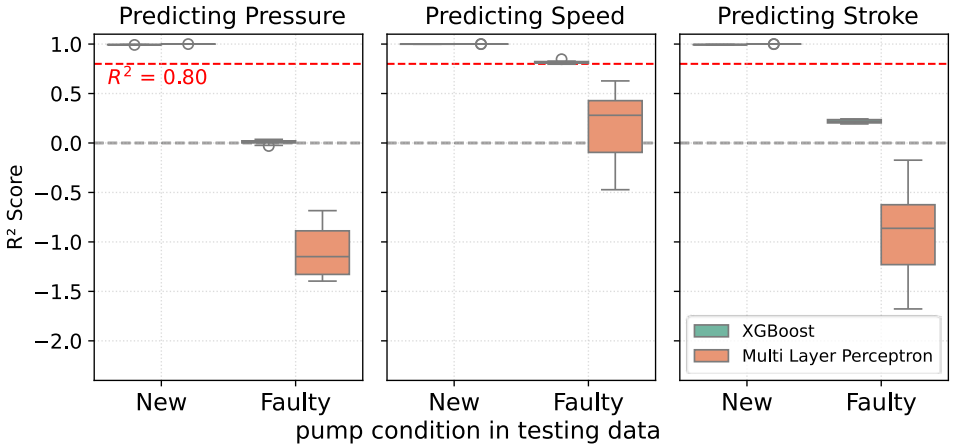

Figure 4.5 Prediction of pressure, speed and stroke with XGBoost and MLP on new and faulty condition training samples, with only new condition samples used for training

While training solely on healthy pump data yields limited generalization capability, extending the training set to include fault conditions significantly improves model performance. Figure 4.6 demonstrates this effect: when trained on a comprehensive dataset comprising all fault types (new condition, valve plate cavitation stages, axial clearance, and slipper wear), both XGBoost and MLP models achieve R^2 values exceeding 0.98 for all operating parameters.

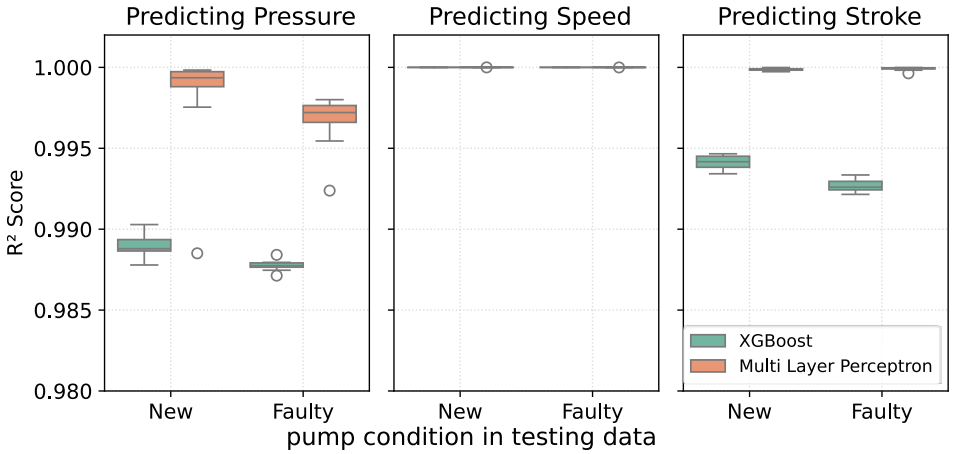

Figure 4.6 Prediction of pressure, speed and stroke with XGBoost and MLP on new and faulty condition training samples, with samples from all fault types used for training

This analysis confirms that accurate operating condition prediction solely from acceleration data is feasible, provided the training dataset captures the full range of expected pump conditions. Since industrial applications initially provide only healthy pump data, an adaptive training method is proposed. As the pump ages, the model is continuously retrained using its own predictions as 'quasi-true' labels, as long as internal performance metrics

remain stable. This process could allow the model to adapt emerging degradation patterns and maintain high OC prediction quality over the pump's service life.

4.7. Proof of concept for Edge Deployment

Implementing the model directly on an embedded system enables a secure, self-contained "smart sensor". This study validates the deployment of the MLP model on a low-cost ESP32-S3 microcontroller (< 10 €). Although XGBoost showed slightly higher accuracy in certain analyses, the MLP was selected as it lends itself more readily to efficient conversion into C++ code. The final model architecture accepts 703 input features (700 base features and three operating parameters). It consists of 3 hidden layers with 238, 41, and 187 neurons respectively, and produces a single output using the tanh activation function.

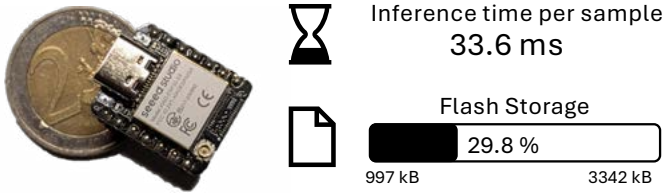

Figure 4.7 Validation of the 703-feature MLP model on a 10 €-ESP32 microcontroller: despite its complexity, the model occupies only 29.8 % of the storage and enables real-time predictions

For deployment, the optimized MLP model used in Section 4.4 (with knowledge of operating conditions) was converted to a C++ implementation via the ONNX format. Validation was performed by sending test samples to the microcontroller to measure real-world inference performance. As shown in Figure 4.7, the compiled code requires 997 kB, occupying only 29.8 % of the available flash storage. The average inference time is minimal at 33.6 ms per sample. This confirms that complex leakage prediction is viable on low-cost hardware.

5. SUMMARY AND OUTLOOK

This paper successfully demonstrated the foundational work for a low-cost, vibration-based "virtual sensor" for axial piston pumps and highly diverse operating conditions. The key findings are: 1) Predicting leakage flow for unknown fault types is only possible when the pump's operating conditions (OCs) are included as features. 2) These OCs (pressure, speed, and stroke) can be accurately predicted ($R^2 > 0.98$) using ML models from the same vibration signal. 3) This high accuracy is critically dependent on a robust training dataset that includes examples of various fault conditions; models trained only on healthy data fail to generalize. 4) The entire leakage flow prediction can be deployed on a low-cost (<10€) ESP32-S3 microcontroller with a minimal footprint (997 kB) and fast inference time (33.6 ms per sample), confirming its viability for edge computing.

The outlook for this work is focused on developing a fully autonomous, cascaded prediction system. This involves first predicting the OCs from the vibration signal (e.g., analytically calculating speed and using ML for pressure and stroke), and then feeding these predicted OCs into a second model to accurately estimate leakage. Future work will also explore more sophisticated feature engineering, such as using the heatmap analysis to define custom

frequency bands and combining the leakage prediction with anomaly detection for event recognition. Also feature types fit for leakage flow prediction may not represent the best features for OC prediction further motivating more in-depth feature engineering approaches. For a fully standalone system, calculating features directly on the microcontroller is essential. Future work will explore the ESP32-S3's dual-core design to run feature extraction and model inference in parallel. On a systemic level, the connectivity of modern microcontrollers opens the possibility of using Federated Learning (FL) a method where only model parameters, not raw data, are shared—to train robust models across a fleet of pumps without compromising data security.

6. ACKNOWLEDGEMENT

The presented research activities are part of the project “Causal Condition Monitoring von Verdrängereinheiten durch Verschleiß- und Schadensdetektion in Korrelation zur Betriebs- und Lastsituation” (Ref. No. 22012 BR/1). The authors would like to thank the Fluid Power Research Fund of the VDMA for the funding and support.

Simon Knoll

Simon Knoll graduated from the Technical University of Dresden in 2025 with a diploma degree in Mechanical Engineering, specializing in fluid power. During his studies, he focused on research related to the slipper–swashplate interface in axial piston pumps and using machine learning with sensor data to monitor pump conditions. He is currently working as a research assistant at the Chair of Fluid-Mechatronic Systems.

Svenja Horn

Svenja Horn received her diploma degree in Aircraft Construction from the Technical University of Dresden in 2018. Since then, she has been working as a research assistant at the Chair of Fluid-Mechatronic Systems, focusing on improving the efficiency and service life of axial piston pumps. Her research concentrates on tribological phenomena at the slipper–swashplate interface, which she investigates using simulations, a hydrostatic tribometer and pump measurements. Furthermore, she applies machine learning algorithms for pump condition monitoring and lifetime prediction.

Improved System Efficiency through Drained Case Operation of Axial Piston Units

Abstract

This article presents a drained case approach for axial piston units in mobile hydraulics to minimize splashing (churning) losses and enhance system efficiency. Utilizing a Venturi valve and existing flushing flows, the system evacuates an oil-air mixture from the motor housing without additional energy input. Experimental validation demonstrated evacuation times of 30–55 seconds and significant reduction in power loss. The solution is applicable with slightly modified standard hydraulic components and supports significant energy savings and lower operating costs in agricultural machinery.

Keywords: Hydraulic efficiency, axial piston units, splashing losses, mobile hydraulics, energy savings.

1. INTRODUCTION

The demand for increased efficiency and reduced CO_2 emissions in mobile machinery, such as self-propelled agricultural machines, has enabled innovation in hydraulic drive technology. Hydraulic drive technology is applied in open-circuit and closed-circuit arrangement to distribute the engine power throughout the machine and towards the point of power consumption. Some modern agricultural machinery – like the JAGUAR 1000 series in Figure 1 – makes significant use of this hydraulic power distribution.

Figure 1. JAGUAR 1000 - Hydraulic system and power distribution

All Open Access articles are peer-reviewed, distributed under the Creative Commons Attribution-Non Commercial 4.0 International

The cylinder-based work functions are supplied by the constant pressure hydraulics (CPH system) which is an open-circuit system which is supplied by a variable work pump at constant 205 bar pressure level. High-power motor-based work functions are implemented as closed-circuit hydrostatic transmission. In total, 4 closed-circuit hydrostatic transmissions are utilized on the JAGUAR 1000 – the ground drive and the feeder drive as well as the variable header drives 1 and 2. Axial piston hydrostatic pumps and motors – in swash plate and bent axis design – are integral to the implementation of closed-circuit transmission due to their reliability, robustness, and power density. Improvements in these critical components can lead to significant cost savings and environmental benefits which will help hydrostatic drives to compete in the market with electric alternatives.

However, splashing losses caused by the rotation of the internal components (rotational kit) in the oil-filled housings remain a significant source of inefficiency [1, 2]. Reducing power losses will prevent substantial heat dissipation into the oil and simplify the thermal management on the mobile machine. Draining the oil from the case of the hydrostatic components significantly reduces the power loss and is referred to as drained case operation at CLAAS. This paper examines the innovative system solution for drained case operation and minimized hydro-mechanical power losses in mobile machines as introduced to the market at Agritechnica 2025.

2. FUNDAMENTALS OF HYDROSTATIC TRANSMISSIONS

Hydrostatic pumps and motors are components which are design to convert mechanical power into hydrostatic power (pump) and back to mechanical power (motor). The hydrostatic transmission (HST) in Figure 2 combines pump (1) and motor (2) into a closed-circuit system that provides an infinitely variable ratio from the pump input shaft towards the motor output shaft. This closed circuit must be pre-charged via the charge pump (3), filter (5), relief (4) and charge valves (6) to reduce air content in the oil and thereby increase the stiffness of the drive. Heated oil is flushed from the system into the cooler (9) via flushing (7) and purge valve (8). High pressure relief valves (10) protect the system against overload. Due to the dual high-pressure lines, the HST can be operated in four quadrants – forwards, reverse, uphill, and downhill.

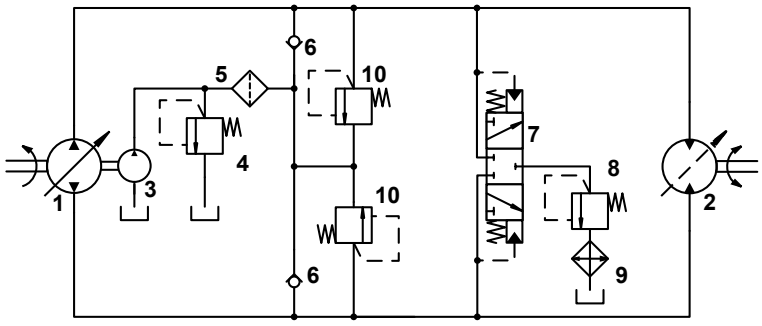

Figure 2. Hydrostatic transmission in closed-circuit system [3, 4]

Most of the hydraulic flow constantly circulates inside the closed-circuit system to transmit the hydraulic power from the pump to the motor. Consequently, the required exchange volume in the hydraulic tank is reduced and it can be designed smaller.

Axial piston units (pumps & motors) are complex components that are developed for efficient conversion of mechanical into hydraulic energy and vice versa. In mobile machinery the power of the Diesel engine is converted into hydraulic flow and pressure by the hydraulic pump. The hydraulic power is converted back to mechanical power and motion by the hydraulic motor. Axial piston units operate on the principle of axial movement, in which pistons slide dynamically within cylindrical bores, driven by a swash plate (pump) or by a bent axis (motor).

Losses in hydrostatic units are differentiated in volumetric and hydro-mechanical losses. While volumetric losses impact the flow of the hydrostatic unit, hydro-mechanical losses impact the torque. Splashing losses are caused by the rotation of the internal kit of the hydrostatic unit in the oil-filled housing (see Figure 3, left) and are considered part of the hydro-mechanical losses. These losses are strongly dependent on the rotational speed of the hydrostatic unit und reach significant values. Due to higher speed levels of hydrostatic motors, the splashing losses in hydrostatic motors are generally higher. Draining the oil from the housing (Figure 3, right) prevents the splashing and thereby eliminates the splashing losses in the hydrostatic unit.

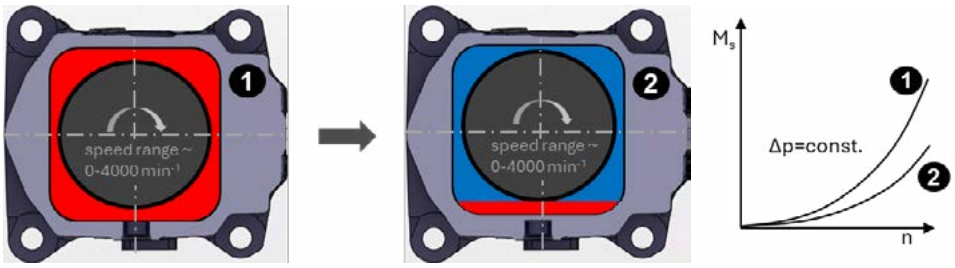

Figure 3. Sectional view of hydrostatic unit with full (1) and drained (2) housing

The introduced benefits of drained case operation are well known to the industry since many years [5]. The component suppliers can develop the hydrostatic units to allow drained case operation, but the OEM must develop a system solution around this hydrostatic unit to get drained case operation started. With the introduced system solution, the benefits of drained case operation outweigh the additional system cost.

In 2025, Grimme presented the outcome of a real-life study of drained case operation on a self-propelled beet harvester. The four motors of the hydrostatic ground drive are drained from oil by air from the compressed air system of the machine. There was no negative effect identified on the components or the hydrostatic system and the expected savings from test stand measurements were reproduced in real life on a real machine [6].

3. DEVELOPMENT OBJECTIVES AND TECHNICAL CHALLENGES

During the development of the JAGUAR 1000 series, new hydraulic functions had to be considered in the thermal management of the machine. It became obvious that drained case operation had to be implemented to control the losses in the hydraulic system. Further development of the serial solution for drained case operation on the CLAAS SCORPION telehandler allowed for reduction on the power losses.

Summary of the key requirements during the development:

- Integration into compact, cost-sensitive mobile hydraulic system
- Minimize splashing losses in standard hydrostatic components during field and road operation (close collaboration with supplier required)
- Leverage existing flushing flows in the Venturi nozzle to avoid additional power consumption
- Rapid and complete evacuation of the motor housing during operation
- Effective de-aeration of the evacuated oil to prevent cavitation and maintain lubrication in the hydrostatic units
- Compatibility with supplier specifications (e.g. temperature, pressure limits)

The following paragraphs will describe the implementation of the drained case solution in the CLAAS JAGUAR series.

4. DRAINED CASE OPERATION

Drained case operation minimizes splashing losses and leads to a more efficient machine operation. By implementing a suction and ventilation system, the hydrostatic unit can continuously drain fluid from the housing. Reduced thermal load on the system reduces the power needs for cooling of the hydraulic fluid.

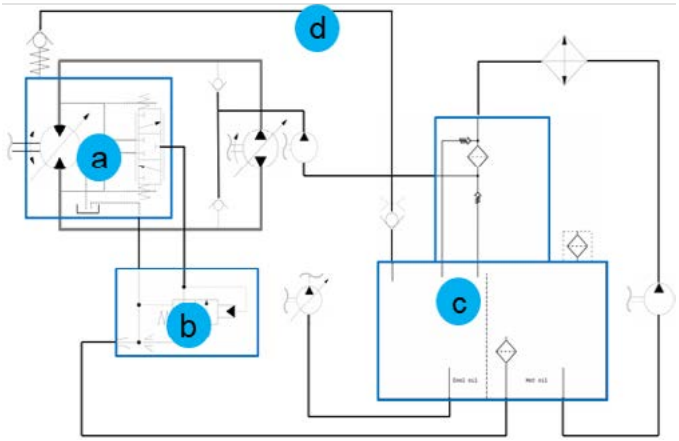

Figure 4. Conceptual schematic of the system solution for drained case operation

4.1. System Layout and Key Components

The system solution for drained case operation is introduced as a conceptual schematic in Figure 4. It becomes obvious that drained case operation cannot be supplied by a single supply, however it must be introduced by the OEM as system integrator.

The key components of the drained case system solution (see Figure 4):

- Hydrostatic motor (a) – Transforms hydrostatic to mechanical power in the closed-circuit transmission and is the source of splashing losses in standard design.
- Venturi nozzle (b) – Utilizes the loop flushing flow from the closed-circuit hydrostatic transmission as driving force for the suction from the hydrostatic motor.
- Hydraulic tank and filter system (c) – Separates the air from the hydraulic oil and allows for additional volume from drained hydrostatic motor.
- Ventilation system (d) – Essential for continuous suction of oil-air mixture from the hydrostatic motor.

A robust system solution requires an optimized alignment of components and performance parameters. The interaction between the different machine parts must be analyzed carefully and the required adjustments to the system must be carried out with care. The decision was taken that the Venturi principle shall be used to implement the drained case feature.

4.2. Hydrostatic Motor

The hydrostatic motor is an essential part of the closed-loop hydrostatic transmission and transforms the hydrostatic power into mechanical power which can be utilized in the ground drive or the header drive of the JAGUAR 1000. This main functionality remains intact, but the motor requires some adjustments to allow drained case operation.

The Venturi principle which was selected as the driving force for the evacuation of the housing requires a driving hydraulic flow as the power input to the nozzle. With the loop flushing in the hydrostatic motor, this driving force is already existing in the hardware of the hydrostatic motor. However, this flow must be re-routed from the motor housing to an external port to be connected to the Venturi nozzle.

Adjustments to the hardware and the operation conditions of the hydrostatic motor can only be realized in close cooperation with its supplier. For the initial implementation of the drained case operation, the HMV swash-plate variable motors from LHY were modified to fit the requirements – as single and dual variant. In particular, the motor also had to be prepared to be robust in drained case operation.

The following modifications to the HMV were necessary:

- Re-routing of loop flushing flow to an external port as input to the Venturi nozzle
- Evacuation port at the bottom of the unit (mounting position of Venturi nozzle)
- External flushing supply for the main bearings of the hydrostatic unit

Besides these modifications, test runs for the hydrostatic units were necessary to confirm temperature levels in drained case operation that lead to sufficient viscosity and lubrication in the key tribological interfaces. Figure 5 introduces a cut-away view of the hydrostatic motor which provides an impression of the rotating parts of the hydrostatic kit in the hydrostatic motor.

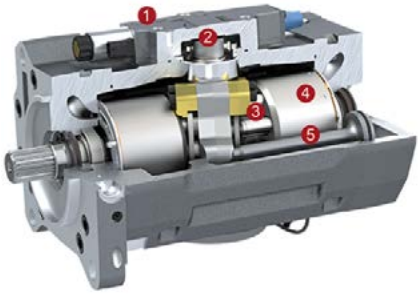

Figure 5. HMV swash-plate variable motor from LHY [7, 8]

4.3. Venturi Valve

The Venturi valve utilizes the Bernoulli effect to generate a suction effect from the loop-flushing flow which is leveraged to evacuate the hydrostatic units. Thereby enabling the evacuation without any additional energy input.

The Bernoulli effect states that the local pressure p_2 of a fluid decreases from the static pressure p_1 as the speed of this fluid increases from v_1 to the accelerated speed v_2. Purposefully increasing the speed of a fluid – e.g. by means of a nozzle – creates suction which is the working principle behind jet pumps. This effect is also well known in pump or valve design and can lead to cavitation as fast jets of fluid occur.

Accordingly, the pressure drop in the suction pressure p_2 versus the pressure in the driving flow p_1 is dependent on the speed of the fluid before (v_1) an after the nozzle (v_2) according to equation 4.1.

$$p_2 = p_1 - \frac{\rho}{2} \cdot (v_2^2 - v_1^2) \qquad (4.1)$$

With the continuity assumption for the hydraulic flow

$$v_1 \cdot A_1 = v_2 \cdot A_2 \qquad (4.2)$$

and the calculation of a round area

$$A = \frac{\pi}{4} \cdot d^2 \qquad (4.3)$$

the dependency on the diameter of the nozzle (d2) versus the diameter of the inlet of the Venturi valve (d1) becomes visible in equation 4.4.

$$p_2 = p_1 - \frac{\rho}{2} \cdot v_1^2 \cdot \left(\frac{d_1^4}{d_2^4} - 1\right) \qquad (4.4)$$

The effect of suction starts as soon as the suction pressure drops below the pressure in the housing of the hydrostatic unit. These assumptions are only valid for ideal, unobstructed, and frictionless flow which cannot be guaranteed in real life applications. Nevertheless, this is the basis for the development of the Venturi nozzle in the CLAAS application.

Figure 6 presents a schematic with the key characteristics of the Venturi valve which consists of the jet nozzle, the intake nozzle, the mixing chamber, and the diffusor. The main design parameters that were developed and confirmed by real experiments are labelled in the schematic. Another critical parameter is the flow rate and pressure in the driving flow from the loop-flushing valve of the hydrostatic motor.

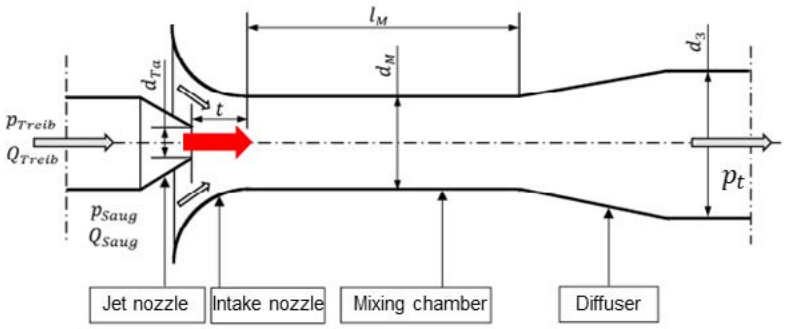

Figure 6. Schematic of the Venturi nozzle applied in the CLAAS Venturi valve

The key advancement in the presented system solution is the utilization of the existing loop flushing flow as the driving force for the suction effect – an efficiency improvement versus existing solutions in the market.

4.4. Hydraulic Tank and Filter System

The hydraulic tank serves as the reservoir for the pendulum volume of the hydraulic system which includes the volume resulting from draining the housings of the hydraulic motors. In the hydraulic system of the JAGUAR 1000, the tank is essential for filtration, thermal separation, as well as the de-aeration of the hydraulic fluid. Figure 7 shows a cut-away view of the tank (left) and the results of the CFD simulation that was performed to optimize the tank design.

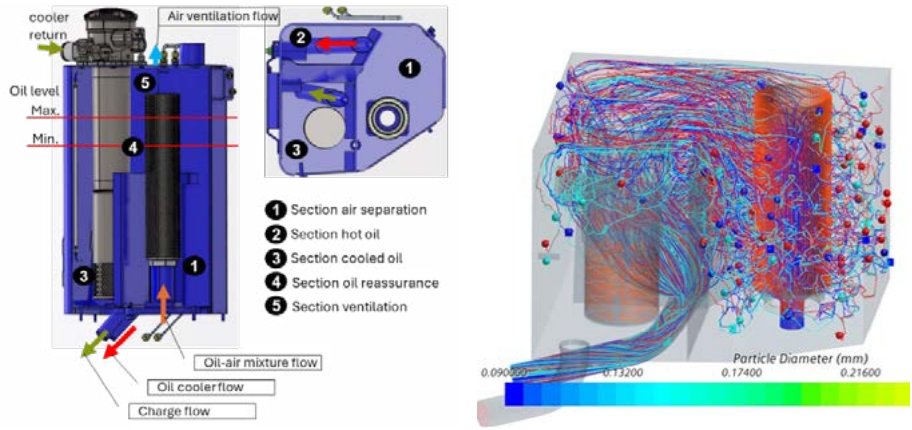

Figure 7. Desing of the hydraulic tank and visualization of CFD simulation

The drained oil-air mixture from the motor housings enters the hydraulic tank through the air separation element which the oil flow passes from bottom to the top in section 1 for the

air separation. After transition to the “hot oil” section 2 the oil it pumped through the oil cooler and returns into the tank via the filter element into the “cooled and cleaned oil” section 3. From this section, the flows for charging of the closed-circuit systems and the work hydraulics are taken. The connection port to the ventilation system (5) is in the cover plate on the top of the hydraulic tank. This port is kept free of oil to guarantee circulation of air in all operation conditions.

The design of the hydraulic tank was optimized for thermal management and de-aeration by means of CLAAS internal CFD simulations. The target for the de-aeration of the oil in the application is volumetric air content of less than 1%.

4.5. Ventilation System

When thinking about the drained-case solution, the need for the ventilation system of the motor housings is not obvious. For the continuous and fast suction of an oil-air mixture from the motor housings, the system must feed air back to the housings. In figure 8 this Venturi valve is mounted to the bottom drain port of the housing while the ventilation port is in the top of the housing.

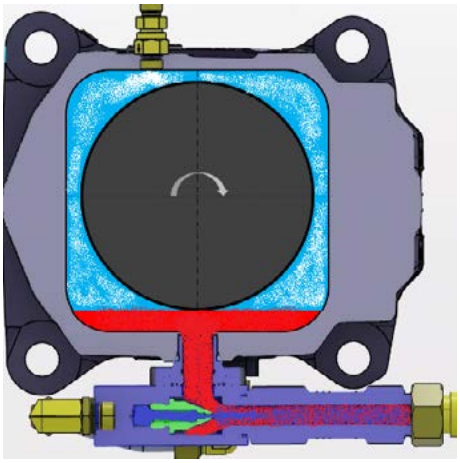

Figure 8. Cross section of drain motor with ventilation (top) and Venturi valve (bottom)

The illustration in figure 9 visualizes the ventilation system, the essential air circuit for the successful drained-case operation. The flow of air through the top port in the cover plate of the hydraulic tank is restricted by a check valve and a restricting orifice. With this restriction, the pressure level in the motor housings can be kept lower.

There is another pre-loaded check valve (0,2 bar) in the top of the motor housing to prevent any oil from entering the ventilation system. When oil enters the ventilation system, draining the motor housings is significantly delayed.

The oil-air mixture is drained from the motor housings by means of the loop-flushing flow for the closed-circuit hydrostatic transmission. The purge valve, included in the Venturi valve, secures the minimum pressure level on the low-pressure side of the closed-circuit system. The air is fed back to the hydraulic tank as oil-air mixture and is separated again in the separation element.

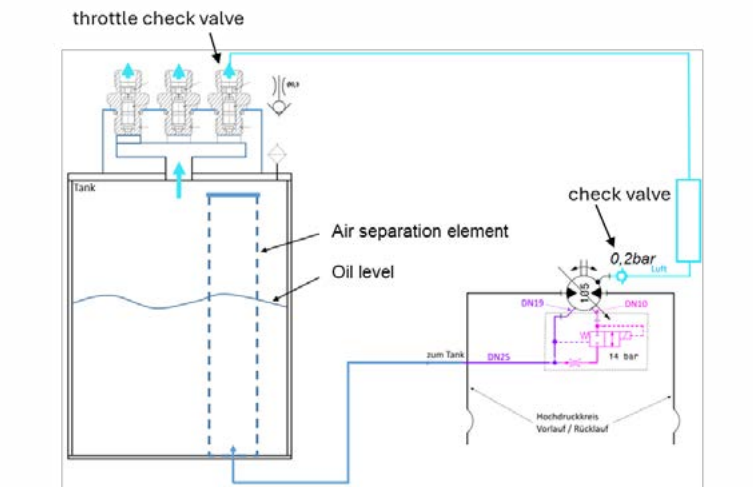

Figure 9. Illustration of the ventilation system for a single motor

The ventilation system is closed towards the environment to keep water, dust and other particles away from the hydraulic system.

5. System Integration in Mobile Machinery

The integration of the system for drained-case operation into a self-propelled forage harvester – or similar mobile machinery – requires careful design modification across various mechanical and hydraulic components. The interaction between these different machine parts – including pumps, motors, filters, and tank – must be analysed thoroughly before actions can be taken.

The introduced solution for drained-case operation is purely hydro-mechanical and does not require any electric actuation. Evacuation of the housings is initiated solely by the loop-flushing flow which starts as soon as sufficient pressure difference is build-up in the hydrostatic transmission. Temperature sensors and software is introduced only as monitoring system to prevent the operation outside of specified limits.

The various modifications to components require close collaboration with the respective suppliers of hydrostatic components, tanks, valves, and filtration system. The additional hydraulic lines of the ventilation system are the only modification which is visible for the outside. This modification requires additional design space on the machine and causes some additional system cost.

The assessment of the operating conditions of the machine is essential to determine the main sources for the heat load on the hydraulic system in critical situations. The data from telematics systems which is available today helps to identify the peaks loads on the cooling system. This way, the required modification and the additional system cost can be balances against other counter measures. Thoughtful introduction of the drained-case operation can lead to a competitive advantage in terms of efficiency and machine performance.

6. VALIDATION AND TESTING

Validation and extensive testing are critical to confirm the operational integrity and functionality of the system solution for drained-case operation. On the one hand, the system must fulfil the performance requirements. On the other hand, the system must be safe and reliable. Precise data acquisition for monitoring of pressures, speeds, temperatures, and fluid flows provided valuable insights into system performance.

For many years, the optimization of the Venturi nozzle was researched and implemented on development machines in the CLAAS hydraulics workshop. The main objective was the utilization of the loop-flushing flow as the driving force. Only this way, the benefits of drained case operation could lead to the required loss reductions on system level.

As mentioned before, the collaboration with our suppliers was essential for the success of the market introduction. The hydraulic motors had to be reliable in drained-case operation at high rotational speeds and pressure loads. Design modifications were confirmed in extensive test series which lead to the approval of the new CLAAS operation conditions. Some temperature thresholds in the monitoring system had to be adjusted based on the created experiences.

Machine level integration tests of the drained-case solution were necessary to confirm that the modifications had no negative impact on machine operation. For the ground drive, which is very relevant for the customer experience, a standard test series was executed with accelerations, decelerations, load changes, reversals, forwards and reverse driving. Finally, the system got approval for serial introduction.

During the testing, it was confirmed that an evacuation time of 30 to 55 seconds was reached by the system. Based on the dynamics in the thermal behaviour of a mobile machine, this duration is considered as “rapid”. Especially when considering the absence of any additional power consumption for the evacuation.

Additionally, the targeted savings in power loss of 5 to 10 kW per hydraulic motor were confirmed during the testing on machine level. This confirmed two things at once. The evacuation of the motor housing was complete and the expected savings from test stands could be reproduced in real machine operation.

Measurements of the volumetric air content in the oil behind the tank element for air separation confirmed a consistent value below 1%. The experience with this value and the required threshold for reliable machine operation was very limited at CLAAS and our suppliers. However, based on long-term validation runs on development machines it was concluded that the existing system design is well suited for the CLAAS lifetime requirement.

This final validation and testing also confirmed that the original development targets were achieved and fulfilled.

7. CONCLUSION AND FUTURE STEPS

This paper has described the transformation approach for reducing the power loss of a system with hydrostatic transmissions by means of a system solution for drained-case operation. The operation of the drained-case system is based on the Venturi effect. High velocity loop-flushing flow through the Venturi nozzle creates a low-pressure zone which is

sucking an oil-air mixture from the motor housing into the hydraulic tank. The air is fully separated from the oil in the tank and a volumetric air content below 1% is maintained. The results which were obtained in the testing and validation phase confirm the effectiveness of the drained-case operation in significantly reducing the hydraulic losses.

The drained case system demonstrated:

- Significant reduction in splashing losses in hydrostatic components
- Utilization of the existing loop-flushing flow which additional power consumption
- Reliable operation across all tested speed and load conditions
- Compatibility with standard hydraulic components and CLAAS machine system

As a conclusion it can be stated that drained-case operation of axial piston units offers a practical and effective method for improving the efficiency of hydraulic transmissions. It is particularly applicable for self-propelled agricultural machinery where space, cooling capacity, and cost constraints are critical.

The achieved savings in power loss of 5 to 10 kW per hydrostatic component (dependent on operation conditions) are sufficient to compensate for the additional system cost. Additional system cost is mainly created by the Venturi valve, the ventilation system, and the air separation element in the hydraulic tank. Reduced power loss translates directly into higher productivity of the agricultural machine and lower operational cost for the machine operator.

As the markets continue to focus on efficiency and fuel consumption, the assessment of power losses will be very relevant for future improvements on system level. The drained-case operation can be one contribution to the benefit of hydrostatic transmissions in the competition with alternative drive technologies.

Future work will focus on expanding the compatibility with various hydraulic components and exploring application in additional CLAAS machines. Efficiency modelling and evaluation of historic data for machine operation will support the introduction of drained-case operation to other machines and functions.

Abstract.

This paper presents the development and implementation of a real-time simulation model for the hydraulic implements of a wheel loader, with a focus on fault detection applications. The model replicates the behavior of the hydraulic system controlling the boom and bucket, incorporating components like load sensing pumps, control valves, and double-acting actuators. It was engineered for real-time performance without sacrificing accuracy, making it suitable for embedded systems. After the validation phase - performed using experimental data from a sensor-equipped wheel loader - the model was then deployed on an embedded platform, where it processes live sensor inputs and compares predicted actuator positions with actual measurements. Significant deviations can indicate faults such as leaks, wear, or sensor drift, allowing early detection and operator alerts. This approach enhances safety and reduces downtime. Ultimately, the model functions as both a virtual sensor and diagnostic tool, and its methodology is applicable to other electro-hydraulic systems promoting wider adoption of virtual simulation in off-highway equipment.

Keywords. Fault detection, real-time, digital twin, virtual model, off-highway equipment, hydraulics.

1. INTRODUCTION

Construction and off-highway machinery are becoming increasingly automated and sensorized, so simulation technology offers a powerful approach for enhancing operational reliability and predictive maintenance [1].

Fault detection in hydraulic systems, particularly for heavy-duty mobile machinery such as wheel loaders, is essential for ensuring operational reliability, safety, and productivity. The main fault detection methods [2] for mobile equipment and hydraulic systems can be classified as follows: Model-Based methods [3][4], which utilize mathematical or physical models to predict expected system behavior and detect faults by comparing measured signals with model outputs; Data-Driven methods [5][6][7], which employ statistical or machine-learning techniques to identify anomalous patterns in sensor data without relying on explicit physical models; Signal-Based methods [8][9], analysing time-domain or frequency-domain

All Open Access articles are peer-reviewed, distributed under the Creative Commons Attribution-Non Commercial 4.0 International

characteristics of pressure, flow or vibration signals; and Hybrid approaches [10], such as Digital Twin [11][12]frameworks that combine model-based and data-driven techniques by integrating physical models with real-time data.

In the frame of model-based fault detection methods, the main approaches are the following: Parity Equation-Based Detection [13] describes the use of parity equations (analytical redundancy) in mobile hydraulic systems to generate residuals and identify faults through threshold-based deviations; Nonlinear Observer with Adaptive Robustness [4] introduces a nonlinear adaptive robust observer addressing uncertainties and disturbances for detecting sensor faults, fluid contamination, and supply pressure deviations; Interactive Multiple Model (IMM) Filters [14] Applies IMM filtering with smooth variable-structure filters to detect and isolate friction and leakage faults in hydraulic actuators; Multi-Model Observer-Based Diagnosis [15] utilizes a bank of parallel models (observers) representing normal and fault conditions where the model with minimal output error indicates the current system state; Comprehensive Parity-Space and Observer Approaches [16] presents a unified treatment of observer-based residual generation, parity-space techniques, Kalman filters, and isolation strategies in a state-space framework.

Traditional maintenance approach on off-highway vehicles is time-based, that means preventive actions are scheduled regardless of the actual condition of the components [17][18]. Time-based approach relies on routine inspections and replacements, which can lead to unnecessary system downtimes and inefficiencies.

The target of this project is failure and predictive maintenance analysis and observation using a hard real time model integrated on physical vehicle electronic control unit (ECU) during standard manoeuvres. In this paper the focus is on the high-pressure circuit of a wheel loader, a heavy-duty construction machine equipped with a front implement used for digging, lifting and transporting bulk materials like soil, gravel, or debris.

In fluid power systems, the application of a failure detection systems can significantly enhance operational reliability, safety and productivity. These techniques can be implemented across various components such as pumps, valves, and motors, enabling early detection of wear or malfunction, preventing failures that could compromise safety.

The condition monitoring of single components inside a hydraulic circuit is described in many papers using different techniques. Raduenz et Al. in [19] describe a method for condition monitoring and fault detection on proportional valves based on spool position and supply current monitoring to detect deviations from healthy behavior, while Kumar et Al. in [20] investigated the condition monitoring of hydrostatic transmission by developing a detailed mathematical model of the system and the analysis of the effects of the loss gap that leads to state the pressure/flow deviation as a key indicator for the fault detection. Applications to hydraulic pumps can be found in [9] and [21]. In particular [9] investigates the use of wavelet analysis for real-time health diagnosis of hydraulic pumps, focusing on pulsation discharge pressure signals rather than vibration signals. Traditional methods (limit checking, spectrum analysis, logic reasoning) struggle due to high noise levels and low signal-to-noise ratios in pressure signals. The proposed method uses wavelet decomposition that provides sub-band signals with distinguishable features; patterns and amplitudes of wavelet coefficients correlate with defect types and this method works on-line in real time without affecting pump operation thus providing robust fault detection in hydraulic systems.

Paper [21] introduces a deep learning approach for anomaly detection in hydraulic piston pumps with demonstrated improvements in diagnostic accuracy. Additionally, in the context of wheel loader applications, [7] proposed a fault diagnosis of a Wheel Loader, but instead of using model based fault detection it exploits a hierarchical approach based on artificial neural networks (ANN) and fuzzy logic in order to identify the subsystem of the vehicle affected by the fault and the type of fault with inputs from 24 sensors.

Building upon this background, the present paper integrates model-based fault detection with a real-time embedded Digital Twin deployed on the vehicle's ECU. This hybrid strategy leverages both physics-based modeling and data-driven insights, thereby enhancing robustness and minimizing false alarms due to noise or disturbances. A time-counter mechanism further filters transient anomalies, ensuring that only persistent deviations above threshold levels trigger fault alerts.

In this activity, a dynamic model of the hydraulic circuit controlling the boom and bucket actuation was developed to simulate the subsystem's behavior under real operating conditions. The simulation model includes key elements such as Load Sensing (LS) pump, control flow valves, and hydraulic double acting actuators. The model was designed with real-time computational efficiency as a core requirement, without compromising model fidelity. This enables its deployment on embedded hardware ensuring responsiveness suitable for continuous monitoring in live operation.

To validate the model, experimental data were collected from instrumented wheel loader operating under various load conditions and duty cycles. Sensor data, including cylinder pressures, actuator displacements, and control inputs, were used to calibrate and correlate the simulation model. The simulation results demonstrate a good degree of correlation with the measured system behavior, confirming its suitability for use as a real time replica.

The correlated model was implemented on a real-time embedded computing platform. The model receives live input signals from the machine's onboard sensors and computes the expected positions of the boom and bucket in real time. This virtual output is continuously compared with actual position measurements of the actuators. Deviations between the predicted and measured positions provide a basis for fault detection. Differences beyond predefined thresholds may indicate potential faults such as hydraulic leakage, actuator wear, sensor drift, or electronic control system anomalies. By analysing these deviations, the system can notify the operator of emerging issues. This early fault detection capability enhances safety, reduces unplanned downtime, and contributes to the overall robustness of the machine.

The proposed solution thus acts as both a virtual sensor and a diagnostic tool in heavy machinery. The work demonstrates how physics-based modeling, when combined with real-time computation and sensor integration, can lead to significant advances in machine reliability. The methodology and implementation described in this paper are generalizable to other systems, not only electro-hydraulic, promoting wider adoption of virtual simulation in off-highway equipment.

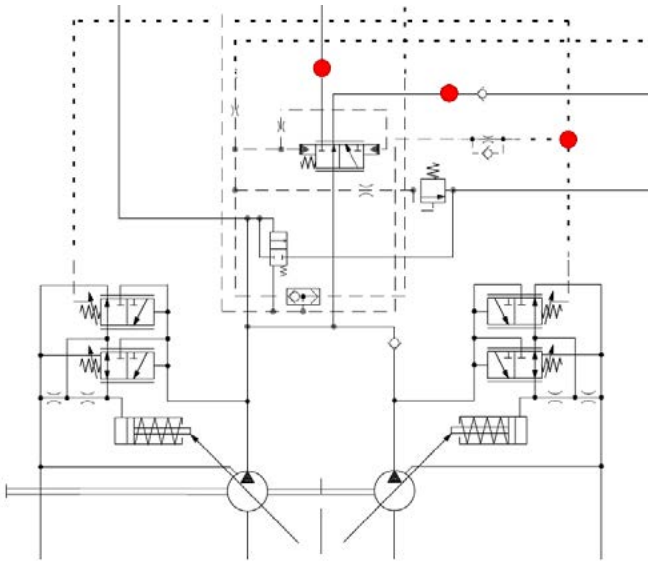
2. DESCRIPTION OF THE SYSTEM

2.1. Wheel Loader

The Wheel Loader considered in this work is a Case 821G, see Figure 2.1, which main characteristics are listed in Table 2.1.

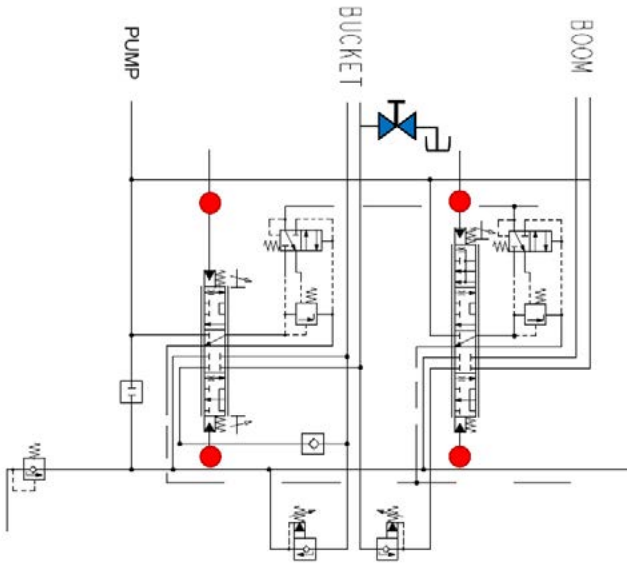
Figure 2.1. Wheel loader Case 821G

Table 2.1. Main vehicle features



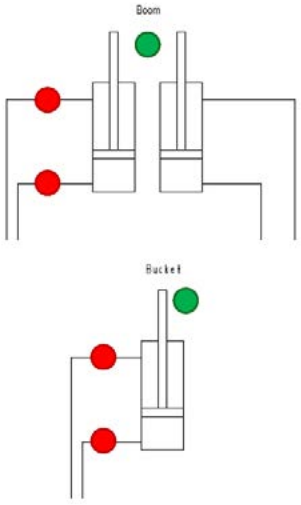
Maximum Engine Power	172 kW
Hydraulic Pump	Tandem, variable displacement
Maximum Oil Flow	236 l/min

2.2. Documentation



The following Documentation is the starting point for the work:

- Hydraulic Schematic
- Mechanical Design 3D drawings
- CAN Configuration
- Electric/Electronic Interface



The main parts of the high-pressure hydraulic circuit of the vehicle are shown in Figure 2.2.

(a)

(b)

(c)

Figure 2.2. ISO drawings of main components: (a) CCLS hydraulic twin pumps; (b) Directional valves; (c) Boom and bucket cylinders. Red dots indicate the position of pressure sensors; green ones the displacement sensors.

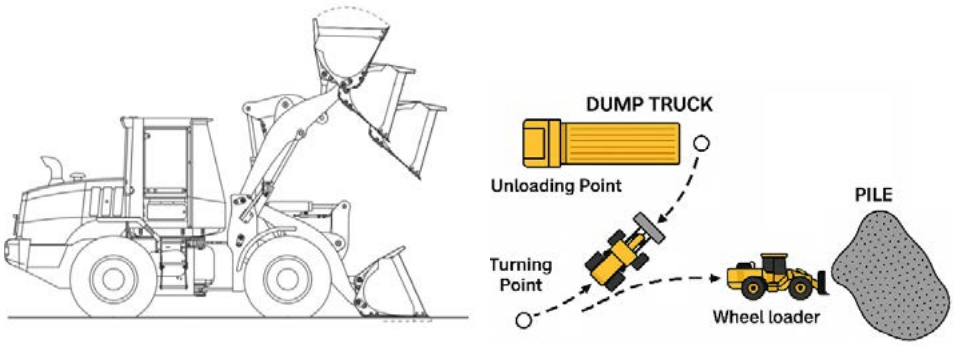
It is a Load Sensing system fed by two twin variable displacement pumps, that work with two slightly different values of pump margin to ensure the pumps works in sequence, Figure 2.2a. A priority valve is present to provide oil first to steering, the most critical function; the

excess flow goes to the implement, boom and bucket. In the case study vehicle, the boom has two cylinders, while the bucket just one, Figure 2.2c. Directional valves are placed to control the flow to boom and bucket, Figure 2.2b: they are hydraulic piloted valves, actuated by a pilot pressure signal provided by electronically controlled valves. These are actuated by the electric signal of the joystick and generate the correct pilot signal to move the spools of the directional valves. In this way, the movement of the driver can control the movement of the implement.

2.3. Procurement and Physical Installation

In order to acquire the needed measurements, the vehicle has been set up with sensor installation. Then a preliminary verification of possible installation issues is made, to ensure that the measurement equipment is correctly in place.

Several sensors were installed on the wheel loader; their position is indicated with a spot in Figure 2.2:



- Pressure sensors (red dots) to measure: boom and bucket pressure in both side of the cylinders; pilot pressure on directional valves, load sensing pressure and pump delivery pressure.
- Electric signals provided by joystick.
- Linear transducers (green dots) to measure the cylinders displacement of boom and bucket. Cable transducers were chosen since the displacement of the hydraulic cylinders is on the order of hundreds of millimeters, see Figure 2.3.

All vehicle CAN signals have been acquired. The sampling rate is 1000 Hz to capture even the fastest system dynamics.

Figure 2.3. Detail of bucket cylinder with displacement sensor installed.

The tests performed are aligned with the standard test procedure of Roading/Transport and Y Cycle. The Wheel Loader implement movements are schematized in Figure 2.4, see the Service Manual of CASE 821G and [22].

(a) (b)

Figure 2.4. (a) Wheel Loader implement movements. (b) Scheme of an Y loading cycle.

2.4. Physical Test

The next step is the physical test on the vehicle equipped with all the needed sensors. The test is led following a Test Procedure, which defines how to perform typical maneuvers such as Roading, Transport and Y Cycle, [22].

3. SIMULATION MODEL

3.1. Model Description

A model of the hydraulic circuit of vehicle has been developed in Matlab/Simulink environment, focusing on the hydraulic high-pressure circuit of front implement (Boom and Bucket). The model consists of the hydraulic power supply unit (Hydraulic Pumps), the pilot pressure valves, the directional valves and the implements actuators (Boom and Bucket cylinders), see Figure 2.2.

All components have been carefully parametrized by combining information obtained from component catalogs, suppliers, or by drawings from internal company documentation. Then the model has also been tuned to match the experimental data.

In more details, the pump model includes volumetric and hydromechanical efficiencies and the absolute and differential compensators are modeled to have a correct prediction of the swashplate angle and its related dynamics. The pump speed is an input to the model and it is calculated from the engine speed (available from CAN) as:

$$\omega_{Pump} = \omega_{Engine} \cdot R \tag{3.1}$$

where R is constant ratio of the pump drive.

The flow rate provided by the pump is calculated by the model as follows:

$$Q_{Pump} = \alpha \cdot V_d \cdot \omega_{Pump} \cdot \eta_v(\omega_{Pump}, \Delta p_{Pump}) \tag{3.2}$$

Where α is the fractional displacement of the pump, V_d the nominal displacement and η_v the volumetric efficiency expressed as a function of speed and pump differential pressure Δp_{Pump}.

The electronic valves that generate pilot pressure signals are pressure reducer valves: they reduce the upstream pressure of a low pressure line in order to maintain the desired pressure value to correctly pilot the directional valves. The model of such electronic valves contains the real software characteristics used in production to achieve the actual relation between joystick actuation and pilot pressure. During the simulation, the actual current signals – wired from the joystick - are used as input of this model subsystem.

The directional valves (including the post compensator) are modelled using the orifice equation:

$$Q_{Valve} = C_d \cdot A \cdot \sqrt{\frac{2 \cdot |\Delta p_{Valve}|}{\rho}} \cdot sign(\Delta p_{Valve}) \tag{3.3}$$

Where C_d is the discharge coefficient (assumed 0.7), A is the metering area, Δp_{Valve} the differential pressure and ρ the oil density. The metering areas of both the main spool and the compensator are provided by supplier to accurately calculate the flow rate across the valves. The differential pressure Δp is given by the difference between the pump pressure and the pressure signals of sensors on boom and bucket actuators.

The displacement of the boom/bucket cylinders is computed from the valve flow by:

$$x = \frac{1}{A_{Cylinder}} \int Q_{Valve}(t) dt \tag{3.4}$$

where $A_{Cylinder}$ is the area of the cylinder.

A picture of a portion of the Matlab/Simulink model is shown in Figure 3.1 with a focus on variable displacement twin pumps, directional valve, compensator and bucket cylinder.

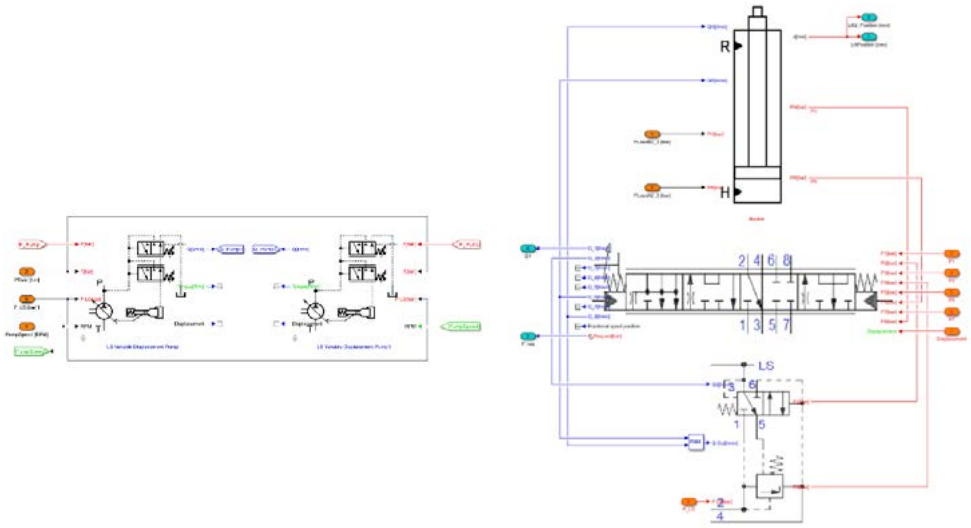


Figure 3.1. Sketch of Simulink model with twin LS pumps, directional valve, compensator and bucket cylinder.

3.2. Model Validation

The model was validated through experimental data, replicating a Y cycle. The graphs in Figure 3.2, show the comparison between experimental data and simulation results of the boom and bucket displacements over time. The y-axes are normalized using a reference value for confidentiality reason.

The correlation between the experimental and simulated curves is high enough for the fault detection purpose. Considering only the bucket and its rising phase, which is the movement studied in this work (falling phase is neglected for fault detection), the maximum deviation between the two curves does not exceed 5%. This deviation is small enough for the purposes of fault detection activity, confirming the robustness of the model and its ability to reproduce real-world behavior.

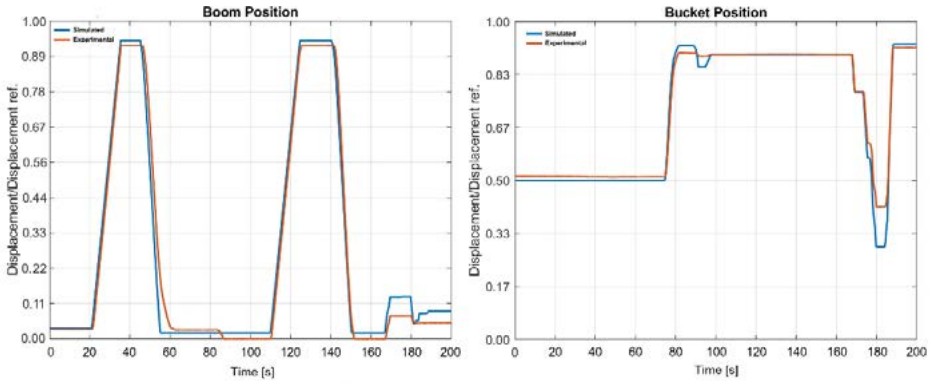

Figure 3.2. Comparison between simulation results and experimental data of Boom and Bucket position.

3.3. Hard Real Time Model on ECU

The validated Simulink model was first discretized then converted and deployed on the vehicle ECU by integrating it within the ECU software. The model in the ECU is able to run in real time and some checks have been done to verify that the results are the same as the Simulink model. The Figure 3.3 shows the bucket position over time, simulation in Simulink in dashed line and real time model with solid line.

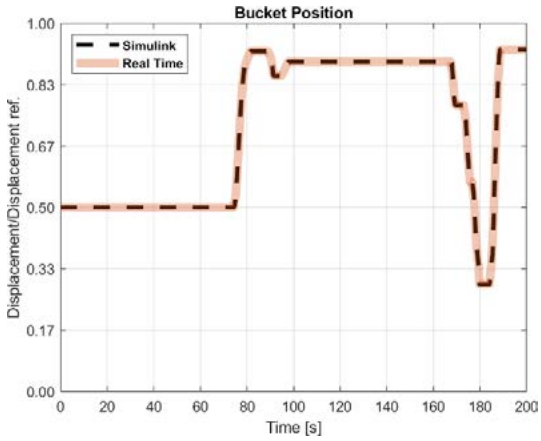

Figure 3.3. Comparison between Simulink simulation and real time model of bucket position.

4. FAILURE DETECTION

Most of the claims on Wheel Loader about the implement regard a slowdown of the cylinders and one of the root causes can be the external drain on Boom or Bucket.

4.1. Physical Test with induced Failure

The study focused on leakage failures because it represents the wear of various components inside the machine, such as directional valves, fittings and hose connections, as well as internal leakage of hydraulic cylinders due to seal wear. During the life of an off-highway vehicle, harsh working conditions and severe environments can lead to damage to some of these components.

In order to test if the mathematical model is able to recognize a possible failure an additional experimental activity was performed, inducing a slowdown only on the bucket. To achieve this, a 3-way valve was inserted in the circuit between the directional valve and the cylinder, Figure 2.2b, to drain oil to the tank so inducing a leakage in the circuit: in this way, a lower amount of oil is sent to the actuator and so the bucket movement is slower. Figure 4.1 shows a 3D image of the 3-way valve highlighted by a circle placed on the bucket hose.

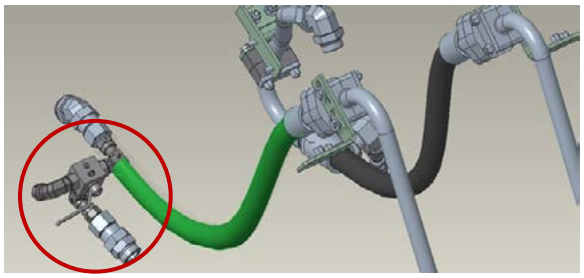

Figure 4.1. CAD representation of 3-way valve positioned on the bucket hose.

The effect of the induced external drain leads to a slower movement of the bucket. To test the model accuracy, several valve openings were set to achieve different bucket speed variations, representative of the cases that can occur during the useful life of the machine. Therefore, the valve opening was set by monitoring the average bucket cycle time on a Y-cycle. In this section, the results are shown for two limit cases according to internal criteria. Taking as reference the simulation output of the bucket position in healthy condition, when a high drain is set then the cycle time increases up to 80% of the lifting time; when a small drain is set then the cycle slowdown is lower and the cycle time increase is about 10% of the lifting time, see Figure 4.2 where axes are normalized using a reference value for confidentiality reason.

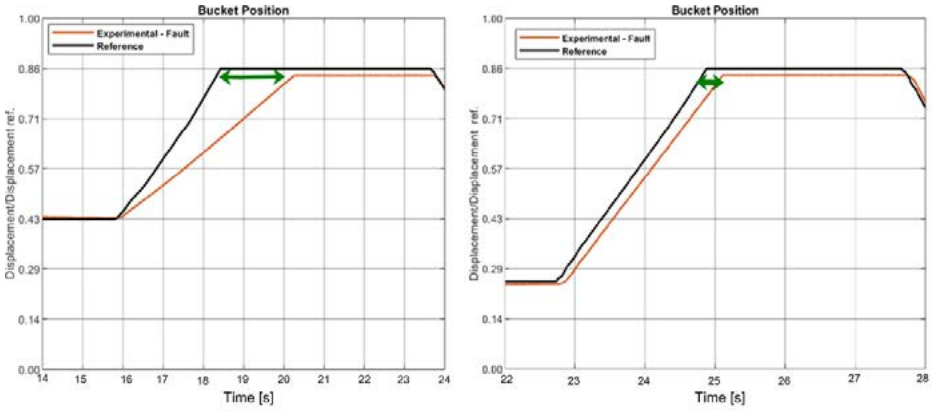

Figure 4.2. Bucket position in case of high and low drain with respect to healthy condition.

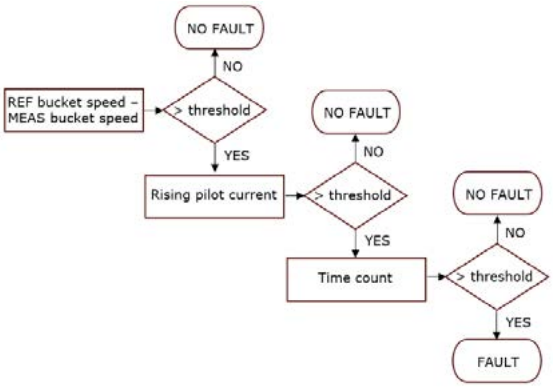
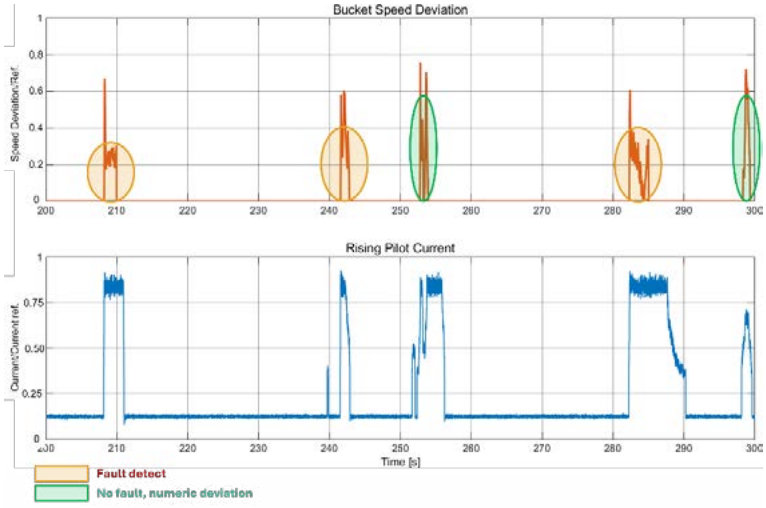
The fault detection algorithm checks the kinematic of the bucket between experimental measurement and the simulation results of the Hard Real Time Model. A flowchart of the algorithm is shown in Figure 4.3. When a deviation in the speed of the bucket movement is detected, the algorithm is able to assess whether this is happening during the bucket actuation by monitoring the rising pilot current. The procedure also checks the time interval of the deviation with respect to the manoeuvre time (obtained by the pilot current): this prevents that numerical speed deviations trigger a fault detection. Monitoring the speed instead of the position of the actuator, leads to a higher accuracy since any position offset due to numerical deviations of the model are neglected therefore avoiding false positives in fault detection. Threshold values were estimated accordingly internal criteria and are confidential.





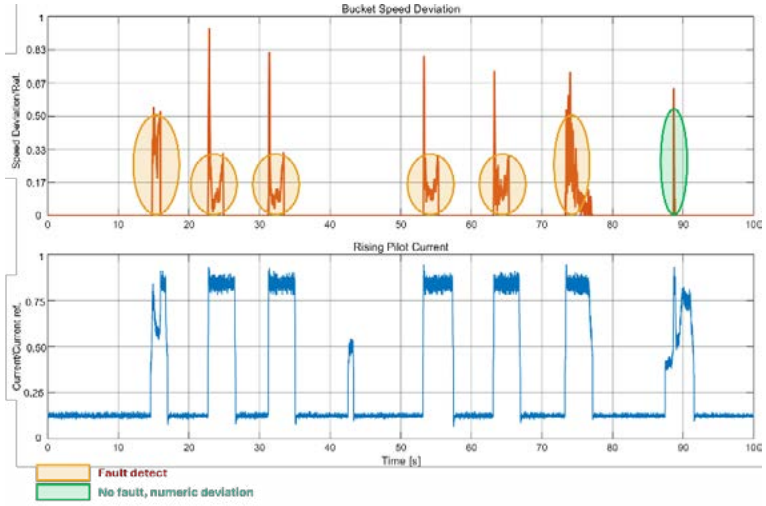


Figure 4.3. Flowchart of fault detection algorithm.

The tests are presented in two conditions: high and low drain. Figure 4.4 (a) shows the plot of the bucket speed deviation together with the rising pilot current (linked to the manoeuvre time) in the high drain condition while (b) is related to the low drain condition. The external drain valve has a constant opening during the entire manoeuvre. The described algorithm detected the faults in correspondence of the parts of the signal highlighted within the yellow

circles, since both the speed deviation and the rising pilot current time thresholds are reached. The speed deviations highlighted with green circles are due to numerical deviations and are not detected by the algorithm because the rising current time threshold is not reached.

(a) High drain condition

(b) Low drain condition

Figure 4.4. Bucket speed deviation together with the rising pilot current in the high drain condition (a) and in low drain condition (b).

The study was limited to the bucket cylinder: once verified the effectiveness of the proposed approach in detecting faults in a hydraulic circuit, the methodology can be extended to the boom cylinder as well. Considering the study of a single actuator allowed to reduce the experimental tests, which are the most expensive part from an industrial perspective, without losing the generality of the methodology. Since the methodology proved promising, the

aspiration is to extend the analysis to a greater number of actuations and a wider range of fault types.

5. CONCLUSION

This paper presented the exploitation of a real time model deployed on real ECU of a wheel loader for fault detection purposes. The development and implementation of a real-time simulation model for the hydraulic implements of a wheel loader is the basis to replicate in real time the behaviour of the healthy system.

The proposed model is deployed on a real-time embedded computing platform, acquiring live data from onboard sensors to estimate boom and bucket positions. These estimates are continuously compared against measured actuator positions. Deviations exceeding predefined thresholds serve as indicators of potential faults, including hydraulic leakage, actuator degradation, sensor drift, or control system anomalies. This model-based fault detection framework enables early anomaly identification, enhancing operational safety, reducing unscheduled downtime, and improving system reliability.

Fabio Scolari received the bachelor's and master's degree in mechanical engineering in 2016 and 2018 respectively, and the PhD in Industrial Engineering in 2022 from University of Parma, Italy, with a dissertation on tribological improvement of hydraulic pumps with texture surfaces. He is currently working as system modelling engineer at CNH. His research areas include simulation, hydraulic system modelling, fuel economy analysis, high performance systems in off-highway vehicle applications.

Federica Grossi received the bachelor's and master's degree in electronic engineering in 2003 and 2006 respectively, and the PhD in Electronics and Telecommunications in 2010 from University of Modena and Reggio Emilia, Italy, with a dissertation on dynamic modelling and control of hybrid vehicles. She is currently working as senior system modelling engineer at CNH. Her research areas include modelling, simulation, software development, fuel economy analysis, high performance systems in automotive and off-highway vehicle applications.

Francesco Pintore received the bachelor's and master's degree in mechanical engineering and the Ph.D. in High Mechanics and Automotive Design & Technology from University of Modena & Reggio Emilia, Italy. He is Manager of High-Performance System Simulation at CNH. He is responsible for High Fidelity 0D/1D model development, looking on entire vehicle performance evaluation, interfacing and providing modelling support to multiple Teams across CNH. He is also responsible for interfacing Modelling Team with electrification, Hydraulics, Driveline and Powertrain Teams across the Company's entire agriculture and construction product portfolio.

Ciro Mariniello received the master's degree in Automation Engineering from University of Sannio in 2011. He started to work in 2011 as Control system engineer with Segula as a resident engineer in Magneti Marelli, in 2012 he started to work in CNH as system modelling engineer, in 2013 he became System modelling European manager. Currently working as System modelling & Dynamic simulator Manager within DA&S Department in CNH.

Enhancing Energy Efficiency in Drilling: Innovative Pipe Handling with Hydraulic Energy Recovery

Abstract.

Geothermal drilling operations involve frequent lifting and lowering of heavy tubulars, making pipe handling one of the most energy-intensive rig subsystems. In conventional designs, the gravitational potential energy released during lowering is dissipated as heat through throttling valves. This paper presents a novel hydraulic energy-recovery concept that integrates a load-compensation cylinder and a gas-charged accumulator to capture and reuse this otherwise wasted energy. The system architecture was modelled in Siemens Amesim, and parametric studies were conducted to optimize accumulator pre-charge and volume. Simulations predict energy-recovery efficiencies up to approximately 70% per lifting cycle, with corresponding reductions in hydraulic-power demand. A prototype was implemented on a Herrenknecht vertical rig and verified during factory acceptance tests, which demonstrated substantial reductions in operating pressure from about 176 bar to 99 bar when compensation was active confirming the predicted load-sharing effect. The concept provides a compact, retrofit-capable solution for improving the energy efficiency of hydraulic pipe-handling systems and offers a practical pathway toward reduced rig-level power consumption and enhanced sustainability in geothermal drilling operations.

Keywords. Hydraulic energy recovery, pipe handling, accumulator, load compensation, tripping, drilling energy efficiency.

NOMENCLATURE

E_{dead}	Mechanical energy required to move the handler's dead load [kJ]
E_{comp}	Mechanical energy contributed by the compensation system [kJ]
E_{uncomp}	Uncompensated residual energy supplied by the HPU [kJ]
$E_{acc,usable}$	Usable accumulator energy (isothermal approximation) [kJ]
$E_{rec,available}$	Available recovered energy after hydraulic losses [kJ]
η_{Comp}	Compensation efficiency = $E_{Compensated}$ / $E_{Required}$

All Open Access articles are peer-reviewed, distributed under the Creative Commons Attribution-Non Commercial 4.0 International

η_{hyd}	Hydraulic round-trip efficiency
p_0	Accumulator pre-charge pressure [bar]
p_1	Accumulator minimum working pressure [bar]
p_{max}, p_{min}	Maximum and minimum accumulator pressures [bar]
V_0	Accumulator effective gas volume [L]
F(h)	Cylinder force as a function of displacement [N]
h	Cylinder stroke displacement [m]
P_{hyd}	Hydraulic power [kW]
Q	Volumetric flow rate [L/min]
η	Overall efficiency factor
N	Number of pipe joints handled per bit change

1. INTRODUCTION

Geothermal and other deep-well applications are gaining renewed importance as global energy policy and security concerns accelerate investment in dispatchable, low-carbon energy sources. Among all drilling activities, the tripping process 'repetitive lifting and lowering of heavy tubulars' remains one of the most energy-intensive operations on a drilling rig. In conventional hydraulic systems, the gravitational potential energy released during lowering is dissipated as heat across throttling valves, resulting in substantial energy loss and increased cooling demand.

To address this inefficiency, the present work investigates a hydraulic energy-recovery subsystem integrated into a horizontal pipe handler. The subsystem captures the energy released during lowering operations and reuses it to assist subsequent lifting cycles. A nitrogen-charged hydraulic accumulator, connected via a dedicated compensation cylinder and control block, temporarily stores hydraulic energy that would otherwise be wasted. This stored energy is then discharged to support the boom cylinder during lifting, thereby reducing the load on the hydraulic power unit (HPU).

The overarching goals of this research are threefold:

1. Quantify the energy requirements of typical pipe-handling cycles and determine the recoverable portion through simulation and testing.
2. Evaluate the effectiveness of the accumulator-based compensation system in reducing mechanical and hydraulic power demand.
3. Validate the simulation results through factory acceptance testing (FAT) and establish a framework for future on-rig performance measurements.

The proposed concept supports broader industry efforts to improve rig-level energy efficiency, reduce emissions, and enable hybridization of hydraulic subsystems with electrical energy-storage technologies. By focusing on a modular retrofit-capable component, the pipe handler this approach provides a practical step toward measurable sustainability gains in geothermal drilling operations.

2. LITERATURE REVIEW

Energy recovery in hydraulic systems is well established in mobile and construction machinery, particularly for applications involving cyclic lifting and lowering motions. In such systems, gravitational potential energy released during lowering is often dissipated as throttling losses. Accumulator-based energy regeneration concepts have been shown to capture this energy and reuse it during subsequent lifting operations, thereby reducing peak actuator loads and instantaneous hydraulic power demand [1]. While high levels of energy recovery can be achieved locally at actuator level through accumulator-assisted regeneration, net system-level energy savings are strongly influenced by hydraulic losses, control strategy, and the proportion of non-compensated operating phases. Experimental and simulation studies show that integration effects limit the direct translation of local recovery ratios into overall reductions in hydraulic power-unit energy demand [2]. In industrial practice, accumulator-based systems are commonly applied for peak shaving and short-term energy buffering, particularly in excavators and cranes, where appropriate control strategies have demonstrated measurable reductions in fuel and electrical energy consumption [3].

For drilling applications, several studies have adapted energy recovery concepts to hoisting and tripping operations. Quan et al. [4] and Zhang [5] demonstrated potential-energy recovery in drilling rigs to reduce motor power demand during lifting; however, these approaches primarily addressed large-scale vertical hoisting systems and did not consider compact, high-cycle pipe-handler mechanisms typical of modern geothermal drilling rigs. More recent research has expanded toward system-level energy management and hybrid drilling-rig architectures. Chupin [6] reported diesel-consumption reductions of 20–30% through integrated energy storage and optimized generator scheduling, highlighting the importance of system-level coordination rather than isolated subsystem optimization. Beyond individual subsystems, improving energy efficiency has become a strategic objective in geothermal drilling operations, driven by operational cost and sustainability considerations [7], [8]. Operational studies further indicate that tripping efficiency and fuel consumption significantly affect overall rig performance and cost structure [9], [10].

3. SYSTEM DESIGN

This section describes the design and functional architecture of the pipe handler equipped with an integrated hydraulic energy-recovery subsystem. The design objective is to minimize the net energy demand on the HPU by recovering gravitational potential energy during lowering and reusing it to assist lifting operations.

3.1. Design Objectives

The main design goals were defined as follows:

- Capture and store gravitational potential energy during the lowering phase of trip-out operations.
- Reuse stored energy to assist lifting during trip in operations, reducing instantaneous HPU demand.

- Maintain full operational safety, controllability, and compatibility with existing pipe-handler geometries.
- Enable compact integration or retrofit within the envelope of standard geothermal pipe-handling systems.

3.2. Functional Description

The horizontal pipe handler is an automated handling system used on geothermal drilling rigs to lift, rotate, and position tubulars such as drill pipes, casing, and tubing between the catwalk and the well centre. A typical handling cycle involves lifting a horizontally positioned drill pipe (up to 13.72 m length and 4500 kg mass), rotating it to a vertical orientation, and handing it over to the top drive within a single operating sequence.

For such operations, Figure 3.1. shows a representative force diagram of compensation relative to the force required to support the pipe handler dead load, with and without an additional pipe weight. The area under the curve corresponds to the potential energy that can be recovered during lowering.

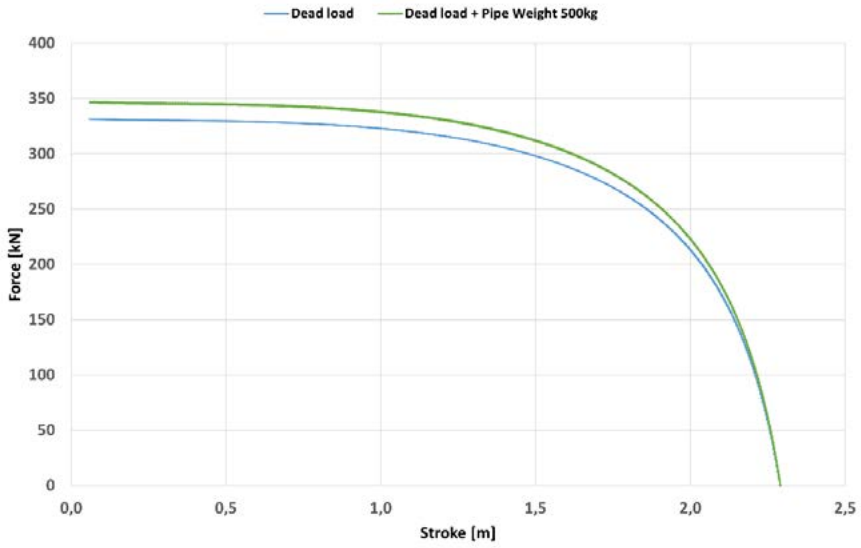

Figure 3.1.: Required Force Diagram of Compensation Cylinder

3.3. Functional Architecture

The pipe-handling system comprises a mechanically coupled boom assembly with hydraulically independent lifting and compensation circuits, as illustrated in Figures 3.2 and 3.3. The primary lifting and lowering motion are provided by the boom cylinder (1), which is driven directly by the hydraulic power unit (HPU, 6) and equipped with load-holding valves to ensure secure positioning in the event of pressure loss. In parallel, two load-compensation cylinders (2) are mechanically coupled to the boom frame but hydraulically decoupled from the HPU and instead connected to a nitrogen-charged accumulator (3) via a dedicated control manifold (4).

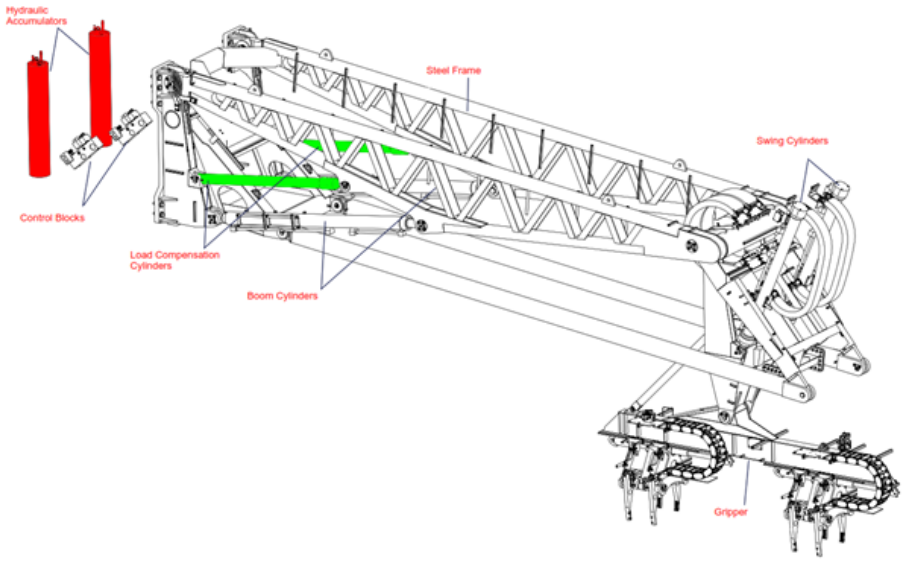

Figure 3.1.: Novel Pipe Handler with load Compensation Cylinder

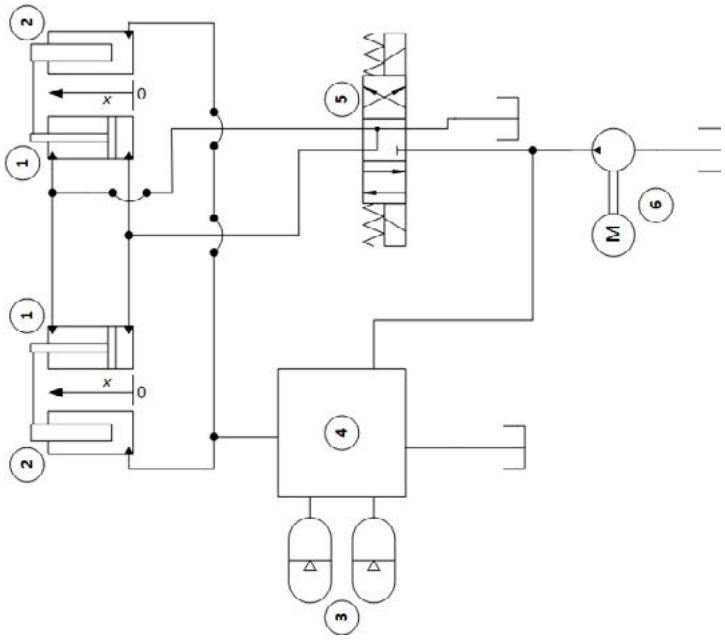

Figure 3.3.: Hydraulic Schematic Novel Pipe Handler

During lowering, hydraulic energy is transferred to the accumulator through compression of the nitrogen gas, while during subsequent lifting this stored energy is released to support the boom cylinder and reduce peak HPU power demand. The control block (5) regulates

hydraulic flow between the compensation cylinders and the accumulator and incorporates directional, check, and relief valves to manage energy transfer, provide over-pressure protection, and isolate the compensation circuit when inactive.

3.4. System Coordination and Monitoring

System operation is monitored using standard pressure and position sensors, providing feedback on cylinder and accumulator pressures as well as boom position relative to the well centre. These signals are processed by a programmable logic controller (PLC), which sequences valve operations, coordinates accumulator charging and discharging, and establishes interlocks with external handling systems. This coordinated control enables repeatable motion and controlled energy exchange during cyclic tripping operations, resulting in reduced instantaneous HPU power demand over successive cycles.

4. ENERGY RECOVERY MECHANISM

The proposed hydraulic energy-recovery mechanism operates cyclically through two complementary phases - lowering capture and lift assist - across the two primary operational modes of the pipe handler: Trip In (running pipe into the well) and Trip Out (removing pipe from the well). Each Trip consists of two sub-cycles, one loaded and one unloaded, forming a complete energy-exchange loop between the boom cylinder, the load-compensation cylinder, and the hydraulic accumulator.

4.1. Trip In: Lifting Loaded, Lowering Unloaded

During Trip In, the handler performs two sequential motions:

Cycle part 1 – Lifting loaded: The handler lifts the dead load plus a pipe segment from the catwalk to the well centre. In this motion, the accumulator discharges previously stored hydraulic energy into the compensation cylinder, producing an assisting force that reduces the effective pressure required in the boom cylinder. This lowers the hydraulic power demand from the HPU and results in smoother lifting dynamics.

Cycle part 2 – Lowering unloaded: After transferring the pipe to the well centre, the handler returns to the catwalk carrying only its dead load. During this lowering phase, the compensation cylinder retracts, forcing hydraulic fluid into the accumulator and re-charging it. Gravitational potential energy from the handler's structure is thus converted into stored hydraulic energy, preparing the system for the next lifting sequence.

4.2. Trip Out: Lowering Loaded, Lifting Unloaded

The Trip Out process follows the inverse energy flow:

Cycle part 1 – Lowering loaded: The handler lowers a pipe segment from the well centre to the catwalk, supporting the combined dead load and pipe mass. The boom cylinder retracts under load while the compensation cylinder directs fluid into the accumulator. The

gravitational energy of the pipe and structure is stored as compressed gas energy rather than dissipated as throttling losses.

Cycle part 2 – Lifting unloaded: Once the pipe is placed on the catwalk, the handler returns to the well centre with only the dead load. The accumulator assists this motion by releasing part of its stored energy into the compensation cylinder, thereby reducing the required boom-cylinder pressure and the hydraulic energy drawn from the HPU. This balanced exchange closes the energy loop for the Trip Out sequence. Summary of Trip cycles and energy flow is presented in Table 4.1.

4.3. System-Level Control and Energy Flow

Over consecutive trips, this alternating sequence of accumulator charging (during lowering) and discharging (during lifting) maintains a nearly steady-state energy balance.

The control block governs this exchange by routing hydraulic flow between the compensation cylinder and the accumulator while preventing over-pressurization. Check and relief valves ensure that accumulator charging is smooth, and that stored energy is released only during commanded lift phases. The result is a cyclic reduction of peak HPU power and smoother hydraulic operation with less throttling loss.

Operation	**Cycle**	**Motion**	**Load Condition**	**Accumulator Energy Flow**
Trip In	Cycle part 1	Lift (Catwalk → Well Centre)	Dead load + pipe	Discharge – assist lift
	Cycle part 2	Lower (Well Centre → Catwalk)	Dead load only	Charge – recover energy
Trip Out	Cycle part 1	Lower (Well Centre → Catwalk)	Dead load + pipe	Charge – recover energy
	Cycle part 2	Lift (Catwalk → Well Centre)	Dead load only	Discharge – assist lift

Table 4.1.: Summary of operational cycles and corresponding energy flow in the pipe handler

4.4. Interpretation

In this sequence, each complete Trip In or Trip Out operation alternates between an energy-storage and an energy-release phase. The oil level in accumulator is maintained within the designed range (p_0 to p_1) by the control block & PLC, ensuring consistent assistance during loaded lifts and safe capture during lowering phases. Over multiple trips, this results in lower HPU energy demand, smoother motion, and measurable reductions in overall hydraulic consumption compared with conventional systems.

5. MODELING, SIMULATION, AND VALIDATION

5.1. Simulation Model

A detailed component-level model was implemented in Siemens Amesim to analyze the dynamic behaviour of the hydraulic load-compensation subsystem. The model incorporated nonlinearities of the accumulator gas law, valve pressure drops, and cylinder dynamics. Parametric sweeps were carried out to optimize accumulator pre-charge, volume, and valve sizing.

Representative input parameters used in the simulations are:

Parameter	**Value**
Boom-cylinder effective area	0.012 [m²]
Boom-cylinder stroke	3.2 [m]
Compensation-cylinder effective area	0.012 [m²]
Compensation-cylinder stroke	2.2 [m]
Typical handled joint mass	500 [kg]
Structural dead load (self-weight)	18,000 [kg]
Accumulator nominal volume	120 [L]
Ambient temperatures tested	–5 [°C], +20 [°C] , +40 [°C]

Table 5.1.: Simulation Parameters

The performance indicator was the compensated-energy fraction, defined as the ratio between energy supplied by the compensation subsystem and the total mechanical energy required by the handler.

The mechanical work during one pipe-handling cycle is obtained by integrating the measured or simulated force–displacement curve:

$$E_{work} = \int_{h_0}^{h_1} F(h)dh \qquad (5.1)$$

For discrete data, the trapezoidal approximation was applied:

$$E_{work} \approx \Sigma_{i=1}^{n-1} \left(\frac{h_{i+1} - h_i}{2}\right)(F_i + F_{i+1}) \qquad (5.2)$$

The accumulator's usable isothermal energy between minimum and maximum pressures is expressed as:

$$E_{acc,usable} = p_0 V_0 \, ln\left(\frac{p_{max}}{p_{min}}\right) \qquad (5.3)$$

Accounting for hydraulic round-trip efficiency η_{hyd}:

$$E_{rec,available} = \eta_{hyd} \cdot E_{acc,usable} \qquad (5.4)$$

The compensation efficiency is then:

$$\eta_{Comp} = \frac{E_{Compensated}}{E_{Required}} \qquad (5.5)$$

5.2. Simulation Results

The total energy required for pipe handling was computed by numerical integration of simulated force-displacement curves (Equation 5.1). All results are expressed in SI units (N, m, J, kJ).

Dead-Load Work

From the measured boom-cylinder dead-load curve:

$$E_{dead} = \int_{h_0}^{h_1} F_{dead}(h)dh = 625.2\ kJ$$

This value represents the total mechanical work per cycle that must be supplied by the HPU when the compensation system is inactive.

Compensation Simulation and Temperature Dependence

Parametric simulations with optimized accumulator pre-charge p_0 generated compensation-cylinder force profiles for several ambient temperatures (Figure 5.1.).

The variation in compensation force with ambient temperature arises from the thermodynamic behaviour of the nitrogen-charged accumulator. For a given pre-charge pressure and volume, higher temperatures lead to higher gas pressure levels, resulting in increased compensation forces, while lower temperatures reduce the available force accordingly. The observed hysteresis between the lifting and lowering curves is primarily caused by heat transfer between the gas and the ambient air. The small discrete force steps near the end positions of the stroke originate from valve cracking pressures, numerical switching of control elements in the simulation model, and damping effects at the mechanical stroke limits. These effects are inherent to realistic hydraulic systems and are intentionally retained in the model to reflect non-ideal operating behaviour.

For the selected operating point at +20 °C, the integrated work areas under these curves (Figure 5.2., Figure 5.3.) yield the remaining uncompensated energy E_{uncomp} that the HPU must supply when compensation is active.

In these simulations, the integrated energy segments E_A+E_B+E_C correspond to the mechanical work that remains to be supplied by the HPU after the compensation system has acted.

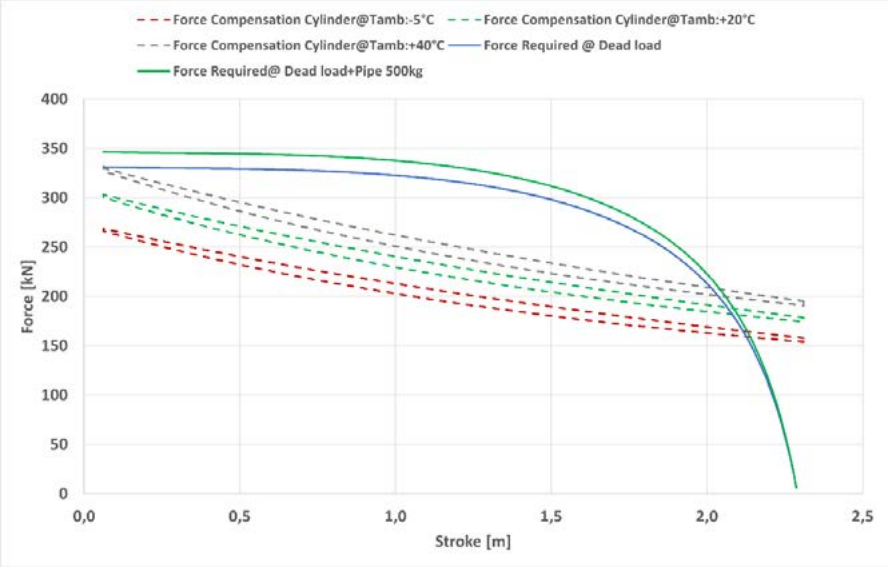

Figure 5.1.: Simulated compensation cylinder Force vs Stroke for varying ambient temperature

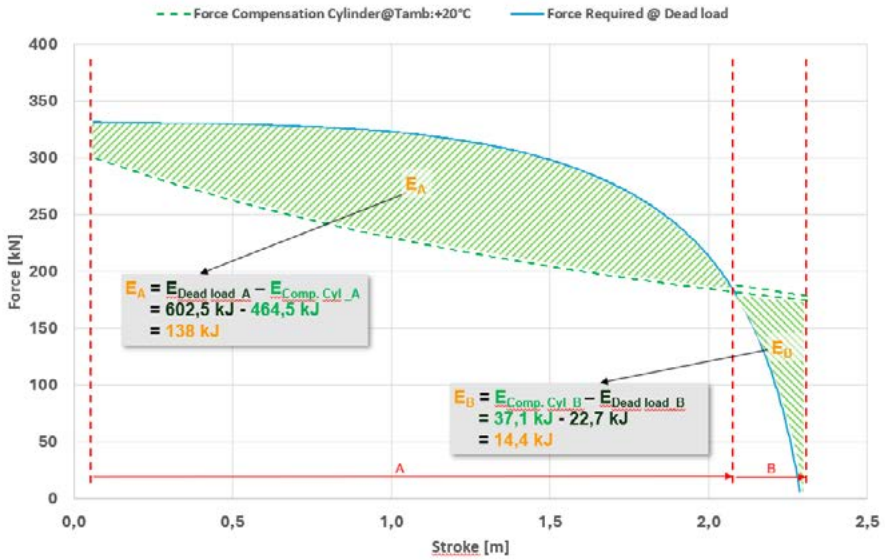

Figure 5.2.: Lift-phase forces and residual (uncompensated) energy segments

Accordingly, this represents the uncompensated energy:

$$E_{uncomp} = E_A + E_B + E_C \qquad (5.6)$$

The effective mechanical energy provided by the compensation system is therefore given by

$$E_{comp} = E_{dead} - E_{uncomp} \qquad (5.7)$$

Hence, when the compensation subsystem is active, the HPU needs only to provide E_{uncomp} while the balance E_{comp} is contributed by the accumulator-assisted compensation circuit. The corresponding fractional reduction in HPU energy demand is E_{comp}/E_{dead}.

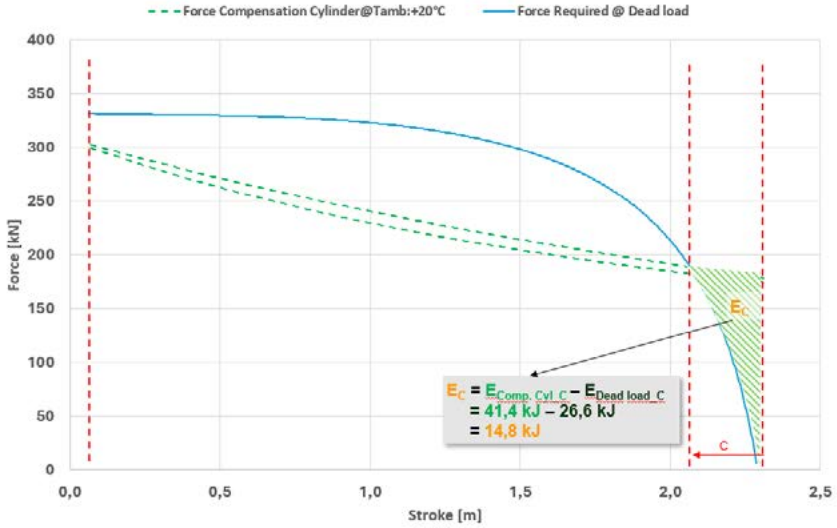

Figure 5.3.: Lowering-phase forces and residual (uncompensated) energy segments

Case 1 – Baseline Dead Load

$$E_A = 138.0\ kJ, E_B = 14.4\ kJ, E_C = 14.8\ kJ$$

Hence Uncompensated work:

$$E_{uncomp} = 167.2\ kJ$$

Compensation contribution:

$$E_{comp} = 625.2 - 167.2 = 458.0\ kJ$$

Energy reduction relative to dead-load energy:

$$\frac{E_{comp}}{E_{dead}} = 0.7326 = 73.26\%$$

Case 2 – Dead Load + 500 kg Pipe

$$E_A = 165.7\ kJ, E_B = 14.4\ kJ, E_C = 14.8\ kJ$$

Hence Uncompensated and compensated work are:

$$E_{uncomp} = 194.9\ kJ$$

$$E_{comp} = 653.9 - 194.9 = 459.0\ kJ$$

And therefore, Energy reduction is :

$$E_{comp} \,/\, E_{dead,new} = 0.7019 = 70.19\%$$

5.3. Results Summary

For the two investigated load cases, the mechanical compensation contribution was 458 kJ and 459 kJ, corresponding to actuator-level energy reductions of 73.3% (dead load) and 70.2% (dead load + 500 kg pipe). It is important to note that the compensation ratios of 70-73% reported here refer to the mechanical load compensation at the actuator level, i.e., the fraction of lifting work provided by the accumulator-assisted compensation cylinder rather than by the boom cylinder. These values therefore describe local energy sharing within a single lifting or lowering cycle and do not yet represent net system-level energy savings at the HPU level.

6. RIG / HPU SCALING FOR FULL DRILL BIT CHANGE

Building on the actuator-level results presented in the previous section, the following analysis scales the pipe-handler energy demand from individual lifting and lowering cycles to a complete drill bit-change operation. In this context, it is essential to distinguish between the local mechanical load compensation achieved within a single cycle and the resulting net hydraulic energy demand at the power-unit level, which is additionally influenced by hydraulic losses, Trip Out operations performed without pipe load, and non-compensated operating phases.

The scaling analysis estimates the HPU energy demand for a full bit-change operation - that is, completely removing a 2,500 m drill string and reinserting it with a new drill bit. Each trip of the pipe handler (PH) corresponds to the movement of one drill pipe joint. A full bit-change therefore consists of successive **Trip Out** and **Trip In** sequences.

Let:

- Dead-load mechanical energy per cycle $E_{dead} = 625.2\ kJ$
- Dead-load + pipe (500 kg) cycle $E_{dead,new} = 653.9\ kJ$
- Compensation energy (dead-load cycle) $E_{comp,1} = 167.2\ kJ$
- Compensation energy (+500 kg cycle) $E_{comp,2} = 194.9\ kJ$
- Pipe joint Length $L_j = 13.72\ m$
- Borehole Depth $d = 2500\ m$
- Number of joints $N = {}^{d}/_{L_j} = 183$

6.1. Per-Cycle and Per-Trip HPU Energy

For hydraulic round-trip efficiency η :

$$E_{C1}(\eta) = E_{dead,new} - \eta E_{comp,2} \qquad (6.1)$$

$$E_{C2}(\eta) = E_{dead,new} - \eta E_{comp,1} \qquad (6.2)$$

Trip energy (valid for Trip In or Trip Out):

$$E_{Trip}(\eta) = E_{C1}(\eta) + E_{C2}(\eta) \qquad (6.3)$$

Here η denotes hydraulic round-trip efficiency (fraction of simulated mechanical compensation that is available hydraulically).

Reference (no-compensation) Trip: $E_{no_comp,Trip} = E_{dead,new} + E_{dead} = 1279.1\ kJ$

Full Drill bit change total:

$$E_{total}(\eta) = 2 \cdot N \cdot E_{Trip}(\eta) \qquad (6.4)$$

Estimated savings:

$$Savings(\eta) = \left(1 - {E_{Trip}(\eta)}/{E_{no\ comp,Trip}}\right) \cdot 100 \qquad (6.5)$$

6.2. Numerical Results

Hydraulic Efficiency η	E_{C1} (kJ)	E_{C2} (kJ)	E_{Trip} (kJ)	E_{Trip} (kWh)	E_{Total} (kWh)	Energy per m (kJ/m)	Est. Savings (Mech)
1.0	459.0	458.0	917.0	0.255	93.23	134.3	**28.3 %**
0.9	478.5	474.7	953.2	0.265	96.91	139.6	**25.5 %**
0.8	498.0	491.4	989.4	0.275	100.59	144.9	**22.7 %**
0.7	517.5	508.2	1025.6	0.285	104.27	150.2	**19.8 %**

Table 6.1.: Simulated mechanical energy per Trip and for full bit-change (2500 m, 183 joints)

The results summarized in Table 6.1. represent the net HPU energy demand for a complete drill bit-change operation when the compensation system is active and Energy per meter refers to total HPU energy normalized by drill-string length. Although actuator-level analysis indicates mechanical load compensation ratios of up to approximately 70-73%, the corresponding system-level HPU energy savings are reduced to approximately 20-30% once hydraulic losses, Trip out operations performed without pipe load, and non-compensated operating phases are considered. These values therefore provide a realistic estimate of the achievable energy reduction under practical operating conditions.

7. PROTOTYPE VALIDATION AND PRELIMINARY RIG TESTS

The hydraulic compensation subsystem and its associated control components were installed on the vertical rig and evaluated during the factory acceptance tests (FAT). These initial tests were performed to confirm basic functionality, safety, and control logic prior to field commissioning. Although limited in duration, they provided valuable insights into system performance under real load conditions.

7.1. Factory and Preliminary Observations

During FAT, a clear difference in boom-cylinder pressure was observed between compensated and uncompensated configurations. The reported pressures represent characteristic average lifting pressures evaluated over the loaded lifting phase used here as a representative measure for estimating instantaneous hydraulic power. The actual pressure varies continuously along the cylinder stroke due to geometry, friction, and dynamic effects.

- **Without compensation (cylinder inactive):** required pressure 176 bar
- **With compensation active:** required pressure: 99 bar

The relative reduction is therefore:

$$Pressure\ reduction = 1 - \left({}^{p_{active}}/_{p_{inactive}}\right) \tag{7.1}$$

$$Pressure\ reduction = 1 - \left({}^{99}/_{176}\right) = 0.4375 = 43.75\%$$

This reduction corresponds directly to the fraction of lifting force now provided by the compensation circuit rather than by the boom cylinder and hence indicates that the HPU only needed to deliver the residual, or uncompensated, energy E_{uncomp}.

Interpreting pressure reduction as hydraulic power reduction Assuming actuator volumetric flow is approximately unchanged between compensated and uncompensated cases, hydraulic power scales with pressure according to $P_{hyd}(t) = p(t)Q(t)$.

Using the observed pressure change from 176 bar to 99 bar:

$$\frac{p_{active}}{p_{inactive}} = \frac{99}{176} = 0.5625 = 56.25\%$$

i.e. a reduction of 1-0.5625 = 0.4375 or 43.75% in instantaneous hydraulic power. Applied to the analytically estimated, uncompensated reference energy demand for a complete drill-bit change operation energy range varies $P_{inactive} \approx 93$ to104 kWh, this implies:

$$P_{active} = 0.5625 \cdot P_{inactive} = 52\ to\ 58.5\ kWh$$

This simplified estimation is directionally consistent with the mechanical load compensation observed at actuator level, while the lower magnitude reflects the net system-level reduction expected once hydraulic losses and non-compensated operating phases are included.

7.2. Comparison with Simulation and FAT Results

Simulation results predict actuator-level mechanical compensation efficiencies of approximately 70-73% under idealized, loss-free hydraulic conditions. In contrast, the 56.25% pressure and corresponding power reduction observed during factory acceptance testing (FAT) represents realistic, loss-inclusive performance, accounting for hydraulic friction, throttling, line pressure losses, and non-ideal accumulator thermodynamics.

The FAT results confirm the fundamental energy-saving principle of the hydraulic compensation system and validate the simulation predictions at actuator level under realistic

operating conditions. The observed pressure and power reductions demonstrate effective load sharing by the accumulator-assisted compensation cylinder. It is emphasized that these reductions are derived from characteristic phase-averaged lifting pressures and the resulting instantaneous hydraulic power during specific lifting phases. Net energy savings over a complete drill bit-change operation, however, result from time integration of hydraulic power across all compensated and non-compensated motions and should therefore not be inferred directly from phase-specific reductions.

8. CONCLUSION

This paper investigated the application of accumulator-assisted hydraulic energy recovery to drilling pipe-handling systems, with the objective of reducing hydraulic power-unit (HPU) energy demand during cyclic tripping operations. A combined simulation and experimental approach were employed to quantify both actuator-level mechanical load compensation and resulting system-level energy effects under realistic operating conditions. The study focused on a retrofit-oriented solution compatible with existing geothermal drilling rigs and standard hydraulic architectures

At actuator level, the accumulator-assisted compensation cylinder provided a substantial share of the lifting work during cyclic operation. Simulation results demonstrated mechanical load compensation ratios of approximately 70-73%, indicating that a significant fraction of the required lifting energy can be supplied locally by stored hydraulic energy rather than by the boom cylinder. Experimental force–stroke measurements confirmed the predicted trends and revealed characteristic nonlinearities and hysteresis effects, which were attributed to nitrogen gas compressibility, temperature-dependent pressure variation, and frictional losses within the hydraulic system.

Factory acceptance tests (FAT) further showed pronounced reductions in operating pressure and instantaneous hydraulic power during compensated lifting phases. A pressure decrease of approximately 56% relative to uncompensated reference operation was observed, corresponding to a 43.75% reduction in instantaneous hydraulic power during these phases. It is emphasized that these reductions represent phase-specific, instantaneous effects and should not be directly interpreted as total energy savings without considering the full operating cycle.

To assess rig-level impact, the actuator-level results were scaled to a complete drill bit-change operation, accounting for both compensated and non-compensated motions. The resulting analysis showed that, despite high local compensation ratios, the net HPU energy reduction for a full bit-change operation is limited to approximately 20-30%. This difference arises from hydraulic losses, unloaded return strokes, and operating phases in which compensation is inactive. These findings highlight the importance of system-level integration and time-integrated power analysis when evaluating hydraulic energy recovery concepts.

From a practical perspective, the proposed solution offers a favourable balance between achievable energy savings and implementation effort. The accumulator-based compensation concept can be integrated into existing pipe-handling systems with minimal structural modification and moderate additional component complexity. Under typical geothermal

drilling conditions, the resulting reduction in electrical energy demand suggests a payback period on the order of 1-3 years, depending on duty cycle and energy costs.

Overall, the results confirm that accumulator-assisted hydraulic energy recovery represents a technically robust and economically attractive option for improving the energy efficiency of drilling pipe-handling operations. While actuator-level compensation ratios are high, realistic system-level assessments remain essential to avoid overestimation of achievable savings. Future work will focus on extended field trials to validate long-term performance, quantify temperature and aging effects, and refine control strategies for further optimization of rig-level energy efficiency.

He has over 13 years of professional experience in hydraulic system development and engineering applications. Since 2020, he has been working at Herrenknecht AG, where he currently serves as Group Leader Hydraulics. Prior to this, he worked in various hydraulic development roles at several companies in Germany and India. His professional interests include hydraulic system design, energy recuperation, and rig automation, with a focus on sustainable and efficient drilling technologies.

Jürgen Binder began his career with a three-year apprenticeship as a mechanic before joining Herrenknecht AG in 1982. Over the course of four decades, he has worked across machining, assembly, field service, and engineering functions. Following a degree in Mechanical Engineering, he led engineering of small tunneling systems and later advanced to Project Manager for global tunneling projects. With the establishment of Herrenknecht Vertical GmbH, he became General Manager, responsible for the technical development of advanced deep-drilling systems and currently serves as Technical Director. His key interests include engineering innovation, renewable energy systems, and cost-optimized equipment design for sustainable drilling operations.

Dextreme MAX: A Digital Displacement® Excavator System for Energy Recovery and Reduced Losses

Abstract.

We present Dextreme MAX, a hydraulic architecture applied to a 30-tonne electric excavator based on a Digital Displacement pump/motor with multiple independently controlled outlets. The system provides independent actuator supply, eliminates flow-sharing losses, and enables energy recovery / hydraulic transformation via a boom H-bridge valve. On standardized JCMAS cycles, the converted machine reduced DC energy use by 49% in grading and 31% in dig-and-dump, with negligible impact on cycle time; across a representative duty mix this corresponds to ≈35% lower battery power and >53% longer uptime. These gains primarily arise from reduced throttling; additional benefits come from boom-lowering energy recovery. Results indicate that MAX can reduce required battery capacity and cost while maintaining productivity, accelerating electrification of heavy machinery.

Keywords. Digital Displacement, Excavator, Energy recovery, Electrification, Hydraulic transformation.

1. INTRODUCTION

As climate targets tighten, the inefficiency of hydraulic off-highway machinery has become a pressing concern. Excavators, one of the largest and most energy-intensive off-highway segments, typically achieve only 20–30% hydraulic efficiency [1]. Whilst for ICEs this drives high fuel consumption and CO_2 emissions, for electric excavators, this inefficiency is especially costly: batteries must be sized for a full shift, and as the most expensive component, this makes electrification economically challenging. Conventional systems (Negative and Positive Flow Control, Load Sensing) suffer large throttling losses and lack energy recovery [2]. Numerous advanced concepts such as displacement control [3,4], independent metering valves (IMV) [5,6], multi-chamber cylinders [7], two-pressure-rail hybrids [8], and secondary controlled actuators [1] have shown 15–50% efficiency gains in research prototypes. Yet commercial adoption remains minimal due to cost, scalability, complexity, a radical overhaul of the system, and uncertain ROI.

Digital Displacement® (DD) technology offers a more evolutionary path: DD pumps combine high efficiency across the load range with multi-outlet capability [9]. Prior work on a 16-tonne excavator showed that a single “multi-outlet” DD pump could decouple boom/bucket from arm/swing functions, reducing throttling losses while retaining the original hydraulic layout. Reported results included productivity improvements of 10–15%

All Open Access articles are peer-reviewed, distributed under the Creative Commons Attribution-Non Commercial 4.0 International

or fuel savings of 20–30% [10,11] in a diesel machine compared to the traditional NFC system with a tandem-swashplate unit. However, flow-sharing valve blocks as well as a lack of energy recovery still limited the further efficiency improvements.

This paper introduces Dextreme MAX, a novel architecture developed during a two-year project funded by the UK Department for Energy Security and Net Zero (DESNZ).

2. DEXTREME MAX SYSTEM DEVELOPMENT

The Dextreme MAX system aims at eliminating the flow-sharing central valve block by using a DD pump/motor with four independently controlled outlets to supply each actuator of the excavator, removing flow-sharing losses and enabling independent actuator control as well as energy recovery and hydraulic transformation. This new architecture builds on top of the SWAP and FLEX systems presented in [9,10].

2.1. Technology Background: The DD1x0D Digital Displacement Pump/Motor

The DD pump/motor is a radial piston unit based on electronically controlled poppet valves, enabling each cylinder to be switched on or off in real time according to crankshaft position [12] via a dedicated real-time controller, the DPC30. Flow is therefore modulated digitally at the cylinder level, with cylinders producing a full/partial pumping or motoring stroke or idling with negligible loss. This yields high efficiency across the full displacement range, combined with fast dynamics and precise flow control. The DD1x0 family is the first generation of large-format DD machines for prime movers in the 120–250 kW class, targeting 20–40 tonne excavators [13]. A key innovation is the combination of pump/motor capability with ten independently controlled outlets, each operating at its own pressure level. This allows independent multi-actuator supply and new modes of hydraulic transformation. In fact, the DD1x0D can operate as a transformer: some outlets motor while others pump or idle, enabling direct energy transfer between circuits at different pressures (Figure 2.1).

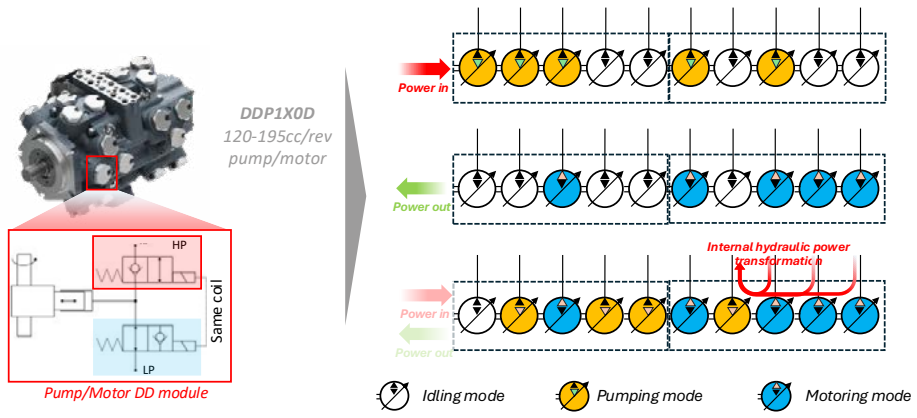

Figure 2.1. The DD1x0D Pump/Motor combines pump/motor/transformer functionality with ten independent outlets

Overrunning energy, such as from boom lowering, can be returned to the drivetrain or transformed to support other actuators. Component tests of the DD1x0 have shown pumping

and motoring efficiencies above 94.5% in the main excavator operating range (150–250 bar, 1400–1800 rpm), with peak motoring efficiency of 96.7%. These results confirm the DD1x0's potential for very high efficiency together with system-level functions like energy recovery and transformation unavailable with conventional pumps [13].

2.2. The DX300 Dextreme MAX System: concept and implementation

The MAX system was demonstrated for the first time on a 30-tonne battery-electric excavator, selected to meet the objectives of the UK Red Diesel Replacement Phase 2 (RDR2) programme [14], which aims to accelerate decarbonisation of off-highway machinery. The project sought to prove that higher hydraulic efficiency can reduce required battery capacity, cutting cost and charging demand while maintaining productivity. Although validated on an electric platform, the same principles directly apply to diesel machines, where lower hydraulic losses reduce fuel use and emissions.

A DEVELON DX300LC-7 crawler excavator was chosen as the test platform. Originally diesel-powered with a two-service NFC hydraulic system, it was obtained in an electric configuration from STAAD B.V., which replaces the engine with an electric drivetrain and battery system (Table 2.1). The model offered representative scale, short delivery time, and strong technical support, enabling integration of the MAX concept to a Technology Readiness Level 7 prototype (TRL7 [15]).

Table 2.1. Electric Drivetrain Specifications

Parameter	Value	Notes / Components
System HV voltage	670-790 VDC	Battery supply voltage
Nominal motor speed	1900 rpm	
Maximum motor speed	2200 rpm	
Continuous motor power	145 kW	Limited at machine level (motor rated 174 kW)
Motor	Danfoss PMI375-T800-1800	Permanent magnet synchronous motor
Inverter	Danfoss EC-1200-450-L240A	DC–AC phase inverter
Motor controller (VCU)	Danfoss MC050-010	Vehicle control unit
Installed Battery Capacity	3x140kWh	1 fixed + 2 swappable

The Dextreme MAX hydraulic architecture comprises four primary services – boom, arm, bucket, and swing – each supplied independently by the DD1x0D. The unit features ten controllable outlets that can be dynamically grouped through a digital distributor reallocating capacity to the actuator requesting it [9]. A schematic comparison between the baseline and MAX configurations is shown in Figure 2.2.

For this prototype, full decoupling of all four services was not implemented due to project time limits and the need to retain the original main control valve (MCV) without altering its core functions. Energy-flow analysis showed that keeping the MCV for the arm and bucket circuits introduced acceptable losses: during high arm-in demands (> 50 % operator input), the "arm 2" and bucket spools continue to share flow through the coupled MCV arrangement.

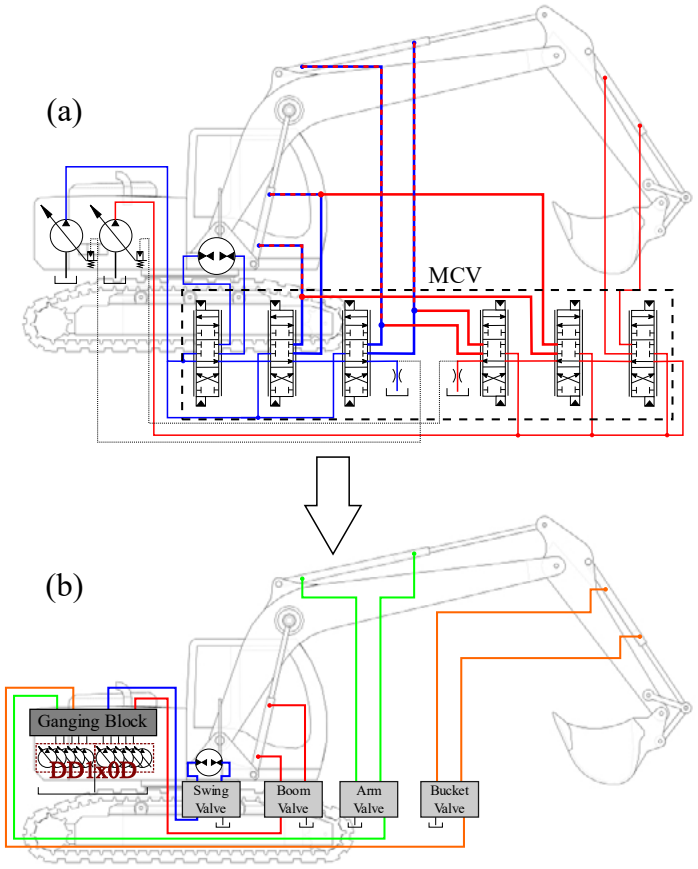

Figure 2.2. Layouts of the original NFC system (a) and the Dextreme MAX system (b).

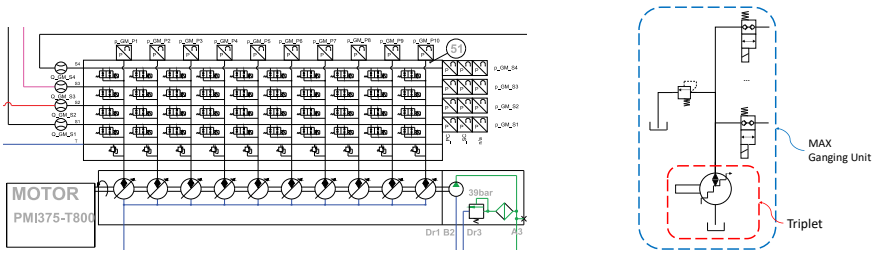
Based on previous studies [7,8], the boom and swing were identified as the main candidates for energy recovery, as they dominate potential and kinetic energy exchange during excavator cycles. The boom typically offers several times higher recovery potential than other actuators and about two to four times that of the swing. Consequently, both functions received dedicated valve services in the MAX demonstrator. Because the DD1x0D operates in an open circuit, practical swing-energy recovery could not be implemented within the project timeframe. Instead, the swing used an independent metering valve to remove flow-sharing and metering losses, while only the boom employed a full H-bridge for regeneration and pressure amplification. Table 2.2 summarizes the configuration of the baseline NFC and MAX systems. To maximize the possibility of energy recovery and simultaneous actuators operation, a DD180D (2x180cc/rev) has been selected, replacing the original 140cc/rev swashplate tandem unit. In addition to the DD180D, two supporting subsystems were added:



- Ganging block – a digital distributor enabling dynamic grouping of pump outlets
- Boom and swing valve – a dedicated arrangement providing advanced control of these actuators

Table 2.2. Service/actuators configurations comparing the original NFC and Dextreme MAX systems

Service ID	**Original**	**MAX configuration**
Service 1	-	Swing
Service 2 (2)	Bucket / Boom 1 / Arm 2	Bucket / Arm 2
Service 3 (1)	Swing / Boom 2 / Arm 1	Arm1
Service 4	-	Boom

2.2.1. The Ganging Block

This valve block, referred to here as the ganging block, connects each service to each DD outlet ("triplet" – three pistons each), enabling the allocation of large capacity to individual services when required. A set of digitally controlled valves is introduced to distribute the flow supplied or absorbed by the DD1x0D among the working actuators. The hydraulic schematic of the ganging block is shown in Figure 2.3.

(a) (b)

Figure 2.3. (a) Schematic of the ganging manifold; (b) MAX ganging unit consisting of a DD1x0 Triplet and four 2/2 valves, and a PRV connected in parallel.

The valves selected for the ganging block are 2-way 2-position, high pressure bi-directional, pilot operated, poppet type screw-in cartridge valve (Danfoss SBV11-12-C). Each valve is normally closed (no free-flow direction) and allows bidirectional flow when energized. In addition, the manifold integrates ten safety relief valves, one per pump outlet.

2.2.2. Boom valve - the H-bridge

Because the DD1x0D is an open-circuit pump/motor, additional valve functionality was required for full bidirectional control of the linear actuators. A dedicated H-bridge valve was therefore developed to manage independent meter-in and meter-out flows, providing anti-cavitation, pressure amplification, and energy recovery during overrunning motions. Building on previous work on independent metering and secondary control [1,16], the design aimed to minimize throttling losses while enabling controlled energy exchange. In the Dextreme MAX system, the H-bridge supports the following key functions:

1. Four-quadrant operation – provide full control of actuator motion across all load and velocity directions, ensuring symmetric functionality in extension and

retraction. For the boom, quadrant I corresponds to resistive extension (lifting) and quadrant II to overrunning lowering.

2. Anti-cavitation (quadrants II and IV) – supply make-up flow to prevent cavitation when the actuator is driven by overrunning loads
3. Flow regeneration (quadrant II) – transfer flow from the head side to the rod side during overrunning lowering.
4. Pressure amplification / differential mode (quadrant II) – apply controlled pressure on the rod-side to raise effective load pressure while reducing flow demand. For the DD1x0D, this maintains constant power transfer with less processed flow, reducing conveyance losses and freeing capacity for other actuators.
5. Normal metering-out (quadrants II and IV) – allow conventional throttling when energy recovery or transformation is not possible.

Together, these modes provide the flexibility, safety, and fallback behaviour required for practical excavator operation.

Several H-bridge topologies were evaluated. A four-cartridge concept ([16]) and Valvistor-type elements were excluded due to flow-capacity limitations and development time constraints. To ensure availability and reliability, the final design employed Danfoss PVG components, as shown schematically in Figure 2.4.

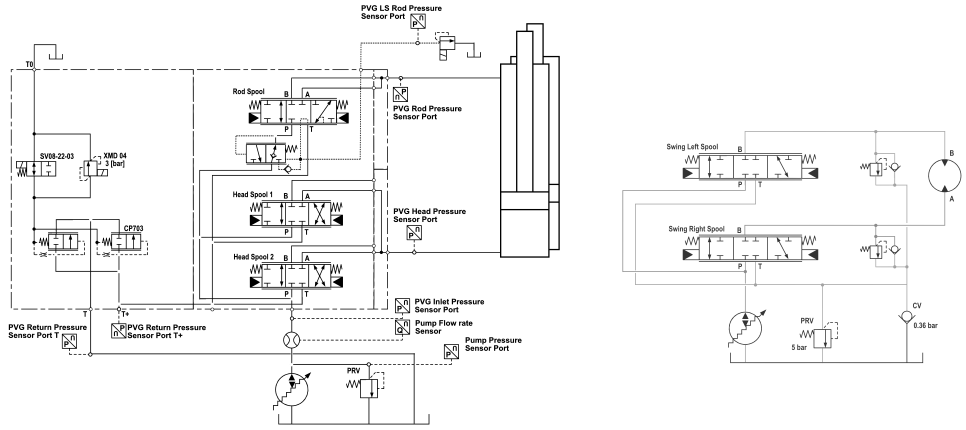


Figure 2.4. Simplified schematic of the Boom H-Bridge and Swing valve

The implemented boom H-bridge employs three PVB valves (2 × PVB128 and 1 × PVB256) to meet the requirements for four-quadrant operation, anti-cavitation, regeneration, pressure amplification, and safe metering-out while handling the excavator's peak flows. The circuit connects pump to head (P–A), pump to rod (P–B), head to tank (A–T), and rod to tank (B–T), enabling full control of both chambers. For stable rod-side pressure regulation, the PVB256 compensator was modified so that the main spool remains fully open while an actively piloted compensator in the rod branch maintains chamber pressure. A pilot relief valve (PRV) defines the pressure reference dynamically, providing faster and more stable control than direct control of the PVG spool. This approach is consistent with [17], which showed the efficiency and safety benefits of active pressure regulation. The resulting PVG-

based layout delivers the required four-quadrant performance using standard, commercially available hardware, ensuring timely and practical system integration.

2.2.3. Swing valve

The swing service valve was implemented using the same independent-metering PVG concept adopted for the boom, but with a simplified layout consisting of two PVB128 as shown in Figure 2.4. All PVB blocks for boom and swing were physically integrated into a single large PVG assembly, interconnected through a custom hydraulic integrated circuit (HIC) block. This approach allowed the services to be grouped in a compact package while providing the necessary functionality for the MAX system.

2.3. Control Logic

The introduction of four independent services in the Dextreme MAX system required a complete redesign of the control strategy compared with previous SWAP and FLEX implementations. The controller must manage flow allocation, displacement distribution, pressure regulation, torque sharing, and boom-specific recovery logic, while ensuring seamless operator control and compatibility with the machine's electric prime mover. Figure 2.5 summarizes the control architecture, highlighting the interaction between displacement control, pressure controllers, torque management, and H-bridge logic.

2.3.1. Flow Allocation and Elastic Pump Distribution

Similar to positive flow control (PFC) systems the joystick pilot pressures are mapped through look-up tables to generate service flow demands. The DD pump/motor provides multiple discrete outlets ("triplets"), which must be assigned dynamically to the active services. In general, the system tries to satisfy the capacity request of each actuator. When the demand exceeds the total pump capacity, proportional displacement allocation is enforced. The 2/2 valves in the ganging block are switched on and off accordingly. As each service is handled separately by the pump controller, the flow is adjusted by controlling the displacement fraction of the instantaneous allocated capacity of the service.

2.3.2. Pressure Limiting

The MAX controller allows for pressure control for all services. A PI controller regulates pump displacement accordingly to limit losses over relief valve, which is common control practice when accelerating the swing function. The pressure setpoint can be changed dynamically based on the operating conditions: for example, because the MAX architecture decouples the boom and swing into separate services, the flow-sharing characteristic of the baseline system during lift-and-rotate operation is lost. To re-establish the expected interaction between these functions, a flow-sharing emulating algorithm is introduced. In this case, the pressure of the swing is limited to the boom service pressure, thereby reproducing the coordination observed in conventional architectures while preserving the independence of the MAX layout.

2.3.3. Torque Control

The torque controller determines the aggregate pump torque request and interfaces with the prime mover. Only the positive torque contributions of each service are considered when

calculating total demand; negative torques from motoring services are excluded to avoid disturbing the expected flow distribution. An anti-lift-off strategy is applied to reduce motoring demand when the shaft speed exceeds a defined threshold, preventing overspeed. In addition, motoring is disabled entirely when calculated negative power falls below the minimum limit specified by the electric motor control unit. Under these circumstances the H-Bridge metering functionality maintains productivity by ensuring requested boom down speed. These safeguards ensure compatibility between hydraulic energy recovery and the electric drivetrain.

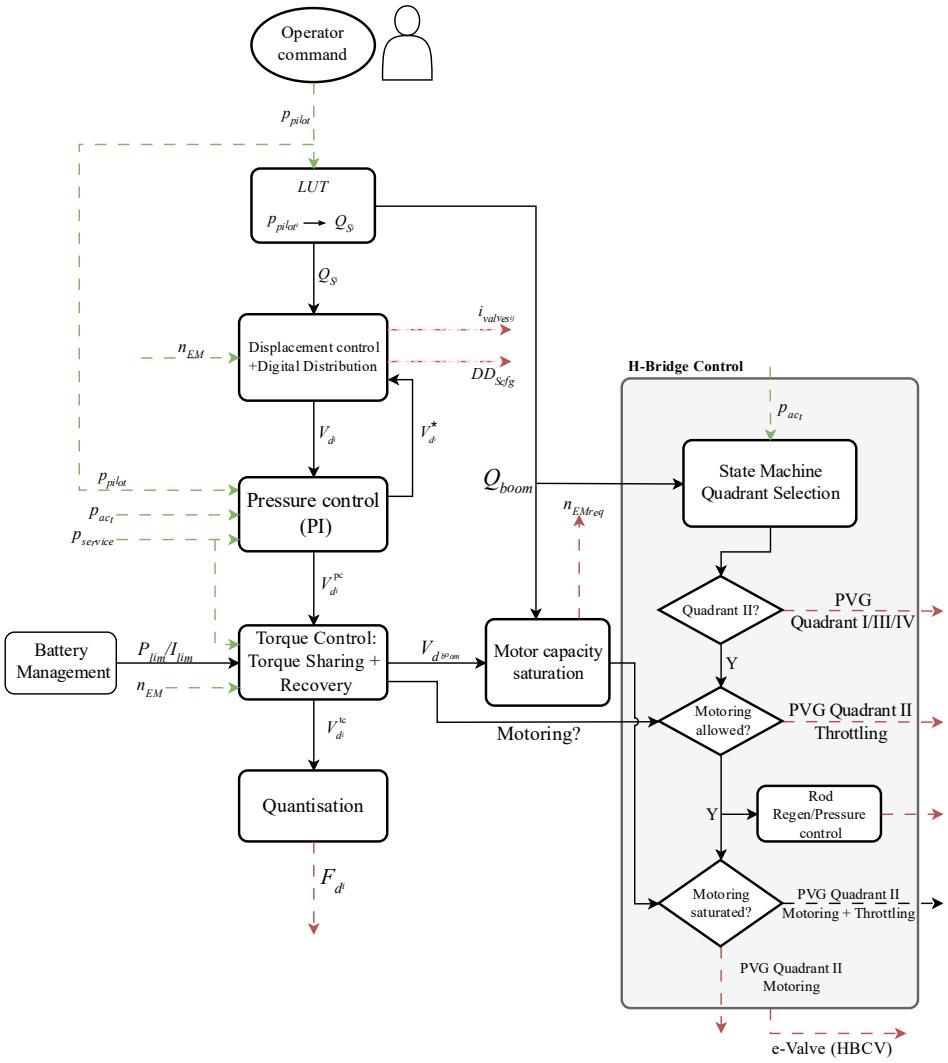

Figure 2.5. Control structure for the Dextreme MAX system

2.3.4. Boom Control Logic

Boom control is critical to the overall efficiency of the MAX system. The boom controller is structured around four quadrants of actuator operation:

- Quadrant I – Resistive extension (lifting).
- Quadrant II – Overrunning retraction (lowering).
- Quadrant III – Resistive retraction.
- Quadrant IV – Overrunning extension.

During resistive operation (Quadrants I and III), the pump supplies the head or rod chamber in a conventional manner. The head spool remains fully open, and motion is regulated entirely through displacement control of the DD180D, with smooth behaviour enabled by its fast dynamic response. Overrunning retraction (Quadrant II, i.e. boom lowering) presents the greatest control challenge. The key issue is managing cavitation risk in the rod chamber while handling surplus flow from the head side. This is addressed through differential actuation, in which part of the head flow is routed to the rod side. In this mode, the rod chamber pressure is actively regulated: either by partial opening of the rod spool or, preferably, by a piloted pressure compensator in the rod branch. The compensator, controlled via an external PRV, provides faster and more stable response. Rod pressure set-points vary with load: a higher-pressure setting is used for light bucket loads to maximize energy recovery, while lower pressure is set for heavy loads to avoid excessive head pressurization or when motoring is not possible. During motoring, because the machine has finite capacity, any excess head flow beyond the motoring limit is throttled to tank. While this introduces some loss, it ensures safe boom lowering and maintains productivity.

2.4. Control System Implementation

2.4.1. Data acquisition

To evaluate the performance of the prototype system, a comprehensive data acquisition (DAQ) alongside the control setup was installed on the excavator. The objective of this setup was to capture all relevant parameters from the working hydraulics – such as arm, boom, bucket, swing, and track systems – as well as from the DD pump outlets. The measurement system consisted of five DEWE-43 data acquisition units from Dewesoft, enabling synchronized high-speed recording across all channels covering hydraulic, mechanical, and electrical domains, allowing a detailed analysis of machine performance, energy flow, and control behaviour. The instrumentation covered the following main sensor groups:

- Hydraulic pressure sensors – installed at each DD pump outlet (service ports), actuator chambers, main control valve, and pilot lines to monitor system pressures and load conditions.
- Flow meters – flow meters on each DD outlet to measure service flow rates and calculate hydraulic power. A screw flowmeter was installed on the Boom Service for better accuracy at high flows during motoring.
- Position sensors – string potentiometers on the boom, arm, and bucket cylinders, and an IMU for the swing for displacement and motion tracking.
- Electrical power sensor – a high current and voltage transducer monitors DC supply from the battery to the inverter.

2.4.2. System controllers

The control system architecture (Figure 2.6) was designed to provide real-time control of the DD system, electric powertrain, and auxiliary subsystems. The setup combines a SpeedGoat Mobile real-time target machine (M3) with two Danfoss XL104-0000.

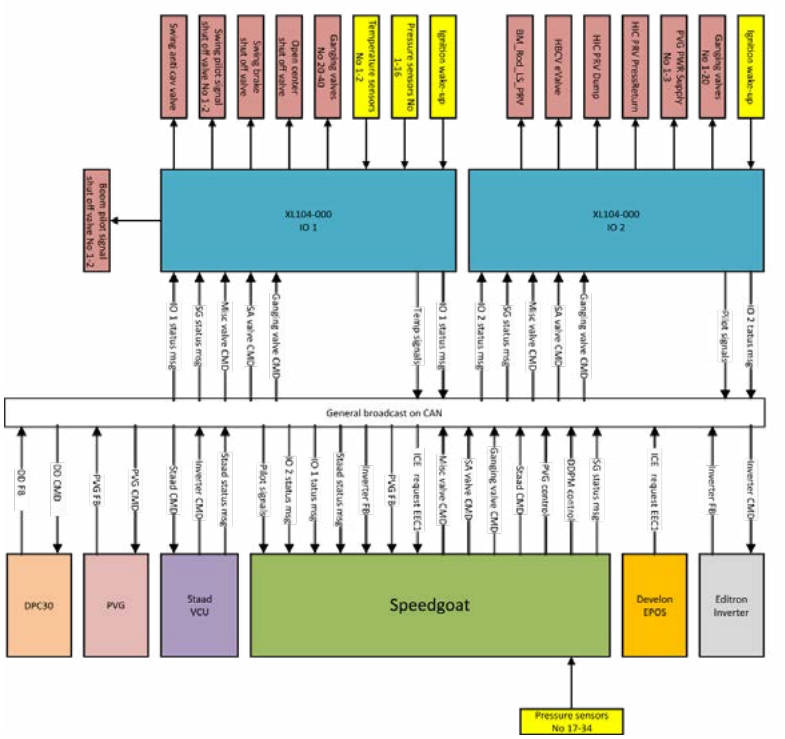

Figure 2.6. Control system architecture showing the SpeedGoat real-time target as the main controller and two Danfoss XL104-0000 units as distributed I/O.

The SpeedGoat unit is equipped with two IO133 modules for analog and digital I/O and one IO602 CAN interface module. It serves as the main real-time controller, executing the system's supervisory control, coordination of subsystems, advanced algorithms such as motoring and digital distribution, power limiting, and fault handling. The control logic was developed entirely in MATLAB / Simulink, and SpeedGoat was chosen for its capability for rapid prototyping. A corresponding Simscape model of the excavator was used to develop and verify the algorithms in real-time before deployment.

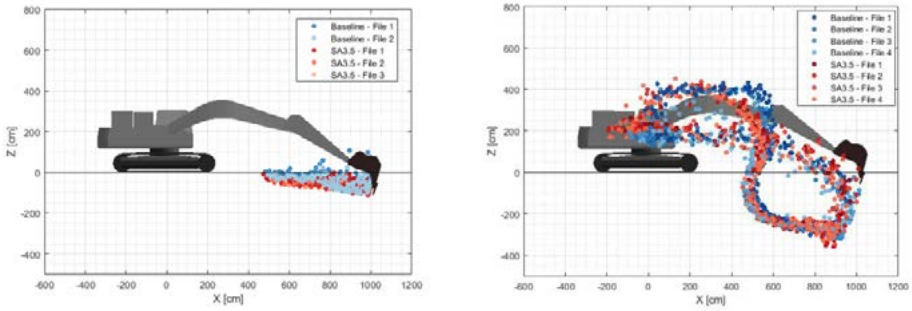
Two Danfoss XL104-0000 controllers act as distributed I/O nodes that interface directly with the hydraulic valves, pilot signals, and pressure sensors. These units provide the required output power to drive the proportional and on/off valves that exceed the current-handling capacity of the SpeedGoat I/O modules. They also serve as functional safety controllers, implementing local safety logic and redundancy for critical valve operations. All components communicate via CAN HS and J1939 protocol including the Danfoss Editron inverter, Develon EPOS, and STAAD VCU, which exchange commands and feedback signals over different CAN networks.

3. TESTING

The RDR2 program required a field trial to demonstrate TRL 7 and controlled testing to compare system performance before and after conversion. To quantify performance, a comprehensive characterisation of the original configuration was undertaken. The tests were designed to capture single-function behaviour, function-prioritisation performance, and simulated duty-cycle operation. Three types of simulated duty-cycle tests were performed:

1. JCMAS air grading (Equivalent of ISO11152-2) (Figure 3.1a)
2. JCMAS air dig and dump (Equivalent of ISO11152-2) (Figure 3.1b)
3. Real dig and dump with gravel (Figure 3.1c)

All tests were designed for repeatability and could be executed both before and after conversion. Operators were instructed to work as quickly as possible, as this typically yields the most consistent results.



(a) (b) (c)

Figure 3.1. (a) JCMAS Air-Grading, (b) Air-Dig and Dump, (c) Real Dig and Dump

Baseline testing of the conventional system was conducted at the Danfoss Application Development Centre (ADC) in Nordborg. To meet project timelines, the post-conversion tests were repeated at a dedicated site near Edinburgh, providing a consistent basis for quantitative comparison and enabling safe operation in MAX mode. Because calibrated gravel was unavailable, real dig-and-dump tests could not be repeated; however, the JCMAS air cycles offered a controlled and repeatable means of assessing Dextreme MAX system efficiency relative to the Nordborg baseline.

Ensuring consistency across test cycles was challenging, as the baseline tests were conducted by a different operator at a separate site nearly a year earlier. The bucket-tracking tool was used to verify motion repeatability, and outlier cycles were excluded from the energy analysis using plotting tools. A sample comparison of bucket paths for the JCMAS tests is shown in Figure 3.2.

Cycle time influenced repeatability since the DDP180D pump's 30 % larger displacement enabled faster operation than the baseline unit. To align cycle durations, motor speed setpoints were adjusted for the converted machine tests, with active control of the EM speed during boom down to maximize energy recovery.

(a) (b)

	BOOM [M]	ARM [M]	BUCKET [M]	SWING [°]	
BASELINE	0.68	0.86	0.74	88	DnD
DEX. MAX	0.72	0.86	0.7	95	
ERROR %	**+5.8%**	**0%**	**-5.4%**	**+8%**	
BASELINE	0.33	1.23	-	-	Grading
DEX. MAX	0.30	1.23	-	-	
ERROR %	**-9.1%**	**0%**	-	-	

Figure 3.2. Comparison of bucket traces for JCMAS test – (a) Grading, (b) DnD; table with error percentage between average actuators extensions across tests.

3.1. Test results

Several tests were conducted for both the baseline and the converted machine using sets of 10 cycles per test for both grading and dig and dump. To ensure a fair comparison, the actuators' extensions have been evaluated, and clear outliers have been discarded. The errors in the actuators extensions (rotation) are between 9% and 0%. In case of the grading, the MAX system boom extension is 9% lower than the baseline, but the absolute value is 0.03m which is difficult to control in a fast and dynamic cycle. Average of the selected cycles results are presented in Table 3.1 and Table 3.2 for air grading and dig-and-dump operations, respectively.

Table 3.1. Air Grading results

Configuration	Cycle Time (s)	DC Power (kW)	DC Energy (kJ)
Baseline	6.78	120.5	817.0
MAX	7.29	56.9	414.8
% difference	+7.5%	-52.8%	**-49.2%**

Table 3.2. Air Dig and Dump (DnD) results

Configuration	Cycle Time (s)	DC Power (kW)	DC Energy (kJ)
Baseline	14.44	99.9	1442.6
MAX	14.59	68.2	995.0
% difference	+1%	-31.7%	**-31%**

General field operation of excavators implies a mix of grading, dig and dump and idling. Each OEM uses a different mix of those with dig and dump being the largest portion of the mix. For electric machines, we can exclude the idle portion as the electric motor can easily be stopped and started when needed. Assuming a duty cycle of 30% air grading and 70% air digging, the MAX system would reduce battery power consumption by 35% without significantly compromising work rate. This would result in 53% longer operating hours.

3.2. Data analysis

Table 3.3 summarizes the energy balance in a series of JCMAS DnD cycles between the baseline and MAX configurations, highlighting where the efficiency improvements originate. Losses associated with the inverter/motor, DD pump, baseline pump, and the AUX systems are estimated using numerical loss models; actuator mechanical losses are embedded in the reported actuator net energy. The different contributions are calculated using a mix of measured data and simulation models hence the small difference with the reported DC energy in Table 3.2.

Table 3.3. Breakdown of the system losses and contribution of energy savings

Energy [kJ]	Baseline	MAX	Δ	% of savings contribution
DC	1449.7	1021.6	**428.0**	
Pump Losses	167.3	85.2	82.1	19.2%
AUX	61.9	33.6	28.3	6.6%
EM Losses	71.5	50.6	20.9	4.9%
Actuator Net	481.8	457.8	24.0	5.6%
Meter In Loss	307.7	142.5	165.2	38.6%
Meter Out Loss	207.4	272.3	-64.9	-15.2%
Open Center Loss	93.9	38.6	55.3	12.9%
Relief Valve	58.1	40.7	17.4	4.1%
Recovered Energy	0.0	-99.7	99.7	23.3%

The total energy savings are primarily attributed to reductions in pump losses, metering losses, and the introduction of energy recovery. Pump losses decrease by 82.1 kJ (19.2 % of total savings), reflecting the improved part-load efficiency of the DD pump. A significant 220.5 kJ reduction in combined open-center/meter-in losses (51.5%) confirms the

effectiveness of independent flow-matching control in minimizing metering losses during multi-actuator operation. The recovery system contributes an additional 99.7kJ (23.3 %), corresponding to energy regenerated during boom lowering. Meter-out losses are not improved and are slightly increased. This is primarily due to the higher flow levels through the arm and bucket circuits, while the same conventional valves were retained.

Overall, approximately half of the total energy savings result directly from reduced hydraulic throttling, with the remaining half achieved through energy recovery and pump efficiency improvements. Figure 3.3 shows a detail breakdown of energy for an Air Dig and Dump cycle of the Dextreme MAX system. It is clear that a significant portion of the energy is still lost in meter out for bucket and arm. This is due to the usage of the original MCV for those actuators. These losses can be addressed with a different valve design in a system developed from scratch. Additionally, a significant part of the boom potential energy is lost through metering: this was due to an error in the control logic parameters preventing a complete opening of the boom load holding valve during boom down operation, wasting more than 30kW of potential power during peak flows. Unfortunately, the issue was discovered after the tests were completed and it will be fixed in the future.

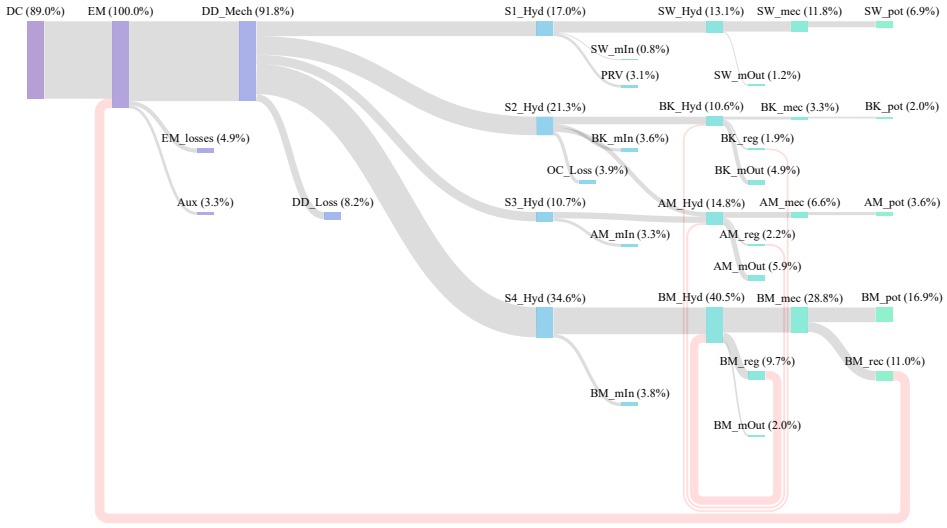


Figure 3.3. Sankey chart of the energy flow for the MAX system in a JCMAS DnD cycle.

4. CONCLUSION AND FUTURE WORK

The Dextreme MAX prototype successfully demonstrated that a fully digital, multi-service electro-hydraulic architecture can significantly improve the efficiency of a 30-tonne electric excavator without compromising performance. Tests conducted on standardized duty cycles showed energy consumption reductions of 31–49%, corresponding to a 35% decrease in electric energy demand for typical operations. A large part of the energy savings stemmed from reduced throttling losses due to independent actuator control, while approximately one-quarter resulted from energy recovery during boom lowering. While the results confirm the potential of DD technology for large excavators, time constraints, some control and hardware limitations hindered full system optimization. Specifically, incomplete opening of

the boom Hose Burst Control Valve prevented full energy recovery, and the current control logic can be refined to improve transient performance and motoring efficiency.

Future work will therefore focus on:

- Enhancing control performance and addressing the identified valve control issue to enable complete boom energy recovery.
- Conducting real dig-and-dump testing once the machine returns to the Danfoss Application Development Centre (ADC) for validation under representative working conditions.
- Investigate and extend the concept to include an electrified swing drive (e-swing), which represents an obvious next step given the electric platform; this addition is expected to further reduce losses and enable additional energy recuperation.

ACKNOWLEDGEMENT

Part of this work was carried out under the Red Diesel Replacement Phase 2 (DEPOWER2) project, *Digital Electro-Hydraulic Power Module with Energy Recovery – Phase 2*, supported by the UK Department for Energy Security & Net Zero (DESNZ) through the Net Zero Innovation Portfolio (NZIP). Project Lead Organisation: Danfoss Scotland Ltd. Project Number: RDR2-01-DFS (con_4308). Project Duration: 04 July 2023 – 30 June 2025.

Biographies

Matteo Pellegri received the BSc (2012) and MSc (2014) degree in mechanical engineering from *Università degli studi di Parma* , and the PhD in Engineering from *Purdue University* in 2018, respectively. He is currently working as a Senior Engineering Manager for Danfoss focussing on systems using Digital Displacement technology. He authored publications in different areas of fluid power and he has been serving as a reviewer for many highly respected journals.

Paul Marshall graduated from the University of Strathclyde in 2016 with a master's degree in mechanical engineering. Since then, he has worked on developing and testing prototype off-highway vehicles using Digital Displacement hydraulic systems for Artemis Intelligent Power and Danfoss Scotland. As a Senior Systems Engineer, he is currently working alongside OEM partners, providing technical leadership on projects aiming to improve the system efficiency of excavators through the application of Digital Displacement pumps and novel hydraulic systems.

Casper Olesen received his M.Sc. degree in Electro-Mechanical System Design from Aalborg University, Denmark, in 2011. He is currently a Senior Systems Engineer at Danfoss Power Solutions, Denmark. His work focuses on the development and analysis of system architectures integrating hydraulic and electrical components, with an emphasis on improving overall performance, comfort and efficiency.

Erik Westergaard is a Staff Engineer with Solutions R&D department of Danfoss Power Solutions. Solutions R&D is responsible for developing system solutions for off-highway machinery through the value-added combination of hydraulic and electrical components with control software. Based out of Danfoss' Nordborg, Denmark, location of the Application Development Center, Erik brings 14 years of off-highway vehicle system-centric experience, blending his practical approach from a farming background with a strong technical education. His contributions focus on steady advancements in product and system development, varying from operator comfort and productivity to system efficiency.

Environmental Sustainable Pneumatics

Dr. Wolfgang Gauchel, Victoria Pohl, Daniel Ditterich

Festo SE & Co. KG
wolfgang.gauchel@festo.com, victoria.pohl@festo.com, daniel.ditterich@festo.com

Abstract.

Environmental sustainability has become a key priority in production and manufacturing engineering, driven by increasing regulatory requirements and customer expectations for reduced environmental impact. Of course, this is also due to the realization that the current economic model cannot be continued for ecological reasons. The transition to climate-neutral and resource-efficient production creates high pressure to adapt to pneumatics. After all the problem lies in the high energy demand (compared to electric drives) and the associated high CO_2 emissions. The assumption that customers switching to green electricity will solve the problem could be too short-sighted.

The focus of this paper is on drive technology, other areas such as vacuum technology are only dealt with in passing. After an introduction including a summary of the European Ecodesign for Sustainable Products Regulation (ESPR) [1] in chapter 1, chapter 2 deals with the possibilities for improving the energy efficiency of pneumatic actuators, including compressed air generation and distribution, as the greatest challenge with regard to CO_2 neutrality. Chapter 3 describes the Product Carbon Footprint (PCF) of pneumatic components, i.e. the CO_2 emissions caused during their production. An initial assessment with regard to the circular economy is provided in chapter 4. Finally, the topics mentioned are summarized in chapter 5 in the form of a comparison between pneumatic and electric drive technology.

1. INTRODUCTION

The German Federal Environment Agency [2] defines six principles that can be used to determine eco-design – and which can therefore be used as a benchmark for environmental sustainable pneumatics. These are

- **Durability**
  An area in which pneumatics has significant strengths due to its reliability and robustness.
- **Repairability**
  Repair kits for pneumatic actuators have been offered for decades. Due to the modularity of their design, maintenance units and valve terminals also have the option of replacing

a defective module, e.g. a valve. In this way, the entire system, in our example the valve terminal, is quickly put back into operation.

- **Resource efficiency**
  This aims to reduce the consumption of energy, materials and water in the production process and during the product life cycle. Behind the water consumption during the use phase but also in the production of pneumatic components, a tick can be set very quickly. The material consumption of pneumatics is also comparatively low, as described in chapter 3 on the Product Carbon Footprint cradle to gate (PCF ctg). Energy consumption, on the other hand, is the central challenge, which is dealt with in detail in chapter 2.
- **Lack of problematic substances**
  In pneumatics, this is usually the case, apart from lead in piezo valves or using of per- and polyfluoroalkyl substances (PFAS) [3]. The last ones are depending on the application used in seals and lubricants [4, 5], partly also in other plastic components.
- **Renewable raw material**
  are hardly used in pneumatics. The majority of pneumatic components consist of aluminum and steel, both of which can be easily and economically recycled (see chapter 4.4). There is potential for further development with regard to renewable raw materials in the field of seals and lubricating greases. Of course, tubes, valve housings, sensor housings or various cover plates made of plastic based on renewable raw materials are also a possibility.
- **Circular Economy (CE)**
  Due to their simple design and robustness, pneumatic components are well suited for the CE-strategies RePair and ReUse as well as ReCycling (see chapter 4). The ReFurbish and ReManufacture strategies, on the other hand, are hardly used at the moment, so they are a future option.

In the following subchapters, important aspects of 'Environmental Sustainable Pneumatics' are discussed. These are energy efficiency (chapter 2), Product Carbon Footprint (chapter 3) and Circular Economy (chapter 4). Chapter 5 summarizes the results.

2. ENERGY EFFICIENCY

Energy efficiency has been a topic in pneumatics for many years. And numerous publications have been published on this subject, including some with an overview character [6, 7, 8].

The energy transition from fossil fuels to CO_2-neutral energy sources requires significant improvements in the energy consumption of pneumatic systems. This is because the demand for electrical energy is increasing significantly as a result of the energy transition – whether for the operation of cars (electromobility), for heating buildings (heat pumps) or for hydrogen generation (electrolyser). In these and many other cases, electricity is needed. Accordingly, (green) electrical energy is and remains a rare resource that should only be used efficiently in the future. For pneumatic applications, this also results in the need for efficiency, as electrical energy is used to generate compressed air (see chapter 2.1). To illustrate the need for energy-efficient pneumatics with a concrete example, reference can be made from the sustainability report of Festo from 2024 [9].

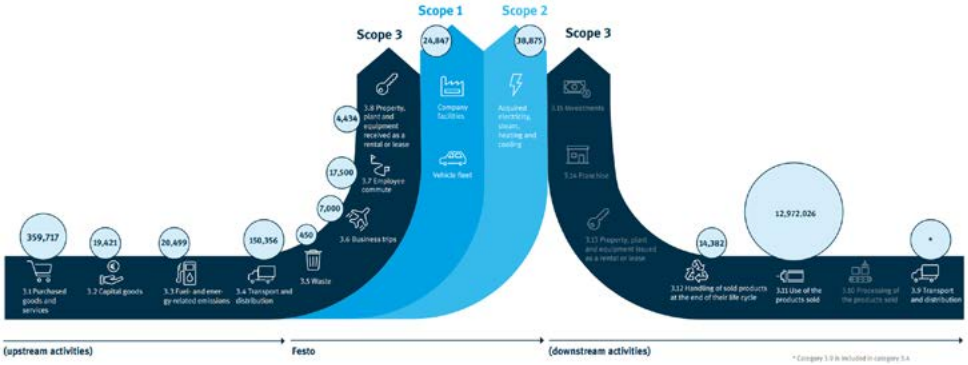

Figure 1. Company Carbon Footprint (CCF) 2024 of Festo [9]

The report shows the Company Carbon Footprint (CCF) of Festo, see Figure 1. 95% of the CCF of Festo is caused by Scope 3.11, the 'use of product sold'. Festo also sells components such as electric actuators, sensors, valves, valve terminals, ... that have a direct electrical energy consumption. But the 'indirect' electrical energy consumption for compressed air generation is by far the largest part of Scope 3.11. About half of the remaining 5% of the CCF is Scope 3.1, the CO_2equivalent (CO_2e) of the 'purchased goods and services'. The next largest share of just under 1% of the CCF is caused by the delivery of supplier or (own) preliminary products to our factories (Scope 3.4, 'transport and distribution'). Both factors are well described by the aggregation of the PCF ctg of the products sold (see chapter 3).

Festo has set itself the goal of reducing greenhouse gas emissions in Scope 3 by 90 per cent by 2050 compared to the base year 2022 [10]. This ambitious climate target was officially validated by the Science Based Targets initiative (SBTi) in February 2025. In the Target Dashboard of the SBTi [11] not only Festo can be found. It reads a bit like the 'Who's Who' of the pneumatics industry and its suppliers: SMC Corporation, Emerson Electric Co. (Aventics), IMI plc. (Norgren), Parker Hannifin Corporation, Schunk SE & Co. KG, Trelleborg AB, ... This demonstrates the importance of CO_2-reduction for the pneumatic industry and their customers, which are also widely represented there.

In the following subchapters, the entire compressed air chain is described from an energy perspective, from compressed air generation (chapter 2.1) to its distribution (chapter 2.2) to the operation of machines and systems (chapter 2.3). Chapter 2.4 concludes the topic of energy efficiency with the control of pneumatic actuators.

2.1. Compressed air generation

Pneumatic energy efficiency starts with the compressor. Since thermodynamic effects inevitably generate a lot of heat during the compression and generation of compressed air [12], and this cannot be used pneumatically, compressor manufacturers are very concerned with the topic of heat recovery [13, 14, 15]. The recovered heat can be used, for example, for heating purposes or to generate required process heat. There are also solutions to heat rooms with the compressors in winter and to cool them in summer by means of absorption chillers [16].

In summary, future improvements in compressor technology to recover heat and reduce specific power consumption for air compression [6] will help pneumatics reduce their CO_2 emissions in Scope 3.11.

In the future, it may become a niche application that compressed air is no longer generated centrally via large compressor stations, but decentral on site. Initial solutions for a decentral pressure supply, e.g. for pneumatic grippers, are already available on the market [17, 18]. Decentralized compressors for vacuum generation for suction cups are also offered on the market for several years [19, 20].

2.2. Compressed air distribution

After generation, the compressed air is distributed in smaller or larger compressed air networks. These must be appropriately dimensioned and designed with a view to the connected loads. To avoid losses due to leaks, regular inspection and monitoring of the compressed air network is helpful. Accordingly, there are various providers – from start-ups to pneumatics suppliers – that are active in this area [21, 22]. Comparable offers are also available from compressor manufacturers [23]. The monitoring of the compressed air network is also partly linked to a management system that determines the most efficient combination of compressors supplying the compressed air network for the current compressed air consumption [24]. Acoustic cameras from various manufacturers have proven to be a practical tool for easy detection of the exact location of the leak [25, 26].

2.3. Design and operation of machines and systems

The basics for efficient design and efficient operation of pneumatic systems in machines and plants are known for a long time. As an example, a white paper by Festo from 2013 describes basic approaches to reducing compressed air consumption [27], cf. Figure 2.

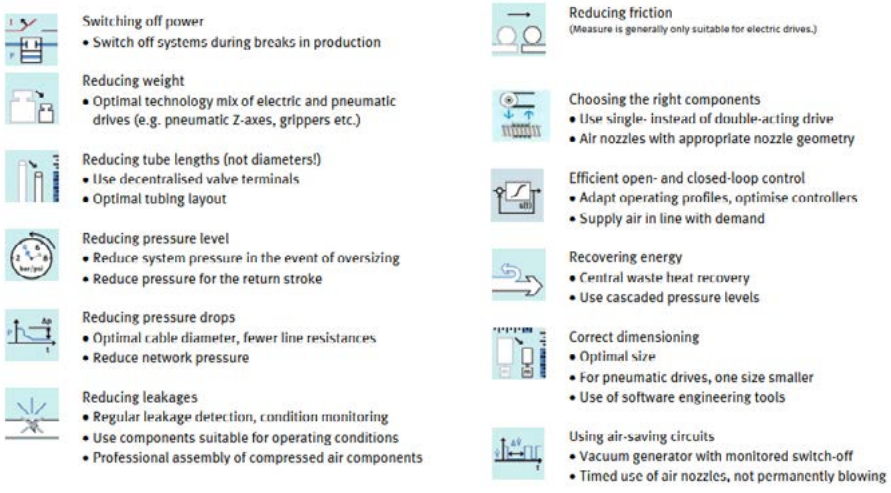

Figure 2. Measures to reduce compressed air consumption [27]

As well as for the compressors and the compressed air network, there are now also solutions for monitoring individual machines and systems. One example is the SFAM flow sensor with integrated pressure sensor from Festo, which can be used to detect compressed air fluctuations, leaks and other anomalies as part of a maintenance unit [28]. In addition, there are also monitoring systems that enable compressed air shutdown or pressure reduction in the event of detected downtimes of the machine/system [29, 30]. E²PME, a start-up from Marly (CH), goes one step further. They offer a data logger that can be used to record and evaluate the pneumatic and electrical power consumption of a machine. In the event of a standstill, electrical circuits can be switched off in addition to the compressed air, which, according to E²PME, allows savings of between 25 and 50 % in stand-by mode [31].

2.4. Pneumatic drive technology and its control

For the individual drive, the correct design and dimensioning is first of all necessary, as made possible e.g. by the web tool pneumatic simulation from Festo [32]. This is based on the Pneumatic Frequency Ratio (PFR), which describes the relationship between the pneumatic natural frequency and the application-specific frequency [33].

-17% ← Change of extension time
+6% ← Change of retraction time
-67% ← Change of air consumption per double stroke

-67% ← Measurement result
-67% ← Simulation result

not appl. ← Non-functional due to technical/safety constraints (s. explanation)

Figure 3. Change in performance and air consumption of energy-saving circuits in comparison to the standard meter-out circuit [34]

The PFR is also discussed in a recent publication in the Journal for Fluid Power [34] by comparing control strategies for pneumatic drives with regard to energy consumption and cycle time for different, typical applications (see Figure 3). As this publication shows, the supply air cut-off offers a way to save up to 20% of energy and time compared to pneumatic meter-out circuit in a wide range of applications. Instead of a 5/2-way valve, this control technology uses a 5/3-way valve with a closed center position, which is switched to the middle position when the end position is reached. As a result, the drive chamber is no longer filled with compressed air. The final pressure in the end position remains low, which saves energy. This has the additional effect that less pressure needs to be exhausted to start the countermovement. Thus, cycle time is shortened. If energy efficiency becomes more important, such a solution may get a stronger footprint in the market.

As can be seen in the right part of Figure 3, more complex energy saving systems are required to achieve greater savings. One example for such a solution is the Motion Terminal VTEM of Festo with the ECO drive app, which is operated at the minimum required pressure depending on the load [35]. At the end of the movement, there is therefore no further increase in pressure in the drive chamber – comparable to the supply air cut-off.

Another example of an energy-saving system is Smart Switching Lite, which is available on the new valve terminal VTUX from Festo [36]. This uses a 5/4-way valve that has two center positions (see Figure 4). In these, the air supply to the ventilation chamber is interrupted, while the ventilation path remains open. This means that no further compressed air is consumed after switching in one of these two middle positions. In principle, as with the supply air cut-off described above, the pressure build-up is stopped – only earlier, during movement and not only when the end position is reached. Accordingly, the pressure in the drive chamber is even lower in the end position – and even less pressure has to be released after the countermovement has been initiated. This further reduces the cycle time.

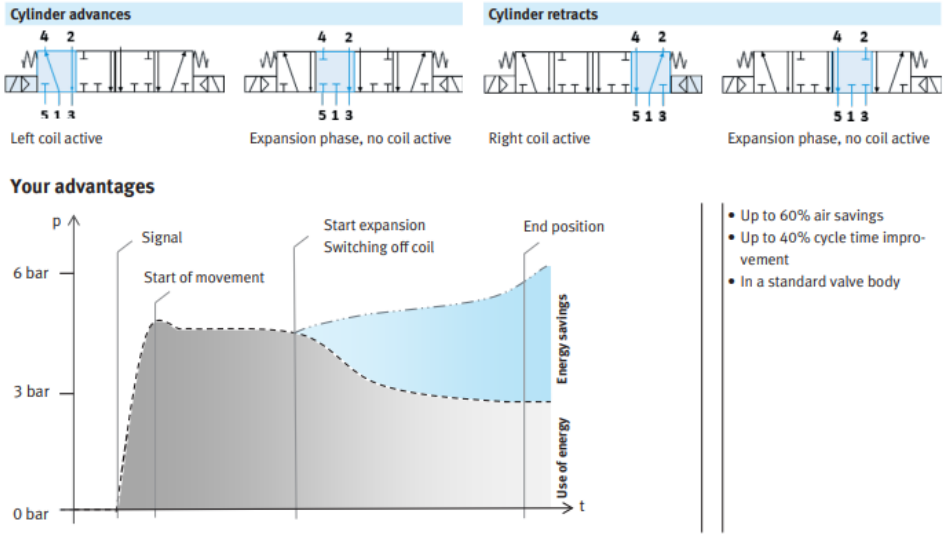

Figure 4. How Smart Switching Lite works [36]

The ECO drive with the Motion Terminal VTEM and Smart Switching Lite on valve terminal VTUX are two examples of what Festo calls Controlled Pneumatics [37]. This describes solutions in which, in contrast to today's common switching pneumatics, control of one or more state variables are possible. This also includes, but is not limited to, servo pneumatics, i.e. the position control of cylinders. Pressure or flow control are also part of Controlled Pneumatics.

In the field of pneumatic vacuum generation, energy savings are made possible by solutions that integrate the ejector itself as well as valve technology to control the supply air and sensors. Such vacuum generator systems reduce the amount of air required to achieve a target vacuum to a minimum. In this way, air-saving functions and functions for energy and process control are possible [38, 39].

3. PRODUCT CARBON FOOTPRINT (PCF)

For a complete CO_2 comparison of different drive solutions, not only the energy consumption in operation and the associated CO_2 consumption is important, but also a 'starting value' is required for the comparison. This is because without the drive having carried out a single stroke, energy has already been consumed to generate the components used, thus CO_2 emissions were generated.

According to the Greenhouse Gas Protocol (GHG) [40], a distinction is made between a Product Carbon Footprint cradle-to-gate (PCF ctg) and cradle-to-grave. PCF ctg is 'a partial life cycle inventory, including all emissions and removals from material acquisition through to when the intermediate product leaves the reporting company's gate'. Cradle-to-grave also includes the use phase of the product (see chapter 2) and the emissions at the end of the life cycle. In the following, PCF is always understood to be PCF ctg. This is because it offers the required 'starting value' for a CO_2-comparison of different drive solutions, comparable to the historical costs [41] in a total cost of ownership (TCO) analysis [42].

The methods for determining this PCF ctg are described theoretically, for example in EN ISO 14067 [43] or the VDMA Guideline 'Calculation of the Product Carbon Footprint in Mechanical and Plant Engineering' [44]. In practice, however, there are some challenges, following is an example:

A pneumatic and an electric drive solution are to be compared with each other for a specific application. On the pneumatic side, all components must be taken into account, from the air preparation unit, covering the fittings and tubes, the valve terminal up to the throttle and cylinder. And these components must be included into the comparison in the right configuration, for example the cylinder with the correct diameter and stroke, the selected end position damping, the desired piston rod shape, ...
In the case of air preparation units and valve terminals, only the proportion required for the individual drive should be considered. The ratio to be taken into account must be calculated even smaller if several drives are supplied with compressed air via one valve – as is usually, for example, in the control of clamps in the body shop of the automotive industry.

It is therefore necessary to provide customers with good support in the design tools in order to be able to compare systems appropriately with each other. In any case, the quality of the data taken into account to determine the PCF ctg must be declared. This is because one

pneumatic supplier only calculates the PCF ctg approximately, the other puts a lot of effort into it. The difference between the two approaches can only be made clear to the customer by information on data quality. Concerning the question how to calculate the data quality of subsystems or even entire drive solutions by using the data quality of individual components or parts, it may be necessary to refine the regulation.

Further refinement of the regulatory framework is required, how PCF ctg calculations can be compared with each other in a simple and clear manner – from individual components to subassemblies to complex systems. This is because a major advantage of pneumatics lies in its low investment costs. Can it really be assumed that a customer will place the extensive documentation of different suppliers next to each other for each of the large number of cost-effective components? And compare them in detail? The 'Example presentation PCF reporting' in the VDMA Guideline [44] comprises 5 pages – unfilled.

The low investment costs of pneumatics correlate with a low PCF ctg. This is because pneumatic components for a drive solution are much more compact and have a lower mass than comparable electric drive solutions. This reduces both the material required in production and the energy required during production, for example when using machinery. The lower PCF ctg of pneumatic compared to electric drive technology can also have a monetary effect. This is because the aggregation of the material share of the PCF of all products sold should result in Scope 3.1 ('purchased goods and services', see chapter 2) of the CCF. As SBTi allows to compensate emissions from the CCF under certain conditions – i.e. certificates from climate protection projects for CO_2-sinks [cf. 45] – a low PCF and CCF also become relevant from an economic perspective. It should be noted, however, that CO_2-compensation is only permitted as a supplementary measure for unavoidable residual emissions that are subject to strict quality requirements [46, 47].

The Carbon Border Adjustment Mechanism (CBAM) [48] is the EU's tool to set a fair price for CO_2-emissions from the production of carbon-intensive goods imported into the EU and to promote cleaner industrial production in non-EU countries. In the medium term, this could have the effect that low CO_2-equivalents of materials and the products produced from them also become economically cheaper.

4. CIRCULAR ECONOMY (CE)

Circular economy (CE) is a 'is a model of resource production and consumption that involves sharing, leasing, reusing, repairing, refurbishing, and recycling materials and products, to extend product life cycle for as long as possible' [49]. In the meantime, with ISO 59000 [50] there exists a family of standards concerning CE. And CE has found its way into legislation. In line with the EU's 2050 climate neutrality goal under the Green Deal, the European Commission proposed in March 2022 the first package of measures to speed up the transition towards a CE, as announced in the Circular Economy Action Plan [51, 52]. CE is also part of the Ecodesign for Sustainable Products Regulation (ESPR), which entered into force in 2024 [53, 54]. As Figure 5 shows, ecodesign requirements such as durability and reliability are described there, in which pneumatics has strengths.

(a) durability;
(b) reliability;
(c) reusability;
(d) upgradability;
(e) repairability;
(f) the possibility of maintenance and refurbishment;
(g) the presence of substances of concern;
(h) energy use and energy efficiency;
(i) water use and water efficiency;
(j) resource use and resource efficiency;
(k) recycled content;
(l) the possibility of remanufacturing;
(m) recyclability;
(n) the possibility of the recovery of materials;
(o) environmental impacts, including carbon footprint and environmental footprint;
(p) expected generation of waste.

Figure 5. Ecodesign Requirements, ESPR Article 5.1 [53]

Other requirements, such as energy and resource efficiency, have already been described in chapters 2 and 3. Requirements such as repairability and recyclability are directly linked to the CE.

In our view, the most important CE-strategies for pneumatics as presented in Figure 6 are ReUse (chapter 4.1), RePair (chapter 4.2), ReFurbish and ReManufacture (chapter 4.4) as well as ReCycle (chapter 4.4) as final step. They will be discussed in the mentioned chapters under perspective of pneumatics. To define the mentioned Re-Strategies, reference is made to ISO 59004 [55], which describes the 'vocabulary' of CE (see Table 1).

One challenge to realize CE in the field of pneumatics can be described using the example of seals. DIN 7716 describes the requirements for the storage of rubber and rubber products [56]. According to this, care must be taken 'to ensure that the products are stored stress-free, i.e. without tension, pressure or other deformations'. However, this is not the case in the installed state of seals. If, for example, for a cylinder or a valve the Re-Strategy ReUse should be used, there may be a significant time interval between the first and the second use. But how long can this be? A week, a month, a year? Or even several? With ReFurbish, too, the question arises, whether seals must be replaced in principle. Or is the sealing still in such a good condition that it can be used in the refurbished component without any significant risk? For lubricating greases, bearings and guides or electronic components [57], there are comparable challenges.

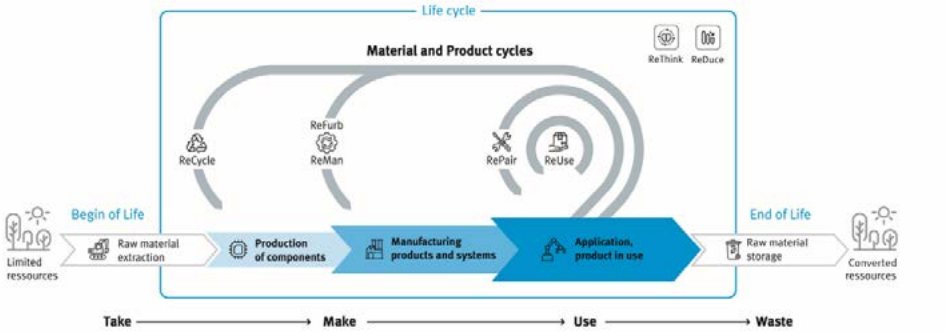

Figure 6. Re-Strategies of the CE

Table 1 – Definition of Re-Strategies in ISO 59004:2024 [55]

Action	Description
RePair	action to restore a product to a condition needed for the product to function according to its original purpose.
ReUse	use of a product or its component parts after their initial use, for the same purpose for which they were originally designed
ReFurbish	restore an item, during its expected service life, to a useful condition for the same purpose with at least similar quality and performance characteristics
ReManufacture	return an item to original condition from both a quality and performance perspective using an industrial process
ReCycle	activities to obtain recovered resources or use in a process or a product, excluding energy recovery

In order to decide on the selection of a suitable Re-Strategy at the end of the first service life, a large amount of information about the component is therefore necessary. In the Factory-X project [58], a proposal for structured data storage (cf. Figure 7) was created for this procedure, called R-Grading. This makes clear that the trends of CE and digitization must be considered together. Moreover, a Digital Twin offers the opportunity to securely and consistent store the large amount of data required over the long service life of the many components, so that a robust decision for a Re-Strategy can be made on this basis.

General Information	Operational Data	History	Physical State
Operator Location	**Environment** • Temperature • Humidity • UV radiation	**Crash Incidence** • Emergency shutdowns • Crash time	**Component operational/functional**
Date of Installation		**Maintenance Operations**	**Technical State**
Expected Wear	**Operating time** • Processing Time • Down Time • Operation Time	**RePair Operations**	**Optical State**
Installation Location		**ReFurb/ReMan Operations**	
	Sensor Data and time series • Pressure Level • Operating Voltage	**Number of power on/off cycle**	
	Compressed Air Quality	**Predictive Maintenance, Condition Monitoring** **Singular Events** • Pressure too low • Pressure spikes • Voltage to low • Voltage spikes **Gradual Changes** • Leakage • Friction	
	Load and stress		

Figure 7. Structure to implement CE-relevant data in an Asset Administration Shell

4.1. RePair

The repair of pneumatic components has a long tradition. The high robustness and reliability of pneumatic components as well as the simple design of the components are certainly reasons for this. Because under these conditions, a repair is worth it, i.e. the replacement of seals or the re-greasing of the components. Spare parts for this are available from Festo, for example, via a spare-part catalog [59], as well as videos to help with the repair [60]. Even tools and repair equipment are available [61].

All the examples mentioned aiming to ensure that the end customer's maintenance staff can repair the pneumatic components on its own. To send back components to the manufacturer for repair is currently not very common in pneumatic drive technology – in contrast to electric drive technology.

As shown in Table 1, there is a definition for RePair according to ISO 59004:2004 [55] ‘restore a product to a condition needed for the product to function according to its original purpose’ But what does this mean in practice? There is a distinction between regenerative repair, i.e. the restore and further use of defective parts or components, and replacement repair, i.e. the replacement of worn or defective components with new components [62]. Replacement repair is probably most common for pneumatic components. This is because a machine/system is repaired by, for example, replacing a defective valve terminal. This is quick and makes it possible for the production plant not to come to a standstill or to restart quickly. The removed valve terminal is repaired, e.g. by replacing a defective valve or another defective module. The valve is repaired by changing the pilot valve, for example. The pilot valve ...
The way in which the repair of pneumatic components will become established and at which of the levels mentioned must and will be tested on the market.

4.2. ReUse

There is probably a long history in the field of ReUse of pneumatic components, even if this is usually not transparent for the manufacturers of pneumatic components. What stops a user from utilizing a valve terminal, a maintenance unit, a pneumatic actuator or even more complex systems such as hall and robot installation platforms (see Figure 8) [63] in the next machine/system when the original machine/system is demounted?

In some cases, the end user is even actively supported in ReUse. For valve terminals and maintenance units, for example, Festo offers a modification aid that supports reconfiguration and thus, reduces the effort required for ReUse [64].

What happens if a machine/system is to be taken out of service and then will be demounted? At latest, the contracted waste disposal company will take a close look at the entire structure and demount valuable components for which it sees a market and ReUse them separately from the remaining parts. It seems, that this is already happening today, because you can find used pneumatic components on various internet portals [65, 66].

In order to increase the ratio of reused components, it would be helpful in future if the component itself – for example via a Digital Twin – provides information about its current 'state of health' and how much of its statistical lifespan it already has consumed. The technical terms on this in the course of the CE are 'Health Management' and 'Remaining Useful Life' (RUL) [67]. This requires access to the data mentioned in Figure 7.

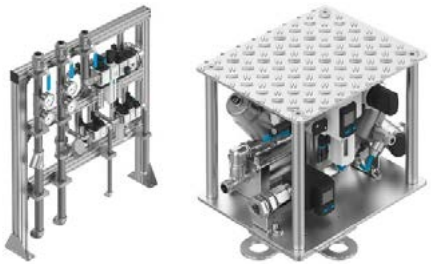

Figure 8. Examples for Hall and Robot Plates (HIP, RIP) [63]

4.3. ReFurbish and ReManufacture

According to the definition of ISO 59004:2004 [55, see Table 1], the take-back/repurchase of components and systems, their reconditioning in different quality levels and the ultimately resale is referred to as ReFurbish and ReManufacture.

While there is a wide range of options for reconditioning motors and motor controllers for electric drives and drive systems [68, 69, 70], this is still largely unknown in pneumatics. The customers of pneumatics, i.e. the machine builders, are already one step ahead. For example, there are offers with integrated pneumatics for rebuild machines [71], pre owned machines [72] or used machines [73]. The general labels for these different terms are ReFurbish and ReManufacture.

Just as with ReUse (see chapter 4.2), Digital Twins are helpful for realizing ReFurbish and ReManufacture for components. This is because the manufacturer of the component needs

information about the usage history of the specific product in order to set a buyback price. How intensive was the use? Under what environmental conditions was it used? Has maintenance and servicing been carried out? If so, how? This and other information (see Figure 7) must be provided by the owner of the component so that the manufacturer of the component is willing to pay a higher price than the scrap price. Only by sharing data an economic benefit for all partners involved can be derived from ReFurbish or ReManufacture.

A specific challenge of pneumatics is that only limited data is available. With this little data, you can certainly achieve important insights in the sense of predictive maintenance [cf. 74]. But since far more data is available for electric drives, more or more accurate information can be derived from it. This fact could result in a disadvantage for pneumatics in the future with regard to ReFurbish and ReManufacture. In the end, it leads to the question already mentioned in the introduction to chapter 4, with which data should a Digital Twin be filled? Fortunately, there are currently some research projects related to fluid power technology such as Factory-X [58], Fluid 4.0 [75] or CliCE-DiPP [76], which deals with the development of Digital Twins based on the Asset Administration Shell (AAS).

For pneumatic components and systems, this raises the question of which of the large number of products a ReFurbish and/or ReManufacture makes sense from an economic as well as an ecological perspective? This is because the deployment, operation and maintenance of a Digital Twin are associated with costs and CO_2e. Even the return transport from the owner/user to the manufacturer cannot be achieved without economic and ecological costs. This significantly limits the number of pneumatic components for which a corresponding offer makes sense.

To put it another way: For typical C-parts such as screws, nuts or washers [77] a ReFurbish or ReManufacture probably doesn't make sense, so not for a Digital Twin. But there is obviously a market for used machines, otherwise there would be no corresponding offers. And somewhere between these two extremes, there is a borderline at which a Digital Twin and the associated CE offerings become ecologically and economically useful.

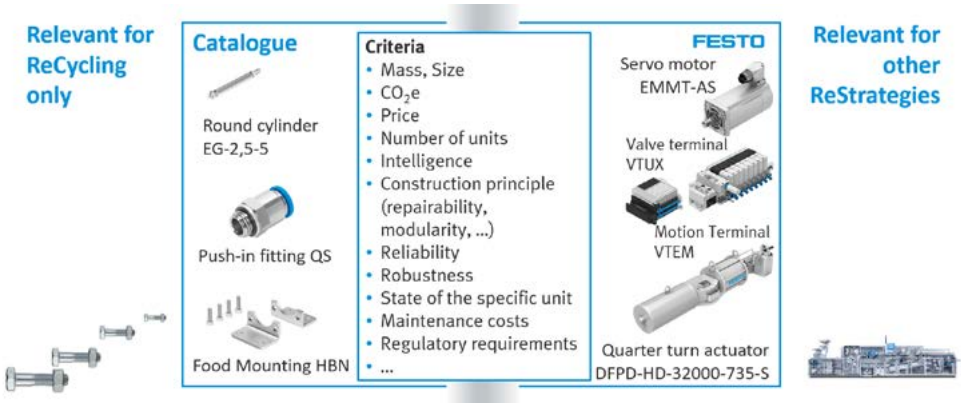

Figure 9. Possible criteria for deciding whether a Digital Twin and the services based on it make sense for CE

This borderline probably runs directly through the catalog of pneumatics suppliers as Festo. To make it concrete with the example of a pneumatic cylinder. Festo offers cylinders with piston diameters from 2.5 mm to 735 mm [78, 79], the product weight for these pneumatic cylinders varies from 2 g to 1.5 kg. It is therefore obvious that the same Re-Strategy does not make sense for all pneumatic cylinders. Figure 9 shows some possibilities for criteria that can be used to draw the mentioned borderline.

4.4. ReCycle

In terms of their mass and very roughly considered, pneumatic components consist of a lot of aluminium, some plastic (in a wide variety of variants) and steel (see the distribution of production materials of Festo [9] shown in Figure 10). In addition, there are some other materials in smaller quantities, e.g. copper, zinc and brass.

For the aluminium production bauxite is needed, which has been declared in the European Union since 2020 as a Critical Raw Material [80]. According to the fifth list of EU critical materials [81], which was published in 2023, aluminium itself is also classified as a Critical Raw material [82, cf. also 83].

Aluminium can be easily recycled as a high-quality metal. The End-of-Life Recycling Rate (EoL RR, [84]) was 69% in Europe in 2021 [85]. Iron and thus steel has an even higher EoL RR, which was already 75% in 2015 [85]. The recycling of plastics is much more complex. For further details, please refer to [86]. With regard to pneumatic components, it should also be mentioned that there are initial considerations to ReCycle sealings [87].

Due to the simplicity of the design of pneumatic components, only a limited number of raw materials are required. On the electronic circuit of a motor controller as example, many more components and raw materials (including critical ones) are used. The recycling processes for electric components are correspondingly more complex to recover the raw materials [88]. Of course, this applies in the same way to the electronic components in pneumatic valve terminals or sensors.

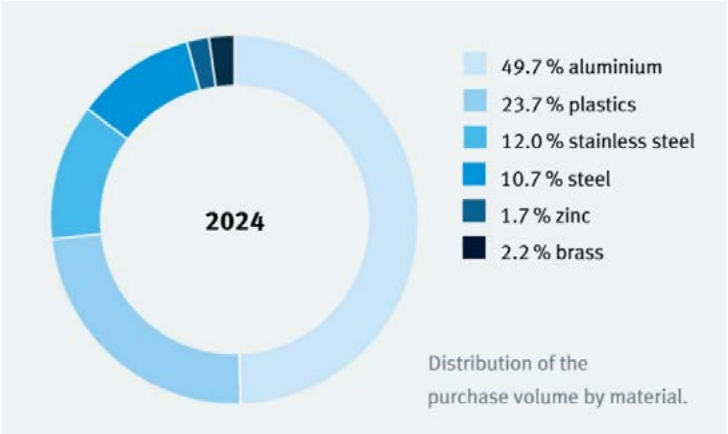

Figure 10. Distribution of production materials of Festo by weight [9]

To illustrate it with another example. Only a few magnets are used in pneumatic drive technology. Although magnet-free electric motors are now available [89], rare-earth magnets [90] are commonly used for powerful motors. And rare-earth elements are critical raw materials [81, 83].

5. SUMMARY AND OUTLOOK

Significant changes are required for pneumatic drive technology to successfully complete the energetic transformation towards CO_2 neutrality on a broad scale. This applies in particular to the high energy and thus CO_2 consumption during the use phase. Controlled pneumatics with solutions such as ECO drive with the VTEM Motion Terminal or Smart Switching Lite as an option for the new VTUX valve terminal offer potential for this. This is associated with an increasing integration of sensor technology, ideally without any significant impact on reliability and robustness of pneumatic systems. This is important in view of a second megatrend in addition to environmental sustainability, which is currently transforming fluid power technology: digitalization. There are definitely opportunities for pneumatics here – even and especially in competition with electric drives.
However, this requires pneumatic research and development to focus more on the integration of sensor technology and the additional customer benefits that can be derived from it (Soft sensors, Functional Mock-Up Units (FMU), predictive maintenance, health index, RUL, ...).

On the other hand, pneumatics offers a number of fundamental advantages that may be relevant in terms of ecodesign. Pneumatic products, for example, are robust and reliable – as significantly fewer components are required for a pneumatic movement compared to an electric movement. System reliability is calculated by multiplying the reliability of all individual installed elements. Another example of the advantages of pneumatics is the simple and cost-effective commissioning. With a 24V power supply (if there is a power supply at all), pneumatic components are suitable for the extra-low voltage range [91]. They are therefore of course subject to the requirements for general product safety [92] - but not the Low Voltage Directive [93]. Accordingly, no qualified electrician in accordance with DGUV V3 [94] is usually required.

Figure 11 concludes this paper with a general comparison of electric and pneumatic drive technology (based on [95 and 96]) as well as a specific comparison in terms of environmental sustainability. In times of change to climate-neutral and resource-efficient production combined with the digital revolution, it is important to reduce the weaknesses of pneumatics – without reducing its strengths.

Criterion	Standard Pneumatics	Smart Switching Lite	Electric Spindel Drive	Electric Tooth Belt Drive

Wolfgang Gauchel received the diploma in mechanical engineering from RWTH Aachen University in 2001, where he also was graduated with a doctorate in 2006. Since then, he is working in the research Department of Festo. He is on the board of the VDMA Fluid Power Research Fund since 2021.

Victoria Pohl received the master's degree in mechanical engineering from the University of Stuttgart in 2021. She then worked as a research associate at the Institute of Industrial Manufacturing and Management (IFF). Since 2024, she has been working in the research department of Festo in the field of circular economy.

D**aniel Ditterich** received his diploma in electrical engineering from the University of Stuttgart and subsequently worked at the Institute of Industrial Automation and Software Engineering (IAS). Since 2010, he has held various positions at Festo, focusing on energy efficiency, digital products, and sustainable automation.

Real-Time Fault Detection in Pneumatic Drive Applications Through Pattern Classification

Vladimir Boyko and Jürgen Weber

Chair of Fluid-Mechatronic Systems (Fluidtronics) – TUD Dresden University of Technology, Helmholtzstraße 7a, 01069 Dresden, Germany, vladimir.boyko@tu-dresden.de

Abstract.

Early fault detection in pneumatic systems is crucial for the prevention of unnoticed energy losses, high energy costs and system failures. According to various estimates, up to 40% of current compressed air consumption can be saved by locating and eliminating leaks. An increasing number of solutions for leakage detection have therefore been proposed in recent decades, which, however, are often cost-intensive, require the use of several additional sensors and cannot be transferred to other machines without extensive customization, leading to their low prevalence in industrial practice of cost-sensitive pneumatics.

This paper proposes a transferable fault detection method for pneumatic linear drives using only one pressure sensor per drive. By integrating neural networks and feature-based classification techniques, the method achieves up to 92.5% classification accuracy on the test dataset. For this purpose, extensive measurement data was generated for various systems and fault scenarios. Data features were extracted in the time and frequency domain using Python's “tsfresh” library and ranked using various feature selection methods such as recursive feature elimination or mutual information. Several classification methods, including Naive Bayes and k-nearest neighbors, were examined and compared with other classification methods such as neural network and cycle time-based fault detection. In this way, a real-time fault detection and localization method can be developed without interrupting machine operation to perform test cycles.

Keywords. Energy efficiency, compressed air systems, pneumatics, pneumatic actuators, fault detection, condition monitoring, energy loss, leakage, friction

1. INTRODUCTION

1.1. Current State

Compressed air is widely used as a practical and easily controllable energy source across many industrial applications. Pneumatic systems are regarded as cost-effective, durable, and environmentally sustainable automatization solutions capable of operating in demanding environments and relatively simple to install and maintain. However, one of the main drawbacks of pneumatic systems is their relatively high energy consumption. This has led

All Open Access articles are peer-reviewed, distributed under the Creative Commons Attribution-Non Commercial 4.0 International

to increased research efforts focused on improving their energy efficiency and developing reliable fault detection methods. Studies have shown that up to 40% of the energy used in pneumatics could be saved through more efficient system design and operation [1].

To realize this potential, several strategies are being pursued in science and industry. Primarily, these include demand-based sizing of components such as actuators, pipes, and compressors, as well as energy-saving circuits [2-7]. In parallel, there is growing attention on condition monitoring and fault detection systems. Recent studies [8,9] indicate that research on fault detection in pneumatic systems has grown considerably in recent years.

However, while many of the proposed approaches achieve reliable fault detection, they often require the integration of multiple additional sensors, making them economically impractical for pneumatic systems with numerous actuators [10]. Around 60% of the fault detection methods analyzed in [8,9] depend on the integration of multiple sensors to detect faults, e.g. several pressure and volume flow signals. Such solutions might provide more information and enable fault localization, but they are often not cost-effective for many companies, which limits their use in industry. Moreover, proposed monitoring concepts are often designed for a specific machine, requiring the methods and identified signal patterns to be extensively adjusted before being applied to a different system.

1.2. Commercially Available Fault Detection Solutions

In pneumatic drive systems, leakage and increased friction are the main sources of energy loss [11]. Detecting faults is challenging due to the robustness of pneumatic drives, which often remain functional even with severe issues like major leaks. Increased friction, caused by seal wear or uneven piston loads [12], is also hard to detect as it does not directly increase air consumption. At the same time, addressing leakages can save up to 40% of air consumption [1,13]. For this reason, numerous fault detection systems for pneumatic drives are available on the market; however, they still present several limitations.

Festo's Motion Terminal (VTEM) offers a "Leakage diagnosis" application that performs a diagnostic test cycle to measure leakage volume flow based on cylinder volume, hose length, and pressure drop, halting operation during the test [14]. Similarly, the Festo MSE6-E2M device [15] and other systems such as [16] detect leaks by monitoring pressure drops in a blocked state or by using flow rate limits. However, such solutions lack fault localization without additional data such as valve actuation signals.

Ultrasonic leak detection allows testing without interfering with the system by using portable devices to sense air turbulences, but is less effective in large or hard-to-reach networks and cannot be used in operating systems due to exhaust noise [17-19]. Thermography is also conceivable, but requires expensive cameras and fails in complex machines where the pneumatic actuators are covered by other parts [20].

Friction from piston or guide wear is usually detected by monitoring pressure changes (which in general can also indicate leaks) or using special test rigs, which are not suitable for live systems [21]. High-frequency vibration analysis can identify increased friction during operation, but requires advanced equipment and protection [22,23].

Another monitoring concept that does not incur any additional costs, can be used during operation, and is therefore potentially suitable for industrial use is known as cycle time-based fault detection. The concept, first presented in [24] and expanded in [25,26], involves

using proximity (reed) switches as soft sensors to detect deviations in the extension and retraction times of the pneumatic drive and to draw conclusions about possible fault sources. This allows faults within the pneumatic drive to be precisely localized. However, this approach is partially limited when monitoring highly dynamic drives with a pneumatic frequency ratio of $\Omega < 1.5$ according to [27].

1.3. Pressure-Based Fault Detection and Summary

The outlined state of the art indicates the demand for monitoring methods in pneumatic drive technology that can be applied across different systems and detect and localize faults during operation with minimum number of sensors. Such a low-cost and widely applicable approach based on cycle time was presented in [24,25], but it still has limitations in terms of distinguishability in some use cases. This paper therefore introduces another online method that uses the differential pressure signal (i.e., the difference between current and reference pressure) captured by a single sensor per drive and evaluated with various pattern classification techniques.

Pressure-based fault detection in pneumatic cylinders has been previously studied before (e.g., [23,28]), focusing mainly on analyzing pressure signals and a limited set of features such as min-max values or kurtosis. Moreover, the transferability of classifiers to different cylinder geometries or tasks as well as the influence of the sensor placement have rarely been examined. In the dissertation [11], the effects of three fault types (external/internal leakage and friction) on 32 algebraic features defined by the author, such as pressure difference and mean value, were analyzed using a pneumatic welding gun. This method requires prior training using a validated simulation model of the target system, which limits its direct transferability to other applications.

In his dissertation [10], Dierolf uses pressure, pressure difference, and flow signal and examines 49 features, selecting 4 for online fault detection in a pneumatic machine at 18 Hz sampling rate for pressure sensors. While the method can be applied to other machines without retraining, it has limitations, such as requiring non-overlapping actuator actions. The classification accuracy in the tested example averaged 39%. Another dissertation by Klein [29] demonstrates the potential of using novelty scores and machine learning for fault detection in a single servopneumatic welding gun with high accuracy (up to 100%). Unlike the standard pneumatic drives examined in this paper, such systems typically include multiple sensors (e.g., several pressure sensors and a position sensor), which simplifies fault detection. Nevertheless, significant challenges were observed, including difficulty detecting increased friction and pronounced domain shifts when operating parameters change. These shifts can potentially make trained classification models ineffective, requiring recalibration of the fault detection system.

The aim of this paper is therefore to explore a broader range of time- and frequency-domain features for fault diagnosis of pneumatic cylinders, compare feature-based classification with neural networks and the cycle time-based method, and evaluate their applicability across different pneumatic drives and for different positions of a single pressure sensor per drive.

2. FAULT LOCALIZATION

Table 1 outlines the typical fault locations in pneumatic linear drive systems considered in the paper.

Table 1. Typical faults in pneumatic drive systems.

Fault	Definition and examples
External leakage	Air leakage from the actuator into the environment (locations a)-b) in Figure 1). Possible causes: ▪ Mechanical damage to the hose or hose aging; ▪ Damaged/worn cylinder wiper; ▪ Loosened/damaged push-in fittings.
Internal leakage	Interchamber leakage (location c) in Figure 1). Possible causes: ▪ Damaged/worn cylinder piston sealing. ▪ Piston detachment from the rod
Increased friction	Additional external force (location d) in Figure 1). Possible causes: ▪ Damaged/worn cylinder piston sealing and/or wiper; ▪ Changed friction conditions of mechanical components (e.g., guide wear or contamination).

Figure 1 illustrates potential fault locations in a standard pneumatic drive with meter-out throttling. To detect the faults from Table 1 with minimal amount of sensors, different positions for the single pressure sensor position shown in Figure 1 (placements 1) and 2)) are proposed.

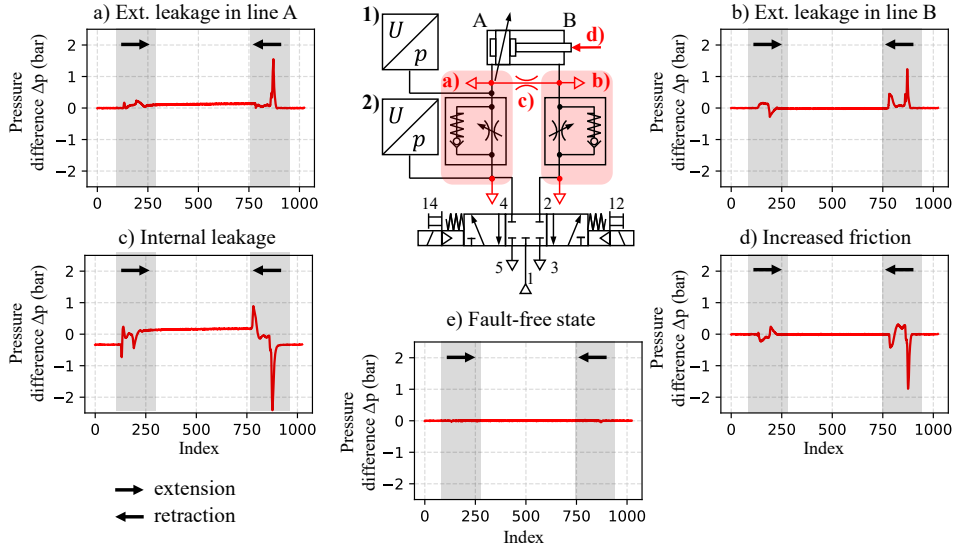

Figure 1. Considered single pressure sensor positions 1) and 2) within a pneumatic drive and potential fault locations a)-d) with corresponding exemplary patterns in pressure difference signals when measured at sensor position 1)

The basic idea behind monitoring the linear drive presented here is to observe the piston-side pressure p_A continuously or periodically. This involves comparing the reference

pressure profile recorded once after commissioning and setup with the repeatedly measured current pressure profile. This results in differential pressure profiles $\Delta p = p_{A,Curr} - p_{A,Ref}$ exemplary shown in Figure 1a-e, the shape of which is to be classified for fault detection and localization.

In the case of leakage in line A, a clear permanent deviation from zero is observed during the standstill in the cylinder's extended state. Corresponding deviations also occur during extension and retraction due to the changed movement time. The deviation is more pronounced during the return stroke, where leakage A accelerates motion due to the quick exhaust effect (see [25]).

Leakage in line B and increased friction also lead to a deviation in extension and retraction times, visible as distinct peaks in the differential pressure signal. Internal leakage alters the pressure profile more severely, leading to significant distortions in the differential pressure signal. In the reference case, by contrast, deviations from zero are absent or minimal, occurring only due to sensor noise or operating fluctuations.

3. USE CASES

For the classification training, measurement data corresponding to fault-free and faulty scenarios was generated on the test bench shown in Figure 2 using the Festo DSBC-32-200-PPV-A (piston diameter 32 mm, stroke 200 mm) and the Hoerbiger R6025/50 (piston diameter 25 mm, stroke 50 mm) double-acting differential cylinders. Leaks were introduced at the locations shown in Figure 1 using additional throttles, as illustrated in Figure 2. Increased friction was simulated with a Festo DSBC-L-50-200-PPV-A pneumatic cylinder (without compressed air supply) mechanically coupled to the guide of the test cylinder.

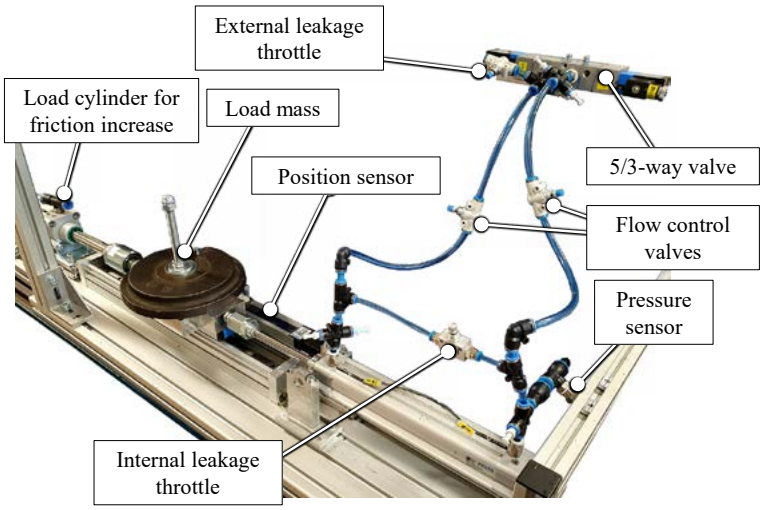

Figure 2. Test bench for pneumatic linear drives

To cover a broad range of operating conditions, the training data parameters were varied according to Table 2. The leakage throttle openings were adjusted to generate two leakage rates (20 l/min and 40 l/min under normal conditions). Throttles connected to the atmosphere at the load cylinder ports were used to generate additional counterforces, representing fault

conditions equivalent to increased friction in the test cylinder. The applied throttle settings resulted in two mean counterforce levels of approximately 20 N and 40 N. These additional force levels were not determined for every operating point of the test cylinder, since the objective was to impose two distinctly different load magnitudes.

The examined drive tasks represent a classic motion task in which a load mass is moved between two positions (load cases 1-1 and 1-2 according to [7]). No pressing or mixed motion-pressing tasks were considered. Approx. 120 pressure profiles per data set were recorded, evenly split between fault-free and faulty cases shown in Figure 1, resulting in about 3000 pressure profiles for training at a 1000 Hz sampling rate. The effect of sampling rate on classification is discussed in Chapter 5.

Table 2. Training data set parameters for pneumatic linear drives

#	Piston diameter (mm)	Stroke (mm)	Hose length (m)	Operating pressure (bar abs.)	Transition time (ms)	Load mass (kg)	Pneum. frequency ratio (-)
1	25	50	5	7	450	11	1.0
2			0.5	7	250	12	1.2
3			0.5	6	500	12	2.3
4			5	6	470	10	1.0
5			0.5	6	500	6	3.2
6			0.5	7	500	12	2.5
7			5	7	800	6	2.4
8			0.5	6	250	12	1.1
9			5	7	250	0.25	3.7
10			5	6	800	6	2.2
11			5	6	250	0.25	3.4
12			0.5	7	500	6	3.5
13	32	200	0.5	6	300	12	1.2
14			5	7	800	6	3.3
15			5	7	600	6	2.5
16			0.5	7	600	12	2.6
17			0.5	7	600	6	3.6
18			5	6	690	8	2.2
19			5	6	800	6	3.0
20			5	6	700	25	1.3
21			0.5	6	600	6	3.4
22			0.5	7	300	12	1.3
23			5	7	700	27	1.4
24			0.5	6	400	6	2.2

The test data in Table 3 was collected to evaluate the classification methods on tasks involving different cylinder geometries and previously unseen operating parameters. Four leakage levels (15, 25, 30, and 40 l/min) and two friction levels (20 and 40 N) were applied. In addition to the pressure signal, cylinder motion times were recorded in the PLC to enable comparison with the cycle time-based method in the final evaluation step.

Table 3. Test data set parameters for pneumatic linear drives

#	Piston diameter (mm)	Stroke (mm)	Hose length (m)	Operating pressure (bar abs.)	Transition time (ms)	Load mass (kg)	Pneum. frequency ratio (-)
1*	50	200	1.5	7	470	31	3.8
2**	40	400	1.5	7	560	0.85	18.2
3	25	50	1.5	7	380	21	1.0

* Festo DSBC-L-50-PPV-A low-friction cylinder with adjustable pneumatic cushioning
** Festo DSBC-40-400-PPSA-N3 cylinder with self-adjusting pneumatic cushioning

4. PATTERN CLASSIFICATION

4.1. Feature-Based Classification Models

The basic procedure for training machine learning models for pattern classification is shown in Figure 3.

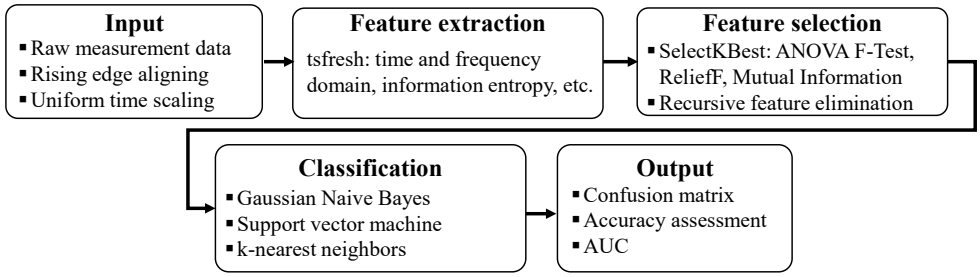

Figure 3. Pipeline for feature-based machine learning in Python

The collected raw measurement data series were singularized so that one file corresponds to a double stroke of the pneumatic cylinder, aligned and scaled to a uniform signal length of 1024 points. Next, the features of the data sets were extracted using the Python library "tsfresh", which extracts 783 features from the time and frequency domains for each profile.

In a further step, four classification models with different combinations of feature selection and classification methods shown in Table 4 were trained and evaluated. The combinations were selected based on established best practices in pattern recognition and machine learning. Filter-based feature selection methods such as ANOVA F-test, mutual information, and ReliefF are widely used with classifiers that do not perform intrinsic feature weighting, including Gaussian Naive Bayes and k-nearest neighbors [30-32]. Recursive feature elimination was combined with a linear support vector machine for classification, following the methodology proposed by Guyon et al. [33].

The training was done using a stratified group k-fold cross-validation with five folds, in which folds were defined by the experimental datasets from Table 2. This ensures that all measurements from the same datasets are assigned to either the training or the validation set, but never split across both (e.g. 1st fold contains datasets 1-5, 2nd fold contains datasets 6-10 etc.) to realistically estimate the performance of the classifier during the training. Within each fold, preprocessing included normalization of all extracted features to the interval [0;1] using min-max scaling and removal of non-informative features via variance thresholding.

Table 4. Combinations of feature selection and classification methods applied in Python for the classification models.

Model #	Feature selection method	Classification method
1	ANOVA F-test from SelectKBest	Gaussian Naive Bayes (GNB)
2	Recursive feature elimination (RFE) with feature ranking via linear support vector machine (SVM)	Linear support vector machine classifier (SVM)
3	ReliefF from SelectKBest	k-nearest neighbors (kNN) with 20 neighbors
4	Mutual information-based feature selection from SelectKBest (MI)	k-nearest neighbors (kNN) with 20 neighbors

The predictive performance of each combination was evaluated on the test data set presented in Table 3, which was not used during training and is therefore unknown to the classifier. Performance was assessed using accuracy and the area under the receiver operating characteristic curve (AUC). The average AUC across all classes indicates how effectively the classifier distinguishes between the different classes.

The described procedure was conducted once for the pressure sensor placement at the cylinder (variant 1) and once at the way valve (variant 2) as shown in Figure 1. In each case, the extension part of the pressure profile and the entire pressure profile (extension and retraction) were examined separately in order to compare performance.

4.2. Neural Network

Another method examined for classifying the pressure profile of the component involves neural networks. Similar to Chapter 4.1, the training data was aligned, scaled to a uniform signal length of 1024 points, filtered, and fed into a neural network for training in the MATLAB environment. The proposed neural network comprises 13 layers in total, including 5 learnable layers: three convolutional layers (1D-CNN) followed by a bidirectional long short-term memory layer (BiLSTM) and a fully connected layer. This allows both local patterns and their global temporal ordering to be captured in the pressure difference signal. The structure of the neural network is presented in Table 5.

The 1D convolutional layers are used as a feature extractor, enabling the detection of characteristic local patterns such as pressure slopes, inflection points, and short-term oscillations that arise from fault events. Their dilation by applying dilation factors of 1, 2, and 4 is used to progressively increase the temporal receptive field of the network while preserving the original time resolution of the signal. This three-stage design represents the minimal depth required to capture local, intermediate, and extended temporal structures without excessive model complexity. Further convolutional layers were avoided, as global temporal dependencies are subsequently modeled by a bidirectional LSTM layer.

The bidirectional LSTM layer models long-term temporal dependencies and explicitly encodes the temporal order of signal components by processing the sequence in both forward and backward directions. This is particularly important for fault patterns that are similar in amplitude but differ in the order of positive and negative pressure lobes. The final fully connected and softmax layers map the learned representation to class probabilities, while

the dropout layer mitigates overfitting. Leaky ReLU activations are employed to preserve information contained in negative signal components and to ensure stable gradient propagation.

The final network depth and parametrization was determined through empirical validation. Investigations on the test dataset confirmed that a three-stage convolutional block provided the optimal balance between sufficient receptive field coverage and generalization capability.

Table 5. Neural network structure

#	Layer	Description and Parametrization
1	Sequence input layer	6 input values
2	1D convolutional layer	Local temporal patterns extraction with unchanged time length; 64 filters, kernel size 7, dilation factor 1
3	Layer normalization	Normalization of activations for training stabilization
4	Leaky ReLU	Activation function with negative slope 0.1
5	1D convolutional layer	64 filters, kernel size 7, dilation factor 2
6	Leaky ReLU	Activation function with negative slope 0.1
7	1D convolutional layer	64 filters, kernel size 7, dilation factor 4
8	Leaky ReLU	Activation function with negative slope 0.1
9	Bidirectional LSTM layer	128 neurons, forward and backward detection of time dependencies, output taken from the last time step
10	Dropout layer	Dropout rate 0.5 for regularization against overfitting
11	Fully connected layer	Maps the 256-dimensional feature vector to 5 output nodes
12	Softmax layer	Output of class probabilities
13	Classification layer	Loss function calculation and final classification

The following six values or features were used as input:

- Normalized pressure difference signal: The original signal is normalized by the global standard deviation σ of all training data
- First derivative of the normalized signal
- Positive portion of the normalized signal.
- Negative portion of the normalized signal
- Order feature: A binary feature indicating whether the first positive peak of the signal occurs before the first negative peak.
- Area ratio: The ratio of the area under the positive signal portions to the area under the negative signal portions

In addition to the normalized pressure difference signal, five auxiliary inputs are provided to embed prior pattern knowledge directly into the learning process of the neural network. The first derivative is intended to improve sensitivity to rising and falling edges. The positive and negative signal portions explicitly encode asymmetric pressure behavior, which is characteristic of different fault locations shown in Figure 1. The order feature and area ratio also directly represent physically meaningful distinctions observed in the patterns, such as a pressure increase followed by a decrease during extension vs. the inverse sequence demonstrated in Figure 1b) and d). Their direct specification through auxiliary inputs simplifies training and classification, as such relationships do not have to be implicitly

recognized or derived by the neural network. Together, this multi-channel representation improves class separability, accelerates convergence, and enhances robustness against variability in real pneumatic systems.

Similar to the classification models in Chapter 4.1, the performance of the neural network was evaluated based on accuracy and AUC for two different pressure sensor positions (at the cylinder vs. at the valve) as well as for two different sections of the pressure profile (extension vs. full stroke).

5. RESULTS

5.1. Performance of Feature-Based Classification Models and the Neural Network

After applying the fault classification methods described in Chapters 4.1 and 4.2 to the test data set from Table 3, which was previously unknown to the classifiers, their performance was compared for the different sensor positions and pressure signal sections. Figure 4 and Figure 5 provide an overview of the accuracy and AUC of the feature-based classification models depending on the number of features in comparison to the neural network.

The neural network and feature-based classifiers showed comparable performance. The highest test accuracy (92.5%) was achieved by model #3 (ReliefF with k-NN) using full-stroke signals with 50 features and pressure measured at the cylinder (Figure 4c). The accuracy drop above 100 features across different classifiers indicates overfitting due to feature redundancy. Model #2 (RFE with SVM) was also highly effective, achieving neural-network-level accuracy and AUC across all settings with only five features. Using RFE, the following “tsfresh” features describing global and local changes in amplitude, periodicity, and frequency content were selected for full-stroke classification with pressure measured at the cylinder:

- `longest_strike_below_mean`: Length of the longest continuous sequence of values below the mean value.
- `sum_of_reoccurring_data_points`: Sum over all repeated observations in the time series (i.e., data points that occur more than once) in the time series.
- `fft_coefficient__attr_"angle"__coeff_77`: Phase angle of the Fourier coefficient at coefficient index 77.
- `fft_aggregated__aggtype_"skew"`: Skewness of the frequency spectrum.
- `agg_linear_trend__attr_"intercept"__chunk_len_10__f_agg_"var"`: Measures how much the baseline level of the signal (intercept of a linear trend) fluctuates between consecutive segments of length 10.

The highest accuracy was obtained when measuring the pressure directly at the cylinder. Measuring pressure at the valve reduced accuracy on average by about 11% for the extension stroke and 8% for the combined extension and retraction. This reduction is likely due to varying hose lengths, which cause more diverse pressure signals for the same fault scenarios, whereas cylinder measurements lead to more uniform patterns.

The inclusion of the return stroke (i.e., evaluation of the full stroke) increased the accuracy of the pattern classification by approx. 4.2% for the pressure measurement at the cylinder and by 6.4% for the pressure measurement at the valve the compared to the variant with extension only.

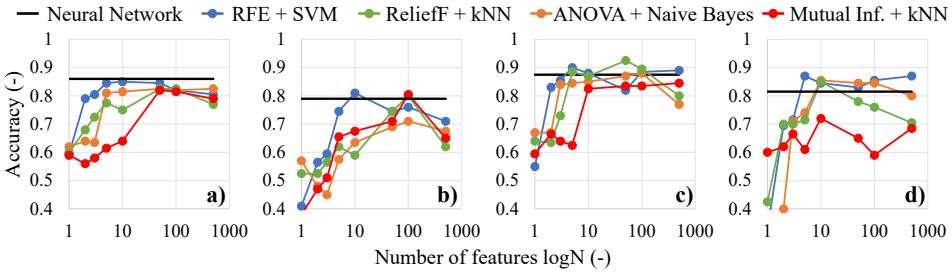

Figure 4. Classification accuracy of the neural network and feature-based models as a function of the number of features, pressure sensor location, and pressure signal segment: (a) cylinder, extension; (b) valve, extension; (c) cylinder, extension + retraction; (d) valve, extension + retraction.

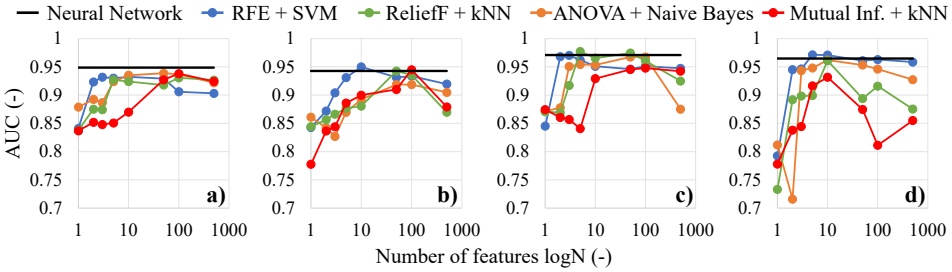

Figure 5. Area under the receiver operating characteristic curve (AUC, average value for all classes) of the neural network and feature-based models as a function of the number of features, pressure sensor location, and pressure signal segment: (a) cylinder, extension; (b) valve, extension; (c) cylinder, extension + retraction; (d) valve, extension + retraction.

Figure 6 shows the influence of the sensor's sampling rate on accuracy and AUC for two selected classification methods (RFE+SVM with 5 features vs. neural network) when measuring extension and retraction pressure profiles at the cylinder. As can be seen, it is possible to reduce the sampling rate from the original 1000 Hz to 100 Hz without significant loss of accuracy. However, further reduction of the sampling rate leads to reduced accuracy.

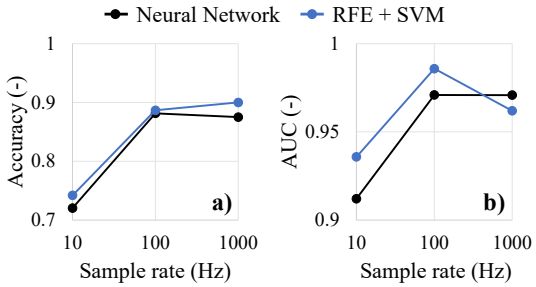

Figure 6. a) Accuracy and b) area under the receiver operating characteristic curve (AUC, average value for all classes) of neural network and classifier RFE+SVM with 5 features depending on the sampling rate of the pressure sensor; pressure measurement at the cylinder, extension and retraction

5.2. Comparison with Cycle Time-Based Method

Finally, the cycle time-based method described in [25] was also applied to the test data set from Table 3. Figure 7 presents the confusion matrices for the selected feature-based classification method and neural network when measuring extension and retraction of the cylinder and compares them with the confusion matrix of the cycle-based method.

The differentiability between the classes is comparably good both for the feature-based method and for neural network methods, with the feature-based classifier in Figure 7a being better at recognizing the error-free state of the cylinder. The cycle time-based method in Figure 7c, on the other hand, encountered difficulties when detecting and localizing minor external leaks of 15 l/min and/or external leaks occurring in the hose between the directional control valve and the throttle valve. Such leaks are particularly difficult to localize, as they often result only in a slight deviation in the cylinder's movement time. Detecting the smaller counterforce increase of 20 N was also problematic. This results in a lower accuracy of the cycle time-based method (74%) compared to the feature-based classifier (90%) and neural network (87.5%).

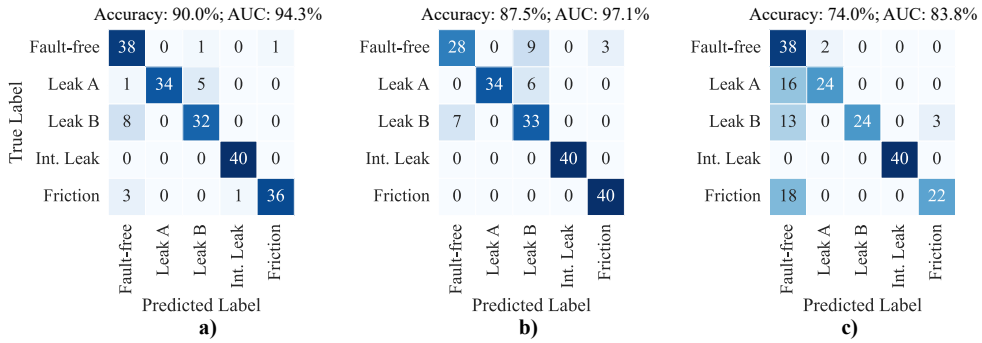

Figure 7. Confusion matrices for test data using different classification methods: a) RFE + SVM (5 features), cylinder pressure, extension + retraction; b) neural network, cylinder pressure, extension + retraction; c) cycle time-based method

6. CONCLUSIONS

This paper presents a fault detection method based on a single pressure sensor per drive combined with various classification techniques. The results show that only a few features are sufficient to detect and localize different fault scenarios with high accuracy (up to 92.5% on the test dataset). Using five features selected by recursive feature elimination and classified with the k-nearest neighbors algorithm, 90% accuracy was achieved. The developed neural network, consisting of three convolutional layers and a bidirectional long short-term memory layer, delivered comparable results. This represents a significant improvement over the cycle time-based soft-sensor method from [25], which achieved 72.4% accuracy on the same test data set. The broad applicability of the method was also confirmed: while training was conducted on cylinders with piston diameters of 25 and 32 mm, the test was performed on other cylinder sizes (40 and 50 mm) and/or under other operating conditions.

However, the method described here still has certain limitations. The current study is restricted to standard horizontal motion tasks. For broader applicability, future work should examine further load cases (e.g., considered in [7]) such as pressing tasks. The training data for various load scenarios and operating conditions can also be obtained through simulation to increase generalizability. Moreover, the method currently requires a pause between extension and retraction cycles and should be extended to continuous-motion applications. High pressure-sensor sampling rates between 100 and 1000 Hz are also necessary to achieve the reported accuracy; reducing the rate to 10 Hz decreased accuracy from 90% to 74.2%. The retrofit with pressure sensors also incurs additional costs that may exceed the cost of the proximity switches. This can be mitigated e.g. by using lower-cost sensors such as Micro-Electro-Mechanical Systems (MEMS) pressure sensors or by their mass production for integration into pneumatic actuators or valves.

Despite these constraints, the proposed method shows strong potential for deployment in typical industrial drive applications. It could be implemented in retrofittable monitoring modules at the cylinder using microcontrollers or mini-PCs, or in valve terminals already equipped with pressure sensors, such as the Festo VTEM, enabling fault detection during operation without dedicated diagnostic cycles.

Jürgen Weber has been appointed in 2010 as a University Professor and the Chair of Fluid-Mechatronic Systems as well as the Director of the Institute of Fluid Power at the TUD Dresden University of Technology, Germany, and took on the leadership of Institute of Mechatronic Engineering in 2018. He finished his doctorate in 1991 and was an active Senior Engineer at the former Chair of Hydraulics and Pneumatics until 1997. This was followed by a 13-year industrial phase. Besides his occupation as the Head of the Department Hydraulics and Design Manager for Mobile and Tracked Excavators, starting in 2002, he took on responsibility for the hydraulics in construction machinery at CNH worldwide. From 2006 onwards, he was the Global Head of Architecture for hydraulic drive and control systems, system integration and advance development CNH construction machinery.

Quasi-Isobaric Compressed Air Reservoirs

Prof. Dr.-Ing. Olivier Reinertz

RWTH Aachen University, Institute for Fluid Power Drives and Systems (ifas), olivier.reinertz@ifas.rwth-aachen.de

Abstract

State of the art compressed air reservoirs are designed in form of isochoric cavities. This implies that all air mass changes, either due to mass demand from the consumers or delivered air from compressors, and temperature changes lead to inherent pressure changes. Therefore, huge reservoir volumes are installed, which necessitate regular and expensive inspection works, and/or significant pressure fluctuations are tolerated, which require inefficient compressor operation at higher supply pressures.

This paper focuses on alternative compressed air storage systems enabling significantly higher capacity to volume ratios compared to conventional reservoirs. The analytically investigated concepts rely on air storage in different sorts of customized volume variable chambers acting against application-optimized arrangements of (hydro-)mechanical loading systems. The resulting benefits and weaknesses of the different variants are discussed with respect to their operational behavior, building space, as well as the requirement for recurring inspections. The paper concludes with an assessment of the required steps for realization of the best suited concept and the opportunities which arise from industrializing the investigated storage systems.

Keywords. Compressed Air Reservoir, Isobaric Storage.

1. INTRODUCTION

1.1. Usage and dimensioning of state-of-the-art reservoirs

Pneumatic reservoirs are widely used in industrial and mobile applications. In literature, two different usage scenarios are commonly distinguished: Firstly, application downstream of air compressors to stabilize network pressure for quasi continuous air demand, especially in industrial applications, and secondly, local application in pneumatic machines and networks to prevent pressure drops during short-term increased air demands.

In the first case, main task of the reservoir is to allow the pressure of the air distributing network to stay in a predefined margin despite fluctuating air supply and demand. For simple compressor controls, which only allow for switching selected compressors on and off, a

All Open Access articles are peer-reviewed, distributed under the Creative Commons Attribution-Non Commercial 4.0 International

minimally required cycle time for switching of the compressors usually exists to prevent the machines from inefficient operation, overheating, and excessive wear.

Varying sizing rules for the required reservoir volume can be found in different handbooks on the design of compressed air systems, e.g. in [1, 2]. These are based on the ideal gas law and a mass balance of inflowing and outflowing air of the reservoir. While the equation in [1] allows sizing for a defined compressor and specific air demand, the worst case of a 50% duty cycle is considered in most cases, as usually, the air demand of a production plants is time variant, and the system has to operate correctly under all circumstances. The equation in [2] includes this assumption of a 50% duty cycle and additionally allows to take varying inlet pressures and temperatures of the compressor and reservoir temperatures into account. By setting these values to standard conditions, both equations are identical and equal equation 1.1. The sizing of the reservoir volume V_{res} is given as a function of the allowable pressure fluctuation Δp and cycle time t_{cycle}, with the pressure at standard conditions p_0, and the volumetric flow of the biggest installed compressor at standard conditions Q_{Comp}.

$$V_{res} = \frac{p_0}{4\,\Delta p} \cdot Q_{comp} \cdot t_{cycle} \tag{1.1}$$

An alternative sizing approach is used, when pneumatic reservoirs are implemented to allow for peak flow Q_{peak} delivery over a defined (short) time Δt [1].

$$V_{res} = \frac{p_0}{\Delta p} \cdot Q_{peak} \cdot \Delta t \tag{1.2}$$

In both cases, pressure fluctuations occur, and the system pressure needs to be selected to allow for correct function of all systems downstream the reservoirs under all operational conditions. In general, this means that the maximum outlet pressure of the compressor must be higher than the required pressure in the application by the sum of all permissible pressure fluctuations of the reservoirs connected in series and the line losses. The impact of this additional pressure is discussed in the next subchapter.

1.2. Influence of pressure margins on system efficiency

It can be assumed as a rule of thumb that well-dimensioned and well-maintained compressed air stations require approximately 145 % of the energy that would be necessary for isentropic compression to generate compressed air [3]. Hence, an estimate for the mass specific energy demand w of a compressed air station, which delivers the pressure p_{out} from ambient air with pressure p_{in} and temperature T_{in} is given by equation 1.3, wherein c_p denotes the isobaric heat capacity and κ the isentropic number [4].

$$w(p_{out}) = 1.45 \cdot c_p \cdot T_{in} \cdot \left[\left(\frac{p_{out}}{p_{in}}\right)^{\frac{\kappa-1}{\kappa}} - 1\right] \tag{1.3}$$

For the simplified case of a compressor with on/off control, which delivers, when switched on, a pressure independent mass-flow into a downstream reservoir with time invariant outflow, the cyclic pressure increases and decreases in the reservoir are linear over time. The average energy demand of the compressor $\overline{w}$ at a pressure between $p_{out} = p_{req}$ and $p_{out} = p_{req} + \Delta p$ can be calculated by equation 1.4.

$$\overline{w} = \frac{\int_{p_{req}}^{p_{req}+\Delta p} w(p)\ dp}{\Delta p} \tag{1.4}$$

The following figure shows the impact of the pressure control band on specific energy demand for compressed air delivery. It becomes evident that several percent in efficiency can be gained simply by reducing the pressure control band, which is aspired by actual more complex compressor control schemes.

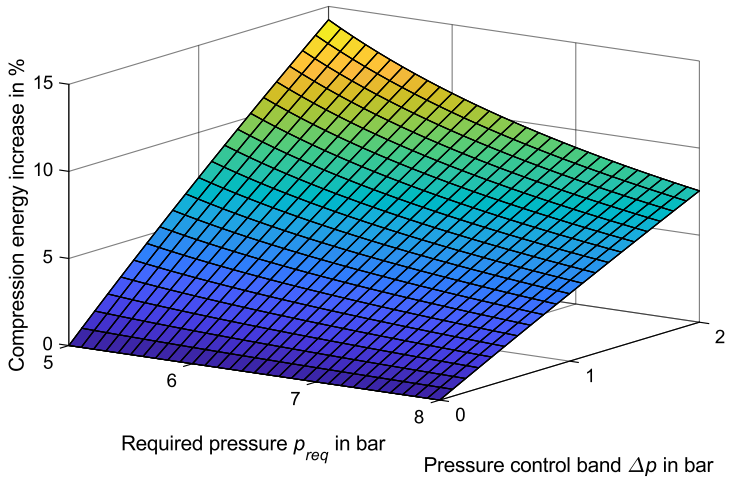

Figure 1.1. Influence of pressure control margin on energy demand for compressed air generation

Despite the derivation of the preceding equation under the assumption of a constant reservoir outflow, the above stated results are generally applicable to all kinds of systems with time-variant compressed air demand as long as no timewise coupling of reservoir outflow and compressor cycles exists, which is rarely the case in industrial systems.

1.3. Normative demands on certification and inspection of conventional reservoirs

The stored energy and associated risks of compressed air reservoirs grow with pressure and volume. Therefore, reservoir classification by means of the product of rated pressure and volume is used to specify design, manufacturing, documentation, commissioning, and recurring inspection procedures and requirements. Figure 1.2 depicts the categorization of reservoirs according to Directive 2014/68/EU by reservoir volume V and rated pressure PS. The categories are numbered in order of increasing demand in all aforementioned areas. [5]

Additionally, directive 2014/29/EU handles the making available on the market of simple pressure vessels, which cover welded pneumatic reservoirs manufactured in series for stationary use up to a PS·V product of the vessel of 10,000 bar·l and the resulting obligations of manufacturers, importers, and distributors. [6]

In the scope of this paper, the impact of quasi-isobaric reservoirs on system integrator and machine user duties are focused. In Germany, the required inspection tasks and intervals at commissioning and during the use phase are regulated in Annex 2, Table 4 of the *Betriebssicherheitsverordnung* (Operational Safety Regulation) [7]. Therein, it is distinguished between internal inspections, which require the reservoir to be depressurized and accessible, and strength tests, which require all safety valves to be dismounted and the

reservoir to be entirely filled with water for pressure and leak tightness testing. Obviously, such tests are time consuming and thus expensive.

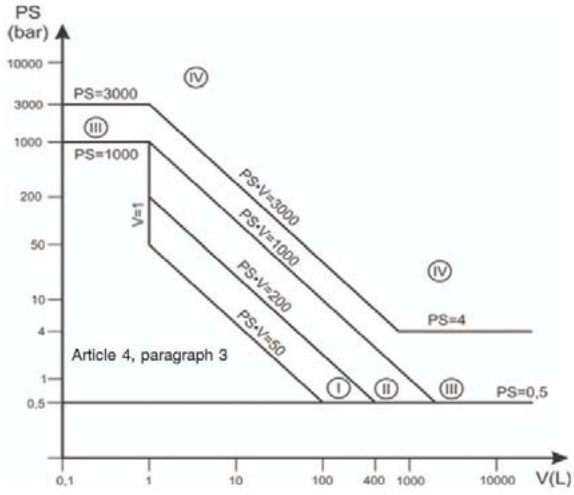

Figure 1.2. Classification of compressed air reservoirs according to [5]

The required inspection tasks for a specific reservoir depend on the categories of Directive 2014/68/EU, with the sole exception that reservoirs, which are designed to store internal relative pressures of less than 1 bar, are exempt from inspections regardless of their size. Table 1 provides an overview of mandatory inspection tasks during commissioning and in operation. Herein, it is distinguished between the inspection by notified bodies (NB) and user inspectorates (UI).

Category	**Commissioning**	**Periodic internal inspection**	**Periodic strength test**
Article 4, paragr. 3	-		
I	UI	UI (all 10 years)	UI (all 10…15 years)
II	NB		
III & IV		NB (all 5 years)	NB (all 10 years)

Table 1: Inspection duties of compressed air reservoirs

It becomes obvious that sizes, which are covered by article 4, paragraph 3 are very favorable, as no inspection duties result. As the product of pressure and volume for this category is limited to 50 bar·l, only small reservoirs fulfill this requirement, e.g. for a rated pressure of 16 bar, reservoir size is limited to 3.125 l. In case of higher required volumes, categories I and II at least do not require an external supplier for inspection. Nevertheless, training the user inspectorate and shutdown of the reservoir are required for inspection, still resulting in significant costs. For reference, pneumatic reservoirs with up to 12.5 l and 16 bar pressure ratings are covered by category I, while category II allows for up to 62.5 l.

1.4. Dimensioning of quasi-isobaric reservoirs

Quasi-isobaric storage of compressed air demands for a volume variable reservoir. Therewith, pressure fluctuations can be minimized, leading to higher efficiency of the compressed air supply or better system performance, and the installed reservoir volume can be drastically reduced. The volume change ΔV_{QIB} of a quasi-isobaric reservoir with comparable operational behavior to a conventional reservoir with Volume V_{res} is given by equation 1.5.

$$\Delta V_{QIB} = V_{res} \cdot \frac{\Delta p}{p_{req}} \tag{1.5}$$

Especially for small allowable pressure changes, huge differences in volume occur. If a quasi-isobaric reservoir is used for optimization of compressor cycling, equation 1.5 can be inserted into equation 1.1 and the variable reservoir volume in equation 1.6 results.

$$\Delta V_{QIB} = \frac{1}{4} \cdot \frac{p_0}{p_{req}} \cdot Q_{comp} \cdot t_{cycle} \tag{1.6}$$

For peak flow demands, equation 1.2 and 1.5 are combined and lead to equation 1.7.

$$\Delta V_{QIB} = \frac{p_0}{p_{req}} \cdot Q_{peak} \cdot \Delta t \tag{1.7}$$

1.5. Hysteresis losses on volume variable cavities

Several designs of volume variable cavities are used in actual pneumatic actuators. While cylinders with sliding seals are the common solution, also diaphragm arrangements exist. Seal friction or plasticity of sealing diaphragms leads to hysteresis of such actuators, which ultimately results in pressure deviations in the investigated reservoirs between filling and discharge. Moreover, the breakaway force of friction loaded sealing systems is especially relevant for the application, as it leads to dynamic excitation.

Multiple investigations demonstrate the strong impact of pressure and standstill time on the breakaway force of pneumatic cylinders [8, 9]. With the assumption of rare and short standstill periods of the accumulator piston in operation, a standstill time of less than 10 s can be assumed. In this case, *Meuser's* measurements on a cylinder with 25 mm diameter show a breakaway force per seal length of up to F_{FrL} = 0.28 N/mm at a differential pressure of 6 bar [8]. Slightly lower values have been measured by *Wakasawa et al.* for a cylinder with 32 mm in diameter [9]. Equation 1.8 estimates the friction force induced pressure hysteresis Δp_{Fr} of a cylinder based quasi-isobaric reservoir with piston diameter D.

$$\Delta p_{Fr} = 2 \frac{D \cdot \pi \cdot F_{FrL}}{D^2 \cdot \frac{\pi}{4}} = 8 \frac{F_{FrL}}{D} \tag{1.8}$$

The reducing effect of seal friction with increasing diameter is based on the quadratic increase in pressure loaded surface counteracting the only linearly increasing sealing length. Based on *Meuser's* data, for a piston diameter of 200 mm, a hysteresis in pressure of Δp_{Fr} = 112 mbar between filling and discharge occurs.

Even more relevant for the application is the reduction in friction force over speed at small velocities and the change in friction force between acceleration and deceleration of the piston in the mixed lubrication regime, which lead to stick-slip behavior and corresponding velocity and pressure oscillations. According to measurements from *Fujita et al.*, the friction

force at deceleration to standstill can be as low as half of the breakaway force [10]. Therewith, pressure fluctuates during charging and discharging a quasi-isobaric piston reservoir by Δp_{Fr} / 4, which equals ca. 28 mbar for the before stated example of the 200 mm piston, as shown in figure 1.3.

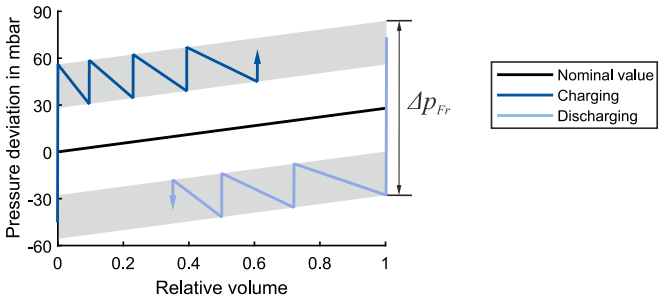

Figure 1.3. Schematic pressure cycle of a seal friction subjected quasi-isobaric reservoir

By using diaphragms for sealing of the quasi-isobaric reservoir, stick-slip effects and pressure deviations can be significantly reduced. Nevertheless, deformation of the elastomeric material with its visco-elastic material properties and possible friction between the deforming diaphragm and housing still contribute to some deviations in pressure.

A quantification of these effects in terms of pressure deviations in the aspired application is hindered by the strong impact of material selection and geometric design of the diaphragm. Therefore, only a rough estimate from comparable devices in literature can be achieved. *Bedarff* models in his PhD-thesis an active air spring for passenger cars. For model validation, a cyclic motion at constant pressure is experimentally investigated, which corresponds exactly to the application in a quasi-isobaric reservoir. The hysteresis amplitude in force amounts to ca. 0.6 % of the nominal value at an outer diameter of ca. 150 mm [11]. Hence, by using a rolling diaphragm, pressure hysteresis of the quasi-isobaric reservoir can be reduced by half in comparison to a conventional cylinder if operated at 6 bar_{rel}. Also, in the case of diaphragms, the use of higher diameters leads to reduced hysteresis.

1.6. Intermediate conclusion – Potential of quasi-isobaric reservoirs

Increasing efficiency of industrial compressed air systems requires lower pressure control bands to be realized. Thereof, the problem arises, that conventional reservoirs in compressor stations have reduced effectiveness in storing and providing compressed air to the systems, which can only be counteracted by raising reservoir size. Usage of quasi-isobaric reservoirs decouples the pressure control band from reservoir size and allows significant reduction in reservoir volume in comparison to actual design rules. Additionally, using quasi-isobaric reservoirs enables downsizing pressure loaded volumes, which can have significant effect on commissioning and inspection by the classification in lower categories according to Directive 2014/68/EU. Despite seal friction and material losses of diaphragms hinder true isobaric behavior, increasing the piston or diaphragm diameter reduces these effects to a reasonable value, thus allowing for quasi-isobaric systems.

2. CONCEPT DEVELOPMENT AND ANALYSIS

Concepts, which allow quasi-isobaric conditions in pneumatic reservoirs, require the reservoir volume to increase drastically with raising pressure in the aspired operating point. Meanwhile, the mechanical work performed by the moving walls of the reservoir under pressure needs to be stored, to allow for later deflation of the reservoir against system pressure. Out of this simple system description, the system structure for all kinds of isobaric reservoir concepts gets obvious:

Grid ↔ Variable volume with force takeoff ↔ Energy transmission ↔ Energy storage

Thereof, different concepts can be deduced and evaluated. The following table shows an overview of all possible solutions investigated in this paper.

Concept	Reservoir volume	Transmission	Energy storage
1	Pneumatic cylinder	---	Lifting of a weight
2	Pneumatic cylinder	---	Mechanical spring
3	Pneumatic cylinder	Hydraulic cylinder	Hydraulic accumulator
4	Nonlinear actuator	---	Mechanical spring

Table 2: Investigated concepts

In the following subchapters, the different concepts are presented and discussed in terms of filling state induced pressure deviations, adjustability in pressure, and building space. These findings are the basis for concept comparison and decision in the subsequent chapter 3.

2.1. Concept 1: Weight loaded pneumatic cylinder

The simplest concept of a constant pressure reservoir for pneumatic systems consists of a volume variable pneumatic chamber, e.g. a cylinder or bellow, which is loaded by a significant weight. Such arrangements can be found e.g. in the air supply of pipe organs to allow for constant pressure in the pneumatic system [12]. Also in process technology, e.g. for storage of biogas for power generation, comparable arrangements are used with huge storage volumes [13]. Both systems have in common, that the load is integrated into the reservoir piston. This approach is not feasible for typical pressures of pneumatic systems, as even for a steel weight with a density of approx. 7,800 kg/m³, a required pressure of 6 bar_{rel} would result in a height of the weight of approx. 7.8 m. Therefore, an alternative configuration as shown in figure 2.1 is further investigated. It is characterized by a weight, which surrounds a pneumatic cylinder with stroke dependent volume $V_{QIB}(s)$, thus enabling long strokes and compact design. The maximum displacement volume of the reservoir ΔV_{QIB} hence equals the difference between $V_{QIB}(s_{max})$ and $V_{QIB}(s = 0)$ with s_{max} beeing the stroke length. For this case, the width a of the weight with quadratic cross-section and length l can be estimated by equation 2.1 under the simplifying assumption, that the length of the weight l and the cylinder length s_{max} are equal. For given pneumatic parameters, weight density ρ, and gravitational constant g, the length l is the only remaining optimization parameter. For a constant displacement, the assembly gets significantly thinner and lighter with increasing stroke length while material demand and building space are reduced. On the other hand, higher strokes and smaller piston diameters lead to increased velocities, friction, and wear on the piston sealings.

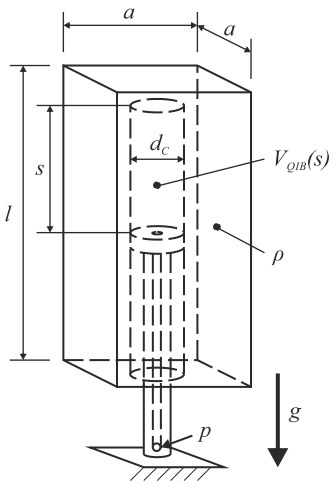

Figure 2.1. Investigated weight loaded cylinder

Equation 2.2 gives a rough approximation of the building space $V_{BS,1}$ required.

$$a = \sqrt{\Delta V_{QIB} \cdot \frac{p - p_0 + \rho g l}{\rho g l^2}} \tag{2.1}$$

$$V_{BS,1} = 2a^2 \cdot l \approx 2 \cdot \Delta V_{QIB} \cdot \frac{p - p_0}{\rho g l} \tag{2.2}$$

Regarding system dynamics, the proposed system allows to deliver constant pressure over the stroke in steady state but represents a dynamic first-order system with very low damping and small eigenfrequency. The undamped eigenfrequency in the highest position, which is the lowest eigenfrequency in operation, can be calculated by equation 2.3 and results directly from the stroke length of the system for given operational parameters [4]. For strokes of 1 to 10 m and usual pneumatic parameters, natural frequencies of the system are in the range of 0.15 to 0.7 Hz. These values are further reduced by the capacity of the connected pipework in an application.

$$f_0 = \frac{1}{2\pi} \cdot \sqrt{\frac{g}{l}} \cdot \sqrt{\frac{n \cdot p}{p - p_0}} \tag{2.3}$$

The usability of passive damping measures to optimize oscillation stability is limited, as these cause speed and thus flow dependent deviations from isobaric conditions. Therefore, weight loaded isobaric reservoirs are only applicable to systems with significantly lower dynamics than their own, which can be the case for central reservoirs in compressed air supply. An application for smoothing dynamic load peaks is not feasible. Furthermore, the huge weight of the system prevents usage in mobile compressors.

2.2. Concept 2: Pneumatic cylinder with mechanical springs

An alternative to the before-mentioned weight loading of the piston is the use of a pretensioned mechanical spring. This enables significantly higher eigenfrequencies due to the strong reduction in moving masses. The downside of this approach is that it leads to increasing pressure with reservoir filling due to the spring stiffness. In analogy to

conventional reservoirs, this pressure fluctuation needs to stay in the allowable pressure margin of the application, which limits the usable spring stiffness. As the pressure margin is usually small in comparison to the absolute pressure, for conventional helical springs, enormous tensioning strokes result. These make the spring assembly with its tensioning mechanism very complex and bulky and tend to fatigue issues on the springs.

Disc springs with their varying stiffness over the stroke can be used for size and complexity reduction. The dimensions of disk springs can be tuned to allow for high stiffness at stroke begin, which is used to generate sufficient pretension force, while the force gets mostly stroke independent over a second stroke regime, which is the working stroke of the quasi-isobaric reservoir. Figure 2.2 shows the force of such an optimized disc spring over its stroke on the right-hand side, based on the force equations in [14]. This optimization is achieved by means of sheet thickness *t* being 0.707 times the height of the truncated cone *h*, which is formed by the disc in unloaded state. In the diagram, the stroke is scaled to the height *h*, while the force on its value at constant stiffness.

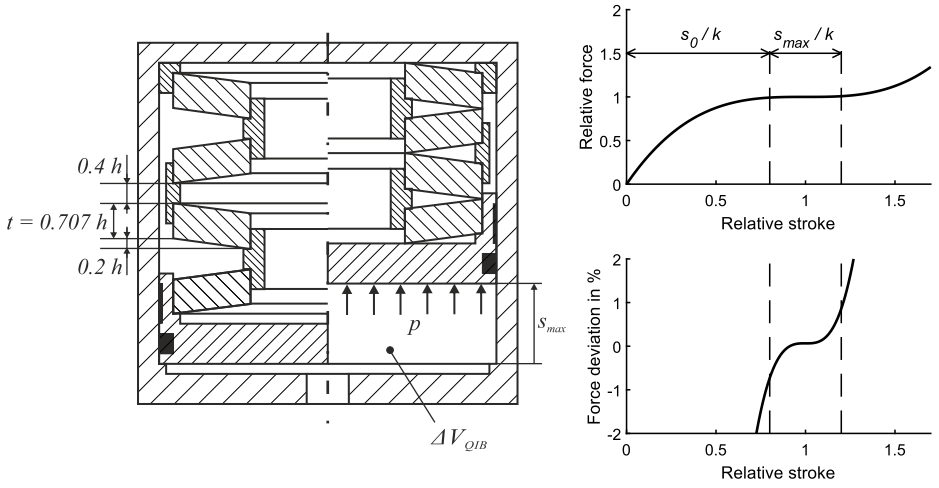

Figure 2.2. Disk spring reservoir concept and force characteristics

For disc spring compressions between 80 % and 120 % of *h*, the force stays constant with an accuracy of better than ±1 %. Thereof, it can be concluded that if using *k* disc springs, the pretension stroke s_0 of the spring assembly has twice the size of the piston stroke s_{max}. Meanwhile, very small pressure variations are ensured, which is a huge optimization in comparison to piston loading by constant stiffness helical springs.

The building space of the disk spring loaded reservoir $V_{BS,2}$ can be approximated from the volume change in operation ΔV_{QIB} by scaling it with the pretensioned length of the spring assembly divided by the stroke length s_{max}, as shown in equation 2.4. The numbers result from the schematics in figure 2.2, left and the disk spring design for constant force behavior.

$$V_{BS,2} \approx \frac{(0.4 + 0.2 + 0.707) \cdot h \cdot k}{0.4 \cdot h \cdot k} \cdot \Delta V_{QIB} \approx 3.3 \cdot \Delta V_{QIB} \qquad (2.4)$$

However, the design and fabrication of the disc springs need to be very exact, as small tolerances in the design parameters, e.g. in sheet thickness, can lead to decreasing force over the stroke of the disc spring in the operational regime. This will ultimately result in unstable behavior of the arrangement, as pressure drops with increasing filling state. Furthermore, such tolerances can lead to a deviation in operating pressure of the reservoir, as the generated force in the constant force regime of the disc springs deviates from its design value.

A further drawback of the design consists in the inability to set pressure adjustments. By changing pretension, stroke regimes with significant pressure increase over the stroke are part of the operational range and the quasi-isobaric properties are lost.

2.3. Concept 3: Hydro-pneumatic reservoir

The third concept is based on a hydraulically loaded pneumatic piston. A significant reduction in building space is aspired by increasing the internal pressure of the hydraulic system in comparison to the pneumatic side and therewith its energy density. In contrast to the hydraulic bootstrap accumulator, discussed e.g. by *Ketelsen at al.* [15], the hydraulic loading is deemed to be passive. Hence, a hydraulic accumulator, which loads a hydraulic piston to act against the pneumatic cavity is investigated. The precharge level of the accumulator results in sufficient air pressure, while its size and therewith its capacity allows control of the pressure increase over the stroke. Figure 2.3 shows a schematic representation of the investigated concept. Compressed air is marked in blue, hydraulic fluid in orange.

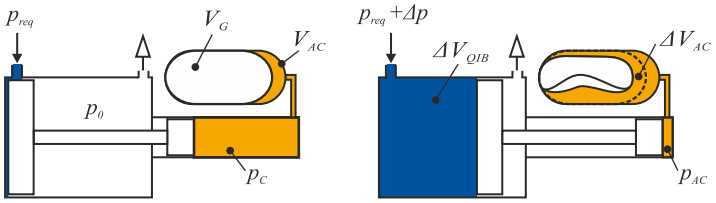

Figure 2.3. Concept of the hydro-pneumatic reservoir; left: discharged, right: charged

As a strongly simplified thermodynamic model of the hydraulic accumulator, a polytropic change of state with polytropic number n is assumed. When the pneumatic side is loaded, the liquid volume ΔV_{AC}, which is pressed by the amplifier piston into the hydraulic accumulator leads to a decrease in its gas volume and thus to a pressure increase. The accumulator pressure p_{AC} is described by equation 2.7 with the precharge pressure of the gas side p_C, and the gas volume of the accumulator V_G, which is present if the pistons stand at their left end stop. This volume is used as a reference for the precharge pressure adjustment.

$$p_{AC} = p_C \left(\frac{V_G}{V_G - \Delta V_{AC}}\right)^n \tag{2.7}$$

The piston amplifier acts as a transformer with area ratio α between the hydraulic and pneumatic system. Herein area ratio $\alpha << 1$ describes the quotient of the hydraulic to the pneumatic piston surface. The force equilibrium and energy balance lead to equations 2.8 and 2.9, which both describe the energy transmission through the amplifier piston:

$$p_C = \frac{p_{req} - p_0\,(1-\alpha)}{\alpha} \approx \frac{p_{req} - p_0}{\alpha} \tag{2.8}$$

$$\Delta V_{AC} = \Delta V_{QIB} \cdot \alpha \tag{2.9}$$

Thereof, for a given required system pressure, pressure margin, and required air volume of the quasi-isobaric accumulator, the following equation 2.10 defines the accumulator dimension, as the nominal accumulator volume V_{AC} should be slightly bigger than the calculated gas volume in reference position.

$$V_{AC} > V_G \approx \frac{\Delta V_{QIB} \cdot \alpha}{1-\sqrt[n]{\frac{p_{req}-p_0}{p_{req}+\Delta p-p_0}}} \tag{2.10}$$

The resulting building space $V_{BS,3}$ can be roughly approximated by the sum of the pneumatic and hydraulic displacement of the piston amplifier and the volume of the hydraulic accumulator, as shown in equation 2.11.

$$V_{BS,3} = \Delta V_{QIB}\left(1+\alpha+\frac{\alpha}{1-\sqrt[n]{\frac{p_{req}-p_0}{p_{req}+\Delta p-p_0}}}\right) \tag{2.11}$$

For an isothermal accumulator, this simplifies to equation 2.12. It is obvious that for small area ratios of the amplifier, relevant reductions in space occur.

$$V_{BS,3} = \Delta V_{QIB}\left(1+2\alpha+\alpha\frac{p_{req}-p_0}{\Delta p}\right) \tag{2.12}$$

A further benefit of hydro-pneumatic systems is the ability to simply adjust the pretension and thus working pressure of the system by the precharge pressure of the accumulator. This allows for pressure adjustments on a running system, e.g. to incrementally reduce operation pressure of a compressed air network for energetic optimization.

2.4. Concept 4: Nonlinear pneumatic actuator with mechanical spring

A further solution for quasi-isobaric behavior can be achieved by using unconventional pneumatic actuators for the realization of the reservoir volume with increasing active area over the stroke. As has been shown in [16] actual designs for pneumatic actuators realize either reducing forces or constant forces over the stroke at constant pressure. But, by implementing novel actuator design schemes, as shown e.g. in [17] for machine suspension, rising force over the stroke arrangements can be achieved. In the case of quasi-isobaric reservoirs, the use of such actuators as reservoir volume has the big advantage that the force characteristics of the reservoir volume can be tailored to the force stroke behavior of the loading spring. Therefore, in the following, the direct coupling of an unconventional actuator with mechanical springs, as shown in figure 2.4 is investigated.

For the quadratic correlation between volume *V(s)* and stroke *s* of the reservoir in equation 2.13, the force *F* on the loading device is given in equation 2.14. The force balance with a loading spring with stiffness *C* and pretension stroke s_0 results in equation 2.15, which describes the reservoir pressure as a function of the stroke.

$$V(s) = as^2 + bs + V_0 \tag{2.13}$$

$$F(s,p) = \frac{\partial V}{\partial s}\cdot(p(s) - p_0) = (2as+b)\cdot(p(s) - p_0) \tag{2.14}$$

$$p(s) = p_0 + \frac{C}{2a}\cdot\frac{s+s_0}{s+\frac{b}{2a}} \tag{2.15}$$

For a given volume stroke characteristics with parameters a, b, and V_0 and spring stiffness C, a distinct pretension stroke exists, which allows the system pressure to stay constant over the entire volume change of the reservoir. This pressure is achieved with a pretension stroke of $s_0 = b/(2a)$. Moreover, especially for small values of b, and hence small forces at stroke begin, pretension of the springs can be very low and almost the entire working stroke of the springs can be used for energy storage, which makes this arrangement particularly material efficient regarding the mechanical spring.

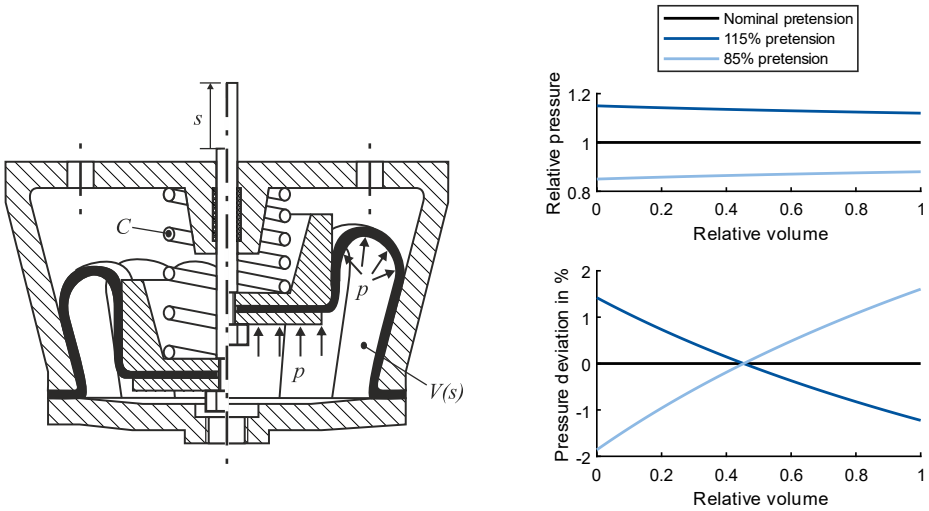

Figure 2.4. Investigated nonlinear pneumatic actuator with mechanical spring and its force deviation over the stroke for $b = 8\ a\ s_{max}$

On the other hand, if pressure adjustments by changing spring pretension are considered, the pretension stroke should be maximized to allow for small deviations in pressure over the stroke and thus stored volume. To achieve a pressure fluctuation over the stroke of less than ± 2 % at a pressure adjustment range of ± 15 %, the pretension stroke of the spring must be equal or higher than four times the piston stroke s_{max}. Hence, significant spring length and pretension stroke are required to allow for adjustability.

The change in pressure over the filling state is shown in figure 2.4 for the nominal pressure and deviating pressure settings by ± 15 %. The loss of the constant pressure over the stroke operation is clearly visible at varying pretension. Moreover, lower pressure settings can cause the system to have negative fluidic impedance, and thus to be unstable if connected to sufficient grid capacity. The impact of the slight negative impedance in the depicted case on system stability is to be further analyzed. Due to its small amount, it can probably be stabilized by sufficient viscose friction of the arrangement.

Finally, also this design has the major advantage in that it is very compact. Its required building space is estimated from figure 2.4 to be approximately four times its displacement volume, as shown in equation 2.16.

$$V_{BS,4} \approx 4 \cdot \Delta V_{QIB} = 4 \cdot (V(s_{max}) - V_0) \tag{2.16}$$

3. CONCEPT EVALUATION

First, the different concepts are compared by means of their general characteristics, as shown in table 3.

The weight loaded concept 1 has its only major benefit in being simple in realization. The required small piston diameter and long stroke and the additional guiding elements to prevent the system from tilting lead to high hysteresis and seal wear and poor dynamics.

The disc spring loaded concept 2 has advantageous dynamics, higher piston diameter, and small pressure increase over the stroke but lacks adjustability while being difficult in maintenance due to the long pretension stroke and high stored energy of the springs. Also, realization has high demands on accuracy of the disc springs to allow all sequential springs of the system to work exactly in the required working regime.

The hydro-pneumatic concept 3 is very advantageous in adjustability and dynamics, while complicating maintenance by requiring additional seals, a pressure medium, a system for flushing the fluid and for filling the gas into the accumulator, and multiple hydraulic components.

Lastly, the spring-loaded nonlinear actuator concept 4 is beneficial in all categories despite its simplicity in implementation, as this new kind of actuator first needs to be developed. Maintenance therefore is difficult to evaluate, as it is strongly design dependent.

	Concept	1	2	3	4
Criterion	Adjustability	+	- -	+ +	+
	Small hysteresis	- -	+	-	+ +
	Dynamics	- -	+ +	+ +	+ +
	Simplicity	+ +	0	+	- -
	Maintenance	0	0	-	0

Table 3: General concept comparison (Rating from poor to good: -- / - / 0 / + / ++)

In the following, the concepts are further investigated by sizing and comparing the capacity of exemplary solutions for two different applications. First, the concepts are evaluated for use in compressed air supply, with huge volume changes at lower speed. Subsequently, decentralized implementation to smoothen peak flow demands and associated pressure drops is evaluated.

3.1. Usage in compressed air supply

Reservoirs in compressed air supply are used to smoothen the grid pressure and therewith to allow the compressor control to react on differences between compressed air generation and consumption. Meanwhile, it is aspired to keep the reservoir pressure as constant as possible slightly above the required system pressure, which should be adjustable in a defined margin. By means of the quasi-isobaric reservoir, inspection duties can be minimized, which means, that in best case, a category II classification ($PS \cdot V < 1000$ bar·l) is targeted.

To compare the different concepts, their realizable displacement volumes as a function of the allowed pressure margin are calculated and depicted in figure 3.1, left. A required pressure of 7 bar_{abs} and a building space with a ground surface of 1 m² and 2 m in height are

assumed. The main components and their arrangement were sized for all concepts to fit in the building space and to the allowed pressure margin. From this figure, several conclusions can be drawn:

The weight loaded system consists of one or several parallel arranged cylinders with a stroke of 1 m to fit in the height limitation and a lumped piston surface of ca. 0.1275 m². The weight is assumed to be fabricated from steel and has a mass of ca. 7.8 tons. This makes the system impractical while its displacement is rather limited compared to the other systems. The disc spring loaded system has the highest capacity at small pressure margins but does not allow any correction in system pressure. Therefore, it is also not well suited for the application.

The hydro-pneumatic reservoir achieves the highest capacity at bigger pressure margins. For smaller values, its displacement capability increases with pressure margin. In this parameter region, the restrictive parameters are the limited hydraulic accumulator size, which was set to 300 l, and its assumed maximum pressure of 300 bar. For higher pressure margins, the displacement volume of the compressed air piston limits the achievable effect, as a displacement of 1 m³ cannot be overcome in the building space under the assumption of an air piston with coaxial hydraulic loading piston and circumferential hydraulic accumulators.

By using a spring-loaded nonlinear actuator, the second-best usage of the building space at small pressure margins results. Very likely this concept has the best weight to displacement ratio, as it does not rely on heavy disk springs, a weight, or heavy hydraulic components.

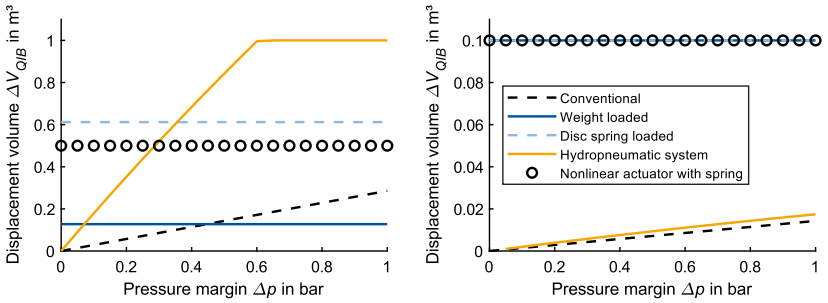

Figure 3.1. Comparison of quasi-isobaric concepts with a conventional reservoir, left: for 2 m³ build space, right: for up to 2 m³ build space and category II classification

If it is required to fulfill category II to allow for longer inspection intervals and to circumvent regular inspections by notified bodies, the rating of the different concepts changes drastically. To calculate the allowable dimensions for category II, the rated pressure of the pneumatic cavity and in case of the hydro-pneumatic system also of the hydraulic accumulator need to be defined. These were set to 10 bar_{rel} for the pneumatic and 300 bar for the hydraulic parts. The results are shown in figure 3.1, right.

To allow for category II classification, the conventional reservoir needs to stay in the PS·V = 1000 bar·l margin and diminishes in size to 100 l. Thus, it can only use a small part of the available building space, and its effectiveness drastically reduces. The cylinder chambers of the weight loaded piston, the disc spring loaded piston, and the nonlinear actuator need also to stay within this margin, which reduces their displacement capacity ΔV_{QIB} to 100 l.

The hydro-pneumatic system in contrast strongly loses in performance, when built to fit into category II. This is because, in all investigated configurations, the hydraulic accumulator needs to be strongly downsized to a nominal volume of only 3.33 l to reach category II. This significantly diminishes its feasible volumetric change of air capacity.

Finally, the missing adjustability in pressure of the disc spring device and the huge mass of the weight loaded system with its associated issues in implementation and dynamics hinder their industrial usage. Therefore, it can be concluded that for practical usage, the nonlinear actuator with spring is the most promising solution despite its required development effort.

3.2. Usage for peak demand

Usually, reservoirs for peak demand supply are smaller sized. Therefore, it is aspired to reduce the pressurized volumes to the point that an article 4, paragraph 3 classification is achieved in all cases. Meanwhile, a maximum ground surface of 0.01 m² and height of 0.5 m are assumed, which enable the conventional reservoir to use the entire building space and categorization limit in parallel. The resulting displacement volumes are shown in figure 3.2.

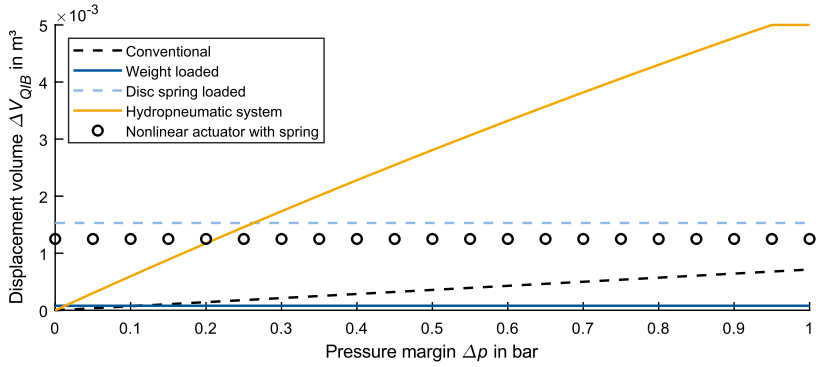

Figure 3.2. Comparison of quasi-isobaric concepts with a conventional reservoir in accordance with article 4, paragraph 3

While all kinds of quasi-isobaric reservoirs can reach a displacement volume of 5 l while falling under article 4, paragraph 3 with sufficient building space, the additional restriction in available space leads to a clear differentiation between the different designs. The hydro-pneumatic system is best suited for higher pressure margins, while the disc spring loaded cylinder and the spring-loaded nonlinear actuator are best suited for small pressure changes. In general, these three kinds of quasi-isobaric reservoirs allow for significant optimization in comparison to regular designs, while the disc spring loaded device lacks adjustability.

4. Conclusion and Outlook

Quasi-isobaric reservoirs have the potential to decrease the building space requirements in comparison to state-of-the-art designs in combination with their demands for regular inspections. Furthermore, the increased capacity of quasi-isobaric reservoirs at low pressure margins can be used to reduce pressure control bands of actual compressor stations to gain several percent in efficiency with corresponding cost savings in comparison to actual solutions. Different concepts for such reservoirs have been developed and compared by means of two different applications. Thereof, it can be concluded that the spring-loaded

nonlinear actuator has the biggest potential of all designs investigated, especially for small pressure margins. In contrast, hydro-pneumatic systems have the biggest potential for higher pressure amplitudes at small scales. In future research, these findings should be experimentally validated. While the hydro-pneumatic system can be built from off-the-shelf components, the nonlinear actuator itself is part of actual research. Furthermore, system and compressor control integration of the novel reservoirs need to be investigated.

Biographies

Prof. Olivier Reinertz received his diploma and his doctoral degree in mechanical engineering from RWTH Aachen University, Germany. He is currently Professor and Scientific Director at the Institute for Fluid Power Drives and Systems (ifas) at RWTH Aachen University. His research focuses on the model-based analysis of fluid power components and systems and the derivation and validation of innovative strategies for efficiency and performance optimization with an emphasis on compressed air and gas-driven systems.

Integration of Pneumatic Systems in Training Devices for Combat Sports

Željko Šitum, Tin Stanišak and Dominik Šarić

University of Zagreb, Faculty of Mechanical Engineering and Naval Architecture, I. Lučića 5, HR-10000 Zagreb, Croatia, zeljko.situm@fsb.unizg.hr, tin.stanisak@hotmail.com, dominik.saric17@gmail.com

Abstract.

The inherent compressibility of air, characteristic of all pneumatic systems, can serve as an advantageous feature in the development of conceptual solutions for training devices aimed at enhancing motor reactions required in combat sports. These devices typically consist of a supporting structure and movable components equipped with striking surfaces. Combat sports such as boxing and taekwondo have historical roots extending far into the past. Although their roles and cultural significance have evolved over time, these disciplines have gained substantial popularity in recent decades, largely due to their commercial appeal and adaptation into various forms of competitive entertainment for broad audiences. Enhancing specific muscle movements, manifested through attributes such as speed, agility, strength, precision, and endurance, is essential in combat sports and can be facilitated through specialized training devices. Pneumatic systems offer a highly efficient and adaptable platform for developing such devices, owing to their operational speed, reliability, and programmability in motion control. Their simple mechanical design and rapid actuation capabilities make them particularly suitable for sports training scenarios, where high dynamic performance and user safety are critical. Accordingly, the development of a system designed to reduce athletes' reaction times to visual stimuli would be of significant benefit. To achieve this, the pneumatic system must be equipped with appropriately selected actuators, a stable load-bearing structure, and a component arrangement tailored to match the user's physical stature. The training apparatus should also feature adjustable components, enabling vertical repositioning to align with the athlete's height, and allow programming adjustments to modulate the speed and pattern of movements, thereby providing a high degree of application flexibility. This paper presents the conceptual design and practical implementation of two devices developed for training defensive techniques and improving reaction times in martial arts disciplines such as boxing and taekwondo. The movement of the pneumatic actuators is randomized, requiring the practitioner to react quickly and appropriately, either by striking the target surface, as in taekwondo, or by dodging or blocking simulated punches, as in boxing. The system includes pneumatic valves and a control unit capable of generating random activation sequences for the pneumatic cylinders, thereby simulating unpredictable movements typical of combat scenarios. A programmable control algorithm was implemented using a Controllino device, and the

developed control software was tested on the fabricated training equipment within sports hall environments.

Keywords. Pneumatic systems, combat sports, reaction time training, martial arts equipment, programmable control.

1. INTRODUCTION

Combat sports, including boxing and taekwondo, require exceptional neuromuscular coordination, speed, precision, and agility. In recent decades, the rising popularity of these disciplines, both as professional sports and recreational activities, has driven the development of advanced training methodologies [1], [2]. A key factor in improving athletic performance in these sports is the enhancement of reaction time, particularly in response to unpredictable stimuli that closely mimic real combat scenarios [3]. Modern training equipment increasingly incorporates technologies such as electromechanical actuators, robotic systems, and sensor-based feedback mechanisms [4]. However, despite their proven effectiveness in industrial automation for tasks demanding speed, precision, and repeatability, pneumatic systems remain underutilized in sports training applications [5]. Pneumatic actuators offer several distinct advantages for athletic training devices: rapid response, smooth motion control, natural impact absorption due to air compressibility, and seamless integration with programmable control systems [6]. This study introduces a novel approach by implementing pneumatic actuation to simulate dynamic and unpredictable combat situations in a safe and controlled environment. Unlike conventional training tools, the proposed devices feature randomized movement patterns of striking or blocking elements, effectively replicating the variability of real-life sparring. Through adjustable air pressure and actuation speed, the system can be customized to suit different user profiles, enabling both novice and elite athletes to train at appropriate intensity levels [7]. Furthermore, the integration of sensors and programmable controllers (e.g., Controllino PLC) allows for real-time monitoring of reaction time, movement precision, and timing accuracy. This feedback not only enhances training effectiveness but also provides objective metrics for tracking athletic progress [8].

This paper presents the conceptual design, development, and practical implementation of two pneumatic-based training devices tailored for martial arts disciplines. The systems were tested in sports hall environments to assess usability and performance. The overarching goal is to contribute to the advancement of intelligent and adaptable sports training equipment that improves reflexive responses and overall athletic readiness in combat sports.

2. PNEUMATIC SYSTEM FOR TRAINING REACTION SPEED IN TAEKWONDO

Martial arts originated as systems of unarmed self-defence and have evolved over centuries into complex disciplines encompassing both physical and philosophical dimensions. Among these, taekwondo stands out as one of the most dynamic and globally popular sports, particularly following its inclusion in the Olympic Games in 2000. The sport emphasizes speed, agility, and precision (especially in foot techniques) and demands rapid responses to visual stimuli during combat. Traditional methods for improving reaction speed often rely

on partner-based drills, where one participant initiates a movement and the other responds. While effective, these exercises require constant human interaction, limiting opportunities for individual training. To address this challenge, a pneumatic training system was developed to provide visual signals that trigger athlete reactions. This chapter outlines the design, implementation, and testing of an experimental system aimed at enhancing reaction speed in taekwondo practitioners.

2.1. System Architecture and Mechanical Design

The proposed system consists of two independently controlled double-acting pneumatic cylinders, each equipped with a circular impact target suitable for kicks or punches. Cylinder movement is regulated by 5/3 solenoid valves, controlled via a Geekcreit UNO R3 microcontroller. All components are mounted on a steel frame that ensures mechanical stability and allows for height adjustments.

The frame is constructed from 25 × 25 mm steel square tubing with a 2 mm wall thickness. Its H-shaped base, formed from four 900 mm tubes, provides a stable foundation. Vertical supports (1900 mm in height) feature machined grooves for adjusting the cylinder mounting height to accommodate different training levels.

Both pneumatic actuators are SMC CP96 cylinders with a 100 mm stroke and a 16 mm piston rod diameter. These cylinders are selected for their high actuation speed (less than 0.5 seconds) and mechanical robustness, critical for withstanding repeated impacts without deformation. Each piston rod is fitted with a 200 mm diameter, 15 mm thick circular board made of laminated wood, topped with a soft impact layer sourced from modified taekwondo armor and focus pads (Figure 2.1). To enhance safety and simulate realistic contact, the piston is depressurized after extension, reducing resistance upon impact.

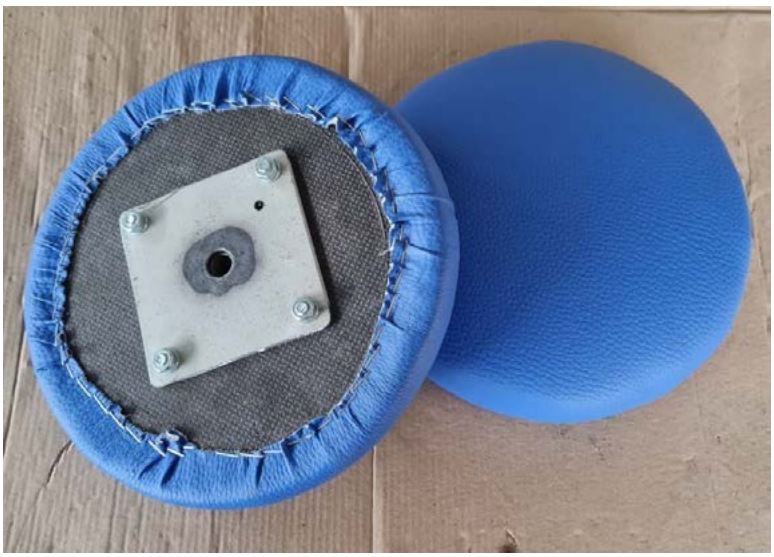

Figure 2.1. Striking Surfaces Mounted on Piston Rods for Taekwondo Training

2.2. Electronic Control System and Software

The control system is based on a Geekcreit UNO R3 microcontroller (ATmega328P), programmed via the Arduino IDE. It manages two SMC SY5000 5/3 solenoid valves that control airflow to the pneumatic cylinders.

Power is supplied by a Schrack LP 746201 AC/DC converter, delivering 24 V DC at 1.5 A, which is sufficient for valve operation and LED indicators. The microcontroller outputs are interfaced through transistors on a custom development board, ensuring safe and efficient switching of the solenoids (Figure 2.2).

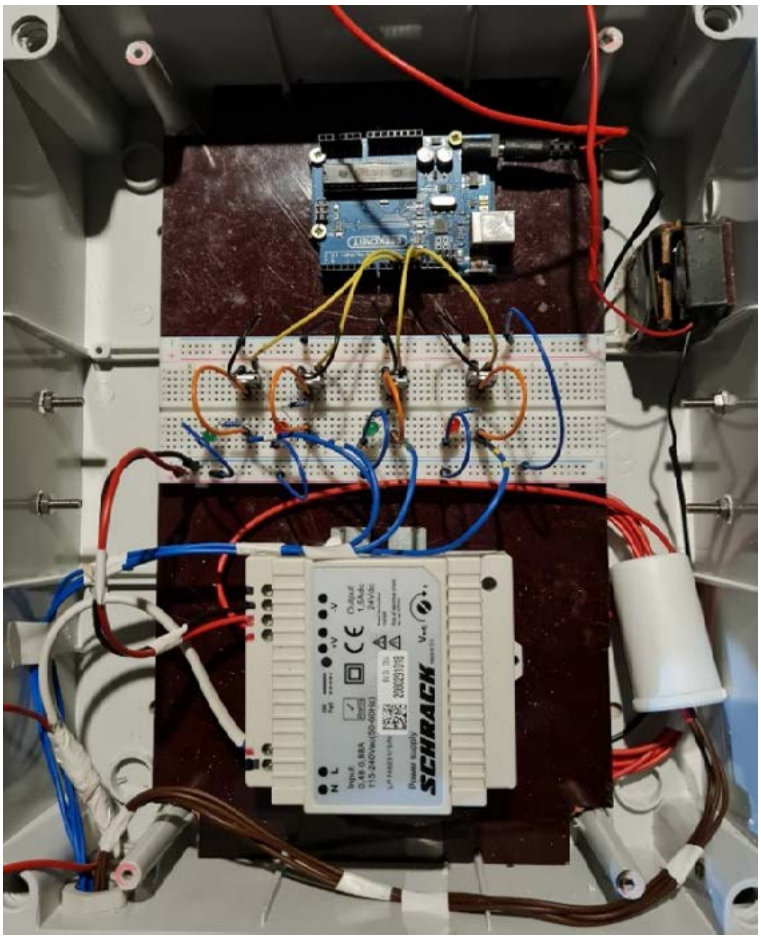

Figure 2.2. Control Box: Microcontroller, Power Supply Unit, and Interface Board

The software initializes all input/output pins and runs a continuous loop that triggers randomized delays and piston activations. This unpredictability simulates real combat scenarios and trains athletes to react quickly and make decisions under pressure. The system supports multiple training modes, including sequential activation, dual-piston challenges, and time-based drills.

2.3. System Assembly and Field Testing

Following component-level validation, the complete system was assembled and tested in its final configuration (Figure 2.3). Initial tests were conducted without user interaction to verify sequence logic and ensure reliable autonomous operation over ten repetitions. Subsequent tests involved athletes responding to piston activations.

Figure 2.3. Final Design of the Taekwondo Reaction Speed Training Device in Operational Setting [9]

After minor adjustments (primarily to the height of the impact targets) the system was deployed in a school gymnasium with primary school students. The device generated strong interest and engagement, indicating high potential for youth training. Further evaluation was conducted at Taekwondo Club Zaprešić, where junior and senior athletes, including European Championship participants, used the system during regular training sessions. Various techniques were practiced, including roundhouse kicks, sidekicks, and punches at different target heights (body and head level). Reaction time was manually recorded using a stopwatch, providing a qualitative baseline for future improvements and confirming the system's effectiveness in enhancing performance. The system achieved a level of stability and safety suitable for regular integration into taekwondo training. Users expressed satisfaction with the innovative experience, especially the chance to train with unpredictable visual cues. The programmable architecture also enables future upgrades, such as:

- Integration of impact-sensitive plates for reaction time measurement;
- Monitor display for real-time feedback and performance tracking;
- Accuracy sensors for hit precision analysis.

These enhancements would transform the device from a basic reaction trainer into a comprehensive smart training platform, offering data-driven insights for athletes and coaches.

3. PNEUMATIC DEVICE FOR TRAINING DEFENSIVE TECHNIQUES AND REACTION SPEED IN BOXING

This chapter presents the development and implementation of a training device designed to improve defensive techniques and reaction speed in boxing. The system uses pneumatic cylinders to replicate incoming punches, prompting athletes to respond quickly and accurately. To ensure reliable operation, the device integrates sensors and programmed control logic that monitor each cylinder's movement, ensuring it returns to its initial position before triggering the next simulated strike. The following sections describe the mechanical design, pneumatic integration, control system, and operational behaviour of the device.

3.1. Mechanical Design and Pneumatic System Integration

The foundation of the training device is a 3D model that incorporates all mechanical and pneumatic components (Figure 3.1). The frame is built using aluminium profiles connected with angular brackets, providing a lightweight yet stable structure. Pneumatic cylinders are mounted on custom-designed plates, which are securely attached to the frame.

Figure 3.1. Designed 3D Model of the Training Device

The primary function of the pneumatic system is to move a focus pad from its resting position to a strike position, simulating a punch. This is achieved using double-acting pneumatic cylinders. Through CAD simulations, optimal stroke lengths were determined. The selected actuators are SMC model C(D)85N16-140C-B. System feasibility was evaluated using SMC's Model Selection Software, which simulated actuator behaviour and confirmed that the chosen cylinders meet the required performance criteria (Figure 3.2). Actuation speed is adjustable via throttle-check valves.

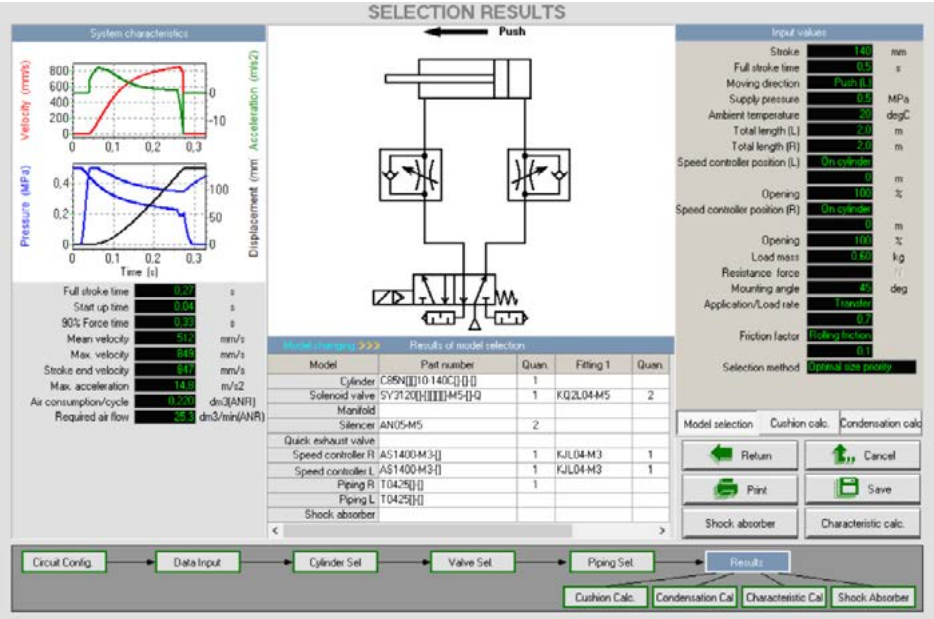

Figure 3.2. Simulation Outputs of Pneumatic Cylinder

(a) (b)

Figure 3.3. Mounting Components onto the Device Frame, a) Joint Connection to the Frame, b) Connection Between Pneumatic Cylinder and Focus Pad

The device uses four pneumatic cylinders, each paired with an angular connector to move a focus pad. These connectors are mounted on axles and rotate using sliding bearings (Figure 3.3a). The core of each pad is made from PPR pipes, chosen for their strength, affordability, and ease of customization. For safety and impact absorption, thermal insulation foam is used as the outer layer, tightly fitted without cutting. Each pad is attached via a 20 mm diameter joint connection, secured with screws (Figure 3.3b).

3.2. Control System and Electronics Integration

The pneumatic actuators are controlled by a Controllino MINI microcontroller, based on the ATMega328 platform and compatible with Arduino. Power is supplied by a 24V Mean Well MDR-20-24 unit, which drives the solenoid valves responsible for airflow control. Controllino MINI simplifies the hardware setup by integrating relay outputs used to control four SMC SY3120-5LOU-C6-Q solenoid 5/2 valves. These valves are compactly arranged on an SS5Y3-20-04-004-Q manifold. Air pressure is provided by a compressor capable of delivering up to 8 bar, connected to the pneumatic circuit via hoses and fittings. Each cylinder's speed and return flow are fine-tuned using AS1201F-M5-06A throttle-check valves with push-lock adjustment. Position sensors (D-M9PL) are powered by Controllino's 5V supply and provide real-time feedback on cylinder status, ensuring safe and accurate operation. All electronic components are housed within a protective control box, as depicted in Figure 3.4.

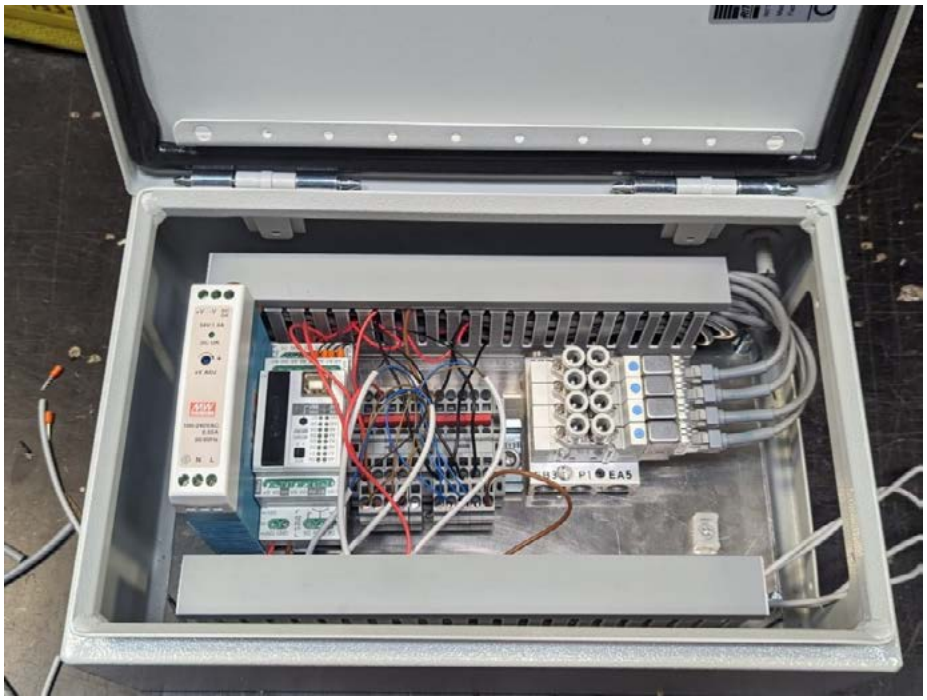

Figure 3.4. Control Unit with Integrated Components

3.3. Operating Principle and System Behavior

The device operates by randomly activating pneumatic cylinders to simulate unpredictable strikes. The control logic ensures that only one cylinder is active at a time and that each activation occurs only after the previous cylinder has returned to its resting position. System initialization involves setting air pressure and adjusting throttle valves to control actuation speed. Training parameters such as strike frequency and response intervals are configured via the Arduino interface.

During operation, the microcontroller continuously monitors sensor inputs. When a randomly selected cylinder is confirmed to be idle, a control signal activates the corresponding valve, initiating the strike. After a brief dwell time to simulate impact, the valve is deactivated, allowing the cylinder to return via spring force or reverse pressure. This cycle repeats, creating a dynamic and reactive training environment.
To ensure safety, the system halts if a sensor fails to confirm a cylinder's position, preventing unintended activation. The fully assembled device is shown in Figure 3.5, illustrating both idle and active states.

(a) (b)

Figure 3.5. Completed Training Device, a) Idle State, b) During Simulated Strike

This device successfully integrates mechatronic and pneumatic technologies to deliver a responsive, safe, and realistic training platform for boxing. Its modular design and programmable features provide a solid foundation for future enhancements, including adaptive difficulty levels, advanced strike pattern algorithms, and real-time performance analytics.

4. CONCLUSION

This study has demonstrated the practical feasibility and benefits of integrating pneumatic systems into training devices for combat sports, specifically taekwondo and boxing. By harnessing the core advantages of pneumatic actuation, such as rapid response, impact absorption through air compressibility, and seamless integration with programmable control systems, two distinct training prototypes were successfully designed, built, and tested in real-world sports environments. The taekwondo-focused device aimed to improve reaction time by presenting randomized visual targets through the extension of striking surfaces.

Athletes were challenged to respond with speed and precision to unpredictable stimuli. Field testing with both youth and professional practitioners revealed strong engagement and confirmed the system's effectiveness in enhancing reflexes and decision-making under pressure. The boxing training device simulated incoming punches using four independently controlled pneumatic cylinders. Athletes practiced defensive manoeuvres such as dodging and blocking, guided by randomized actuation sequences managed by a Controllino microcontroller. Sensor feedback and mechanical safeguards ensured safe operation, while the modular design allowed for personalized adjustments based on user height and skill level. Both devices proved to be stable, adaptable, and safe for use in various training scenarios. They offer a new paradigm in combat sports training, where mechanical systems are used not only to mimic combat situations but also to enhance athletic performance through precise control, repeatability, and data-driven feedback mechanisms.

Future improvements may include the integration of sensor-based performance tracking (e.g., impact sensors, motion detection), real-time feedback through visual or auditory interfaces, and machine learning algorithms for adaptive training programs. Such upgrades would elevate these devices from experimental prototypes to intelligent training platforms, aligned with the broader digital transformation in sports science and athlete development. In summary, the integration of pneumatic systems into combat sports equipment presents a promising and underexplored avenue for improving reaction speed, technical proficiency, and training efficiency. This work contributes to the growing intersection of mechatronics and sport, opening new possibilities for innovation in athletic training technologies.

Abstract.

Faced with the ongoing climate crisis and increased regulatory focus on emission reductions, it is especially relevant to identify key loss mechanisms across industries, responsible for energy consumption and associated emissions not producing any work. Minimizing losses may directly and significantly reduce emissions, fossil fuel dependence, the need for new renewable energy sources , and potential changes to the electric grid. Given the principal losses associated with many fluid power systems, fluid power machinery sectors are likely a source of high emissions when compared to emissions on a global scale. Therefore, this study aims to estimate the global emissions by fluid power machinery. Literature on this topic is generally fragmented, and the most recent and most exhaustive study on this subject was conducted for the United States in 2012, which encompassed both mobile hydraulic, industrial hydraulic, pneumatic, and aviation industries. This 2012 survey was conducted by the Oak Ridge National Laboratory in collaboration with the National Fluid Power Association and major U.S. and European-based industry players. Combining these 2012 findings with global emissions by relevant industries, such as construction machinery and energy production, this paper estimates the global emissions by fluid power machinery, sans aviation hydraulics; these are then grouped according to hydraulic mobile machinery, hydraulic industrial machinery, and pneumatic machinery. The estimation results suggest emissions by fluid power machinery exceed twice that of global aviation, amounting to roughly 5% of the global energy-related emissions. The findings of this study present a novel state-of-the-art assessment of the global CO_2 emissions generated by this sector. Finally, it suggests remarkable potential among multiple decarbonization pathways.

Keywords. Fluid Power Machinery, Energy Consumption, Emissions, Sustainability.

1. INTRODUCTION

Fluid power is a means of power transmission through pressurized working fluids. It includes hydraulics, using liquid as the working fluid, and pneumatics using air/gas as the working fluid, and plays a vital role in modern machinery, automation and transportation. Fluid power technologies are indispensable in applications demanding high power and/or

All Open Access articles are peer-reviewed, distributed under the Creative Commons Attribution-Non Commercial 4.0 International

force density, precision and reliability. Fields of application are virtually countless and Fig. 1.1. illustrates a few examples of the wide application range where fluid power technologies are key enablers, emphasizing its broad versatility and vital role in modern technology.

Figure 1.1. Examples of machinery where fluid power is indispensable.

Fluid power technologies improve resilience, functionality and productivity across industries. An example known to many people is an excavator as shown in Fig. 1.2., where fluid power is an indispensable enabler for its functionality.

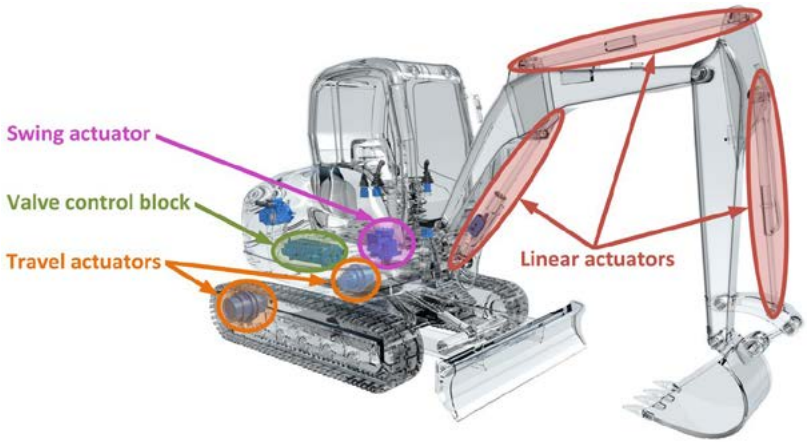

Figure 1.2. Examples of indispensable functions in an excavator enabled by fluid power.

Facing climate change, key challenges for fluid power technology include low system level energy efficiencies, resulting in excessive energy use and associated emissions. Whereas todays fluid power components are rather efficient, system level working principles have largely remained unchanged for decades. To unlock the decarbonization potential of fluid power technologies, energy efficient fluid power system architectures must be at the heart of research efforts, enabling competitive and sustainable technologies.

1.1. Starting Point for Emission Estimates

Studies related to emissions by fluid power machinery in literature is generally fragmented and often related to single machines, single machine categories and so forth, see e.g. [15-18, 26]. The most recent and most exhaustive study on this subject was conducted in 2012 for the U.S. encompassing both mobile hydraulic, industrial hydraulic, pneumatic and aviation industries [1]. The study was conducted by the Oak Ridge National Laboratory in collaboration with the U.S. National Fluid Power Association (NFPA) and 31 industrial partners, including major technology players in both manufacturing as well as OEMs such as Bosch Rexroth, Danfoss, Festo, Poclain Hydraulics, ABB, Siemens, Parker Hannifin, Caterpillar and Sun Hydraulics. The study was targeting the collection and consolidation of specific measurements related to energy consumption, associated emissions and energy efficiencies of deployed fluid power systems [1]. In this context the results may be considered the most broad and trustworthy information on the subject available and is hence used as a reference case for estimating the global emissions by fluid power machinery. As the primary aim here is to estimate the emissions related to mobile and industrial hydraulic and pneumatic machinery, the findings related to aviation in [1] are left out in the following.

1.2. Considerations & Assumptions Applied

The study presented in this paper aims to estimate the global emissions by fluid power machinery in a 2022 scenario, with the reason for this specific year being reference availability. The emission estimates presented uses the 2012 U.S. energy consumption and emission estimates by fluid power machinery [1] as a reference, taking offset in the energy consumption reported here. A main difference from [1] is the emissions by electric energy generation, which generally was lower in 2022 compared to 2012, partly due to a different mix of energy sources, both in the U.S., and globally. Hence, the choices of the emissions per energy unit used in both the 2012 U.S. reference case and the 2022 scenario are considered below for clarity. Note that "CO_2" in the following refers to CO_2 equivalents.

1.2.1. Emissions Related to Diesel Fuel Consumption

Mobile hydraulic machinery remains predominantly powered by internal combustion engines (ICEs) using diesel fuel. According to [1], the emissions per energy unit is equal to 0.249 MMT CO_2/TWh (73 MMT CO_2/Quad), which is in close correspondence with estimates obtainable via other sources, e.g. [5-8]. For this reason, both the 2012 U.S. reference case and the 2022 global emissions scenario uses 0.249 MMT CO_2/TWh for ICE powered fluid power machinery, not accounting for the emissions related to production of the fuel itself.

1.2.2. Emissions Related to Electric Energy Generation

Industrial hydraulic and pneumatic machines are generally electrically powered, and compared to the 2012 study [1], the 2022 emissions/electric energy unit are much different both in the U.S. and globally. The 2012 estimate for the U.S. in [1] suggests emissions related to electric energy generation to be 0.607 MMT CO_2/TWh (178 MMT CO_2/Quad). According to [3], the average 2022 emissions/electric energy unit were for example:

- 0.586 kg CO_2/kWh in China [3]
- 0.292 kg CO_2/kWh in the EU [3]
- 0.386 kg CO_2/kWh in the U.S. [3]
- 0.486 kg CO_2/kWh globally [3]

In addition, [2] suggests that emissions from electric energy generation in the EU in 2022 were even lower than the estimate of [3], namely with emissions of 0.258 kg CO_2/kWh. To be conservative in the emission estimates the 2022 EU emissions per electric energy unit generated as presented in [3] are assumed globally valid.

In addition, it is notable that the emissions per electric energy unit = 0.258 kg CO_2/kWh = 0.258 MMT CO_2/TWh [3] is only 3.6 % higher than the emissions per diesel energy unit = 0.249 MMT CO_2/TWh [1]. Hence, for conservativeness and transparency, **the 2022 global emission estimates assumes that emissions per electric energy unit are identical to those of diesel fuel**, i.e. = 0.249 MMT CO_2/TWh.

1.2.3. Relative Impact of Emissions in the Context of Efficiency

Considering especially the emissions per electric energy unit presented in [1], with 0.607 MMT CO_2/TWh and 0.249 MMT CO_2/TWh for diesel energy, it may seem like diesel fuel being the preferred choice if emissions should be as low as possible. However, here the energy efficiency plays a significant role, with this being highly dependent on the load conditions. As discussed in section 3.2. in the following, the average efficiency of ICEs and electric systems (prime movers) can be assumed to be 45% and 90%, respectively. In this case an ICE producing 1.0 unit of mechanical energy at the output shaft would require 2.2 units of fuel energy, whereas an electric motor/drive unit would require 1.1 units of electric energy to produce 1.0 unit of mechanical energy at the shaft.

Using the emissions per energy unit presented in [1], the corresponding emissions related to producing 1.0 TWh on the shaft would be 0.55 MMT CO_2 for an ICE, and 0.67 MMT CO_2 for an electric motor/drive unit, suggesting that ICE powered machinery emits less CO_2 than electric powered machinery in the 2012 U.S. reference case.

However, whereas emissions by diesel fuel remains the same, the 2022 emissions related to electric energy in the EU was 0.258 MMT CO_2/TWh as discussed in section 1.2.2. Using this measure, and an electric motor/drive unit producing 1.0 TWh on the shaft would emit 0.29 MMT CO_2, corresponding to 53% of the emissions by ICEs with the same output.

It is notable that with an increasing implementation of renewable energy sources, the emissions associated with electric powered machinery will decrease, whereas it for ICE powered machinery will stay the same, assuming fluid power system efficiencies unaltered.

1.2.4. Summary of Emissions per Energy Unit used in the Study

From the considerations above the emissions per energy unit used in the 2012 reference case and the assumed emissions per energy unit for the 2022 global emission scenario, are summarized below for clarity.

2012 reference case for the U.S. emissions by fluid power machinery

- 0.249 MMT CO_2/TWh for diesel energy
- 0.607 MMT CO_2/TWh for electric energy

2022 global emission scenario for fluid power machinery

- 0.249 MMT CO_2/TWh for diesel energy
- 0.249 MMT CO_2/TWh for electric energy

The emissions per energy unit used in the 2022 global emission estimates are indeed conservative from the considerations above, and likely somewhat higher.

Finally, from the above considerations and assumptions as well as the limited sources available, the estimated emissions by fluid power machinery cannot be considered subject to scientific rigour, but rather *best estimates*.

2. ENERGY USE & EMISSIONS BY FLUID POWER MACHINES – THE 2012 U.S. REFERENCE CASE

Following [1], the energy consumption by fluid power machinery in the U.S. in 2012 are summarized in Table 1. For mobile fluid power machinery, the maximum TWh/year measures for *Construction machinery*, *Agriculture machinery* and *Other mobile machinery* are extrapolated from their minimum values using the ratio of maximum and minimum TWh/year for *Total mobile hydraulic machinery* in Table 1.

As the maximum and minimum energy consumption covers estimate ranges, it is assumed that the **average of the minimum and maximum values is representative for the *actual* energy consumption** as specified in Table 1. From this assumption, the % distribution of energy consumption of fluid power machinery is obtained as also specified in Table 1.

Table 1: Energy consumption estimates by fluid power machinery in the US in 2012. Numbers in **bold** font are obtained or directly deduced from [1] and converted from Quads to TWh. Remaining numbers are own calculations.

2012 US Energy Consumption by Fluid Power Machinery	Minimum TWh/yr	Maximum TWh/yr	Avg. TWh/yr	% Avg. TWh/yr
Mobile hydraulic machinery				
- Construction machinery	**68.3**	237.7	153.0	21.7
- Agriculture machinery	**4.7**	16.3	10.5	1.5
- Other mobile machinery	**33.1**	115.3	74.2	10.5
Total mobile hydraulic machinery	**106.1**	**369.3**		
Total industrial hydraulic machinery	**321.2**	**321.2**	321.2	45.5
Total pneumatic machinery	**146.5**	**146.5**	146.5	20.8
Total	**573.8**	**837.0**	705.4	100.0

The estimated CO_2 emissions associated with the energy consumption measures in Table 1 are outlined in Table 2. Here the estimated CO_2 emissions for mobile hydraulic machines are estimated from using 0.249 kg CO_2/kWh = 0.249 MMT CO_2/TWh. As discussed, industrial hydraulic and pneumatic machines are primarily electrically powered, and [1] suggests related emissions of approximately 0.607 MMT CO_2/TWh in 2012 as discussed in section 1.2. Applying these emissions/energy unit measures, the corresponding emissions in Table 2 are obtained, which are nearly identical to the estimates presented in [1].

Table 2: 2012 emission estimates by fluid power machines in the US deduced from [1].

2012 US Emissions by Fluid Power Machinery	Minimum MMT CO_2/yr	Maximum MMT CO_2/yr	Avg. MMT CO_2/yr	% Avg. CO_2/yr
Mobile hydraulic machinery (diesel)				
- Construction machinery	17.0	59.1	38.0	11.1
- Agriculture machinery	1.2	4.1	2.6	0.8
- Other mobile machinery	8.2	28.7	18.4	5.4
Total mobile machinery	26.4	91.8		
Total industrial hydraulic machinery	195.1	195,1	195.1	56.8
Total pneumatic machinery	89.0	89.0	89.0	25.9
Total	310.5	375.9	343.2	100.0

3. GLOBAL EMISSION ESTIMATES BY FLUID POWER MACHINERY – A 2022 SCENARIO

Fluid power system technologies remain virtually unaltered since 2012, i.e. primarily related to throttle control. Similarly mobile hydraulic machines remain primarily powered by diesel fuelled ICEs, and industrial hydraulic and pneumatic systems remain predominantly electrically powered. It has not been possible to account for the % distribution of deployed fluid power machines in different geographic regions. Hence, for conservativeness, the following assumes that the percentage distribution of mobile hydraulic, industrial hydraulic and pneumatic machinery outlined in Table 1 is valid globally.

In 2022, [9] reported that global emissions by construction machines amounted to 400 MMT CO_2/year, a number that has been referenced in several publications, e.g. [10-13]. Applying this measure, the assumptions from section 1.2.4, and the % energy consumption by construction machines in Table 1, emissions are estimated to 18.44 MMT CO_2/ % energy consumption. From this, the global emissions are estimated as in Table 3.

Table 3: Global CO_2 emission estimates by fluid power machines.

Global CO_2 Emission Estimates based on average US Energy % Distribution	% Average TWh/yr	Average MMT CO_2/yr
Mobile hydraulic machinery (diesel)		
- Construction machinery	21.7	400.0
- Agriculture machinery	1.5	27.5
- Other mobile machinery	10.5	194.0
Total mobile machinery		621.5
Total industrial hydraulic machinery	45.5	839.9
Total pneumatic machinery	20.8	383.1
Total	100.0	1,844.5

3.1. Emission Impact of Fluid Power Machinery

To put the estimated emissions by fluid power machinery in perspective, these are compared to the much-scolded aviation sector and the global energy related emissions.

In 2022 international aviation was estimated to be responsible for emitting approximately 800 MMT CO_2/year [14], distributed by 331 MMT CO_2/year for domestic aviation and 470 MMT CO_2/year for international aviation. In comparison fluid power machinery is the same year estimated to emit 2.3 times more than global aviation.

Similarly, the 2022 global energy related emissions are estimated to 36,800 MMT CO_2/year [2], hence the total emission estimate above suggests that fluid power machinery was responsible for 5% of the global energy related emissions.

3.2. Emissions of Fluid Power Machinery related to Losses & Useful Work

Having established the significant emission impact of fluid power machinery, the following aims to quantify which part of emissions that are related to prime mover losses, fluid power system losses and useful work. To investigate this, the average efficiencies related to fluid power machinery segments proposed in [1] are used. Considering the portion of energy use related to mobile hydraulic, industrial hydraulic and pneumatic machinery when combined with the respective average efficiencies, the weighted efficiencies in Table 4 are obtained.

Table 4: Weighted energy efficiencies based on percentage energy use.

Fluid Power Machinery	% Average TWh/yr	Average Energy Efficiency in % [1]	Weighted Efficiency
Mobile hydraulic machinery (diesel)	33.7	**21**	7.1
Total industrial hydraulic machinery	45.5	**50**	22.8
Total pneumatic machinery	20.8	**15**	3.1
Total	100.0		33.0

From Table 4 the overall weighted efficiency of fluid power machinery is found to 33%, meaning that 67% is lost in power transmission processes. Considering now the underlying efficiencies, several reports suggest ICE brake thermal efficiencies in ranges 42-43% [22], 43-44% [23] and 45–46% [24]. Similarly, total efficiencies electric motor plus electric drives and wiring have been estimated to 88.0% [19], 89.8% [20] and [21] suggest efficiencies in the range 80-90%, which is supported by the findings in e.g. [25]. Based on this, the following assumes an average fuel-to-shaft efficiency for ICEs of 45% and an average grid-to-shaft efficiency for electric prime movers of 90%.

Table 5: Energy efficiency estimates on machine subsystem level.

Fluid Power Machinery	ICE/Electric Subsystem Efficiency in %	Hydraulic/Pneumatic Subsystem Efficiency in %	Total Efficiency
Mobile hydraulic machinery	45	47	21
Industrial hydraulic machinery	90	56	50
Pneumatic machinery	90	17	15

Based on these *prime mover* efficiencies the hydraulic and pneumatic (sub)system efficiencies outlined in Table 5 are obtained, such that the total machine efficiencies are in correspondence with those specified in [1]. Hence, these efficiency estimates are used to estimate the associated emissions. Defining energy consumption as the input energy E_{in}, the output energy of a prime mover (ICE or electric) as E_{pm} and the output energy of a fluid power systems E_{fp}, the energy flow in fluid power machinery may be depicted as in Fig. 3.1.

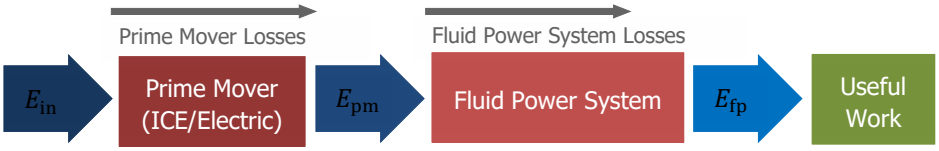

Figure 3.1. Energy flow in fluid power machinery.

Furthermore, defining the prime mover and fluid power system efficiencies as η_{pm} and η_{fp}, respectively, the prime mover losses $E_{\text{pm,loss}}$, fluid power system losses $E_{\text{fp,loss}}$ and useful work E_{uw} may be obtained through Eqs. (3.1)-(3.4).

$$E_{\text{pm}} = \eta_{\text{pm}} E_{\text{in}} \quad , \quad E_{\text{fp}} = \eta_{\text{fp}} E_{\text{pm}} = \eta_{\text{fp}} \eta_{\text{pm}} E_{\text{in}} \tag{3.1}$$

$$E_{\text{pm,loss}} = E_{\text{in}} - E_{\text{pm}} = (1 - \eta_{\text{pm}}) E_{\text{in}} \tag{3.2}$$

$$E_{\text{fp,loss}} = E_{\text{pm}} - E_{\text{fp}} = \eta_{\text{pm}} E_{\text{in}} - \eta_{\text{fp}} E_{\text{pm}} = (1 - \eta_{\text{fp}}) \eta_{\text{pm}} E_{\text{in}} \tag{3.3}$$

$$E_{\text{uw}} = E_{\text{in}} - E_{\text{pm,loss}} - E_{\text{fp,loss}} = \eta_{\text{fp}} \eta_{\text{pm}} E_{\text{in}} \tag{3.4}$$

Noting that emissions/energy unit are assumed identical for diesel and electric powered machinery as discussed in section 1.2., the emissions may be considered proportional to the associated energy consumption. Hence, prime mover loss related emissions $\varepsilon_{\text{pm,loss}}$, fluid power system loss related emissions $\varepsilon_{\text{fp,loss}}$ and the emissions related to useful work ε_{uw}, may be estimated like the associated energy losses Eqs. (3.4), as Eqs. (3.5).

$$\varepsilon_{\text{pm,loss}} = (1 - \eta_{\text{pm}}) \varepsilon_{\text{in}} \ , \ \varepsilon_{\text{fp,loss}} = (1 - \eta_{\text{fp}}) \eta_{\text{pm}} \varepsilon_{\text{in}} \ , \ \varepsilon_{\text{uw}} = \eta_{\text{fp}} \eta_{\text{pm}} \varepsilon_{\text{in}} \tag{3.5}$$

Using the global emission estimates in Table 3, the efficiency estimates in Table 5 and Eqs. (3.5), emissions related to prime mover losses, fluid power system losses and useful work appear as depicted in Table 6.

Table 6: Emission estimates on machine subsystem level.

Emissions related to losses and useful work	Mobile hydraulic machinery in MMT CO_2/yr	Ind. hydraulic machinery in MMT CO_2/yr	Pneumatic machinery in MMT CO_2/yr	Total
Emissions related to ICE/electric subsystem losses	341.8	84.0	38.3	464.1
Emissions related to fluid power subsystem losses	148.2	332.6	286.2	767.0
Emissions related useful work	131.4	423.3	58.6	613.3
Total	621.5	839.9	383.1	**1,844.5**

Due to the proportionality assumption of energy consumption and emissions across machine types, 33% of the emissions are related to useful work, corresponding to the weighted energy efficiency as expected. Furthermore, 25% is associated with ICE/electric system losses and 42% is associated with losses in fluid power systems.

4. DECARBONIZATION PATHWAYS & PERSPECTIVES

From the distribution of emissions related to losses and useful work estimated above, it is evident that there is a significant emission reduction potential for fluid power machinery. Indeed, if all electric energy was generated by renewable energy sources like wind turbines and solar panels, the emission reduction potential would be related to electrification of mobile fluid power machines alone. However, a broadly electrified world will likely not be a reality for decades. In any case, the use of electric energy should be reduced as much as possible to limit the requirement for renewable energy sources, rare earth materials, allow for realistic and commercially feasible battery sizes in mobile machinery etc. Hence, the increase of energy efficiencies to reduce energy consumption should be at the core of future research, development and innovation efforts.

To evaluate the emission reduction potentials by increased energy efficiencies and electrification viewed in a 2022 context as the for the above estimates, Eqs. (4.1)-(4.4) are applied taking offset in useful work, E_{uw}, and hence the reverse calculation process compared to Eqs. (3.1)-(3.4).

$$E_{\mathrm{fp}} = \frac{E_{\mathrm{uw}}}{\eta_{\mathrm{fp}}} \quad , \quad E_{\mathrm{pm}} = \frac{E_{\mathrm{fp}}}{\eta_{\mathrm{pm}}} = \frac{E_{\mathrm{uw}}}{\eta_{\mathrm{pm}}\eta_{\mathrm{fp}}} \tag{4.1}$$

$$E_{\mathrm{fp,loss}} = \frac{E_{\mathrm{uw}}}{\eta_{\mathrm{fp}}} - E_{\mathrm{uw}} = \frac{1-\eta_{\mathrm{fp}}}{\eta_{\mathrm{fp}}} E_{\mathrm{uw}} \tag{4.2}$$

$$E_{\mathrm{pm,loss}} = \frac{E_{\mathrm{fp}}}{\eta_{\mathrm{pm}}} - E_{\mathrm{fp}} = \frac{E_{\mathrm{uw}}}{\eta_{\mathrm{pm}}\eta_{\mathrm{fp}}} - \frac{E_{\mathrm{uw}}}{\eta_{\mathrm{fp}}} = \frac{1-\eta_{\mathrm{pm}}}{\eta_{\mathrm{pm}}\eta_{\mathrm{fp}}} E_{\mathrm{uw}} \tag{4.3}$$

$$E_{\mathrm{in}} = E_{\mathrm{uw}} + E_{\mathrm{pm,loss}} + E_{\mathrm{fp,loss}} = \left(1 + \frac{1-\eta_{\mathrm{pm}}}{\eta_{\mathrm{pm}}\eta_{\mathrm{fp}}} + \frac{1-\eta_{\mathrm{fp}}}{\eta_{\mathrm{fp}}}\right) E_{\mathrm{uw}} = \frac{1}{\eta_{\mathrm{pm}}\eta_{\mathrm{fp}}} E_{\mathrm{uw}} \tag{4.4}$$

Again, noting the assumption that emissions/energy unit are identical for diesel and electric powered machinery (section 1.2), the prime mover loss related emissions $\varepsilon_{\mathrm{pm,loss}}$, the fluid power system loss related emissions $\varepsilon_{\mathrm{fp,loss}}$ and the emissions related to the input energy $\varepsilon_{\mathrm{in}}$ may be estimated as Eqs. (4.5).

$$\varepsilon_{\mathrm{fp,loss}} = \frac{1-\eta_{\mathrm{fp}}}{\eta_{\mathrm{fp}}} \varepsilon_{\mathrm{uw}} \ , \varepsilon_{\mathrm{pm,loss}} = \frac{1-\eta_{\mathrm{pm}}}{\eta_{\mathrm{pm}}\eta_{\mathrm{fp}}} \varepsilon_{\mathrm{uw}} \ , \varepsilon_{\mathrm{in}} = \frac{1}{\eta_{\mathrm{pm}}\eta_{\mathrm{fp}}} \varepsilon_{\mathrm{uw}} \tag{4.5}$$

The emission estimates presented in the following are hence based on Eqs. (4.5).

4.1. Emission Reduction Potential of Fully Electrified Fluid Power Machinery

As previously discussed, industrial hydraulic and pneumatic machines are already largely electrified [1], hence the main emission reduction potentials of electrification are related to mobile hydraulic machinery. These machines remain predominantly powered by ICEs, however the process of electrifying these is ongoing with a the main focus being the replacement of ICEs by battery powered electric motors and drives, while hydraulic systems

remain based of traditional design principles[1]. Hence, following the current trends described, assuming that electrification of such machinery increases the prime mover efficiencies from an average of 45% (Table 5) to an average of 90%, and using Eqs. (4.5.), the emissions appear as in Table 7 for a full electrification of mobile hydraulic machinery.

Table 7: Emission estimates on machine subsystem levels assuming full electrification of fluid power machinery.

Emissions related to losses and useful work	Mobile hydraulic machinery in MMT CO_2/yr	Ind. hydraulic machinery in MMT CO_2/yr	Pneumatic machinery in MMT CO_2/yr	Total
Emissions related to ICE/electric subsystem losses	31.1	84.0	38.3	153.4
Emissions related to fluid power subsystem losses	148.2	332.6	286.2	767.0
Emissions related useful work	131.4	423.3	58.6	613.3
Total	310.7	839.9	383.1	**1,533.7**

Table 7 suggests that a full electrification of fluid power machinery, in a 2022 scenario, would reduce emissions from 1,844.5 MMT CO_2/year to 1,533.7 MMT CO_2/year, amounting to approximately a 17% emission reduction for fluid power machinery.

4.2. Emission Reduction Potential by 50% Fluid Power System Efficiency Increase

Consider now the case of broadly increasing the energy efficiency of fluid power systems with prime mover efficiencies remaining the same as in Table 5. Various works have been reported in literature in the past decades comprising more efficient component designs and especially novel system architectures that reduces conceptual losses, increases energy recuperation capabilities etc. Such developments suggest that energy efficiencies may be significantly increased. It is difficult to establish the exact energy efficiency potential, however, in view of the mentioned development the authors believe that a 50% increase in fluid power system efficiencies is achievable on the average. Using this measure and Eqs. (4.5), the emission estimates for fluid power machinery appears as outlined in Table 8.

While the assumed efficiency increase reduces the energy consumption and the associated emissions related to fluid power systems, the reduced fluid power system losses also reduce the energy throughput of the prime movers, hence the prime mover energy losses and emissions. The results in Table 8 suggest that a 50% increase in fluid power system efficiencies would result emission reductions from 1,844.5 MMT CO_2/year to 1,229.6 MMT CO_2/year, i.e. a reduction of 614.9 MMT CO_2/year corresponding to 33.3%.

It is notable that the emission reduction potential of broadly increasing energy efficiencies in fluid power systems by 50%, is roughly twice that of fully electrifying fluid power machinery while maintaining traditional hydraulic system architectures. This emphasizes the necessity of the fluid power research community and industry to focus on research and development of more efficient components and especially system architectures.

[1] Experiences by the authors at BAUMA fairs in 2022 and 2025 in Munich, Germany.

Table 8: Emission estimates on machine subsystem levels assuming a 50% efficiency increase in all three fluid power machinery groups.

Emissions related to losses and useful work	Mobile hydraulic machinery in MMT CO_2/yr	Ind. hydraulic machinery in MMT CO_2/yr	Pneumatic machinery in MMT CO_2/yr	Total
Emissions related to ICE/electric subsystem losses	227.9	56.0	25.5	309.4
Emissions related to fluid power subsystem losses	55.0	80.6	171.3	306.9
Emissions related useful work	131.4	423.3	58.6	613.3
Total	414.3	559.9	225.4	**1,229.6**

4.3. Emission Reduction Potential of a 50% Efficiency Increase & Electrification

Having considered the emission reduction potentials separately related to a full electrification of fluid power machinery and to a 50% increase in fluid power system efficiencies, the impact of doing both is considered.

Applying efficiencies of 90% for both prime mover types, corresponding to fully electrified machinery, and a 50% increase in fluid power system efficiencies to Eqs. (4.5), the emissions presented in Table 9 are obtained.

Table 9: Emission estimates assuming a 50% efficiency increase broadly, and a full electrification of fluid power machinery.

Emissions related to losses and useful work	Mobile hydraulic machinery in MMT CO_2/yr	Ind. hydraulic machinery in MMT CO_2/yr	Pneumatic machinery in MMT CO_2/yr	Total
Emissions related to ICE/electric subsystem losses	20.7	56.0	25.5	102.2
Emissions related to fluid power subsystem losses	55.0	80.6	171.3	306.9
Emissions related useful work	131.4	423.3	58.6	613.3
Total	207.2	559.9	225.4	**1,022.5**

From Table 9 it is found that the emissions may be reduced from 621.5 MMT CO_2/year to 207.2 MMT CO_2/year for mobile hydraulic machinery, from 839.9 MMT CO_2/year to 559.9 MMT CO_2/year for industrial hydraulic machinery and from 383.1 MMT CO_2/year to 225.4 MMT CO_2/year for pneumatic machinery. These reduction measures correspond to 66.7%, 33.3% and 41.2% for mobile hydraulic, industrial hydraulic and pneumatic machinery, respectively.

In total, emissions by fluid power machinery may be reduced from 1,844.5 MMT CO_2/year 1,022.5 MMT CO_2/year corresponding to 44.6%.

5. SUMMARY

A study on the emission reduction potential by fluid power machinery is presented. With offset in previous studies on energy consumption and energy efficiencies of fluid power machinery conducted for the U.S. combined with conservative estimates for emissions by especially electric energy generation and recent emission estimates for construction machinery, the emissions by fluid power machinery are conservatively estimated to approximately 1,844 MMT CO_2/year in a 2022 scenario. It is found that this emission level corresponds to 2.3 times that of global aviation and approximately 5% of the global energy related emissions.

In addition, the emission reduction potentials offered by a full electrification of fluid power machinery, respectively a 50% increase in fluid power system efficiencies, is investigated, as well the combination of a full electrification and a 50% efficiency increase. The results are shown for comparison in Fig. 5.1., emphasizing the significant emission reduction potentials present under these conditions, separately, and combined.

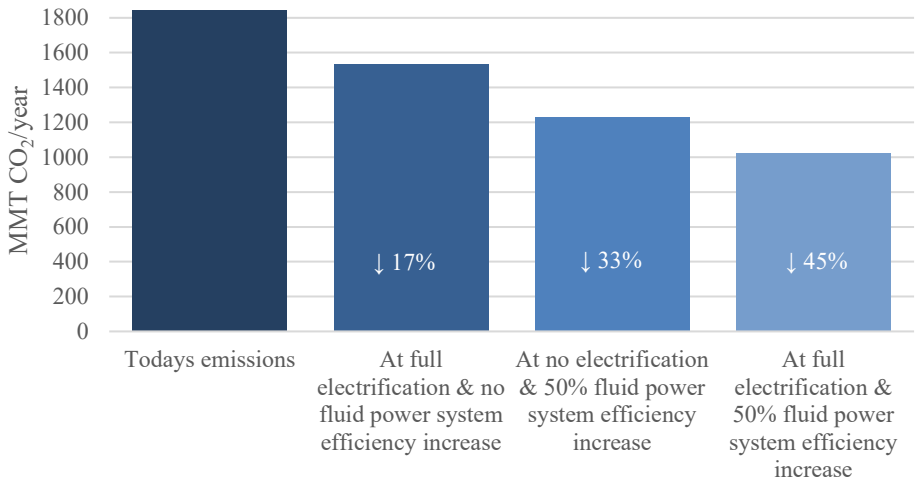

Figure 5.1. Comparison of emission reduction potentials.

In context of the global energy related emissions, the emission reduction potential for a full electrification of fluid power machinery is 0.8%, whereas the emission reduction potential of a 50% fluid power system efficiency increase is a 1.7% reduction in the global emissions. These results emphasize that the emission reduction potentials related to increasing fluid power system energy efficiencies by far exceeds that of electrifying fluid power machinery. However, the potential of a 50% fluid power system efficiency increase and a full electrification has the potential to reduce global emissions by 2.2%. This corresponds to an emission reduction of 822 MMT CO_2/year, exceeding the total emissions by global aviation.

From these estimates of emission reduction potentials, it is found that it is not the electrification of fluid power machinery, which is currently ongoing, that individually possess the largest emission reduction potential, but rather the increase of fluid power system efficiencies. Naturally, however, both increasing system level fluid power efficiencies while electrifying fluid power machinery should be key focus areas for research, development and innovation in the years to come.

Biographies

Lasse Schmidt received the M.Sc. degree in engineering (mechatronics) from Aalborg University, Denmark, in 2008. From 2008 he was with the application engineering group of Bosch Rexroth A/S, Denmark, and from 2010 an industrial Ph.D. fellow also associated with Aalborg University. He received the Ph.D. degree in robust control of hydraulic cylinder drives in 2014. Subsequently, he has been a postdoctoral researcher at AAU Energy while concurrently being with Bosch Rexroth AG. Hereafter he became an Assistant Professor and later an Associate Professor with AAU Energy. He is heading research activities related to electro-hydraulic drive network technology, a field in which he is the founder of the fundamental design and control principles. He has authored more than 70 scientific peer-reviewed publications, and his current research interests are in design and control of electro-hydraulic drives and their integration into both mobile industrial machines.

Prof. Katharina Schmitz studied mechanical and chemical engineering at RWTH Aachen University and Carnegie Mellon University, Pittsburgh (USA) and graduated in 2015 as Dr.-Ing. at RWTH Aachen University. Since 2018, she is a full professor at RWTH Aachen University and director of the Institute for Fluid Power Drives and Systems (ifas). In addition, she is Vice Dean of the Faculty for Mechanical Engineering at RWTH Aachen, a position she has held since 2020. Prof. Schmitz's awards and honors include several best paper awards and the 2023 IMechE Joseph Bramah Medal award.

Tatiana Minav (ASME and IEEE member) is Associate professor in IHA –Innovative Hydraulics and Automation lab, Tampere University, Finland. She has over 18 years' experience working on improving the efficiency of non-road mobile working machines. She has authored 140 scientific publications in total. Her current interests include zonal hydraulics, electro-hydrostatic and electro-mechanical actuators, sensorless position control with direct electric drive in hydraulic systems, AI-based condition monitoring and predictive maintenance, thermal management, energy balance and energy recovery systems in non-road mobile working machines.

Adolfo Senatore started his academic career in 1984, and since 2001 he is a Full Professor and director of Fluid Power Laboratory of University of Naple Federico II, Italy. From 2001 to 2016, he served as President of the Degree Course Council in Mechanical Engineering and from 2014 to 2016 as Teaching Coordinator of the Faculty of Engineering at the University of Naples. From 2017 to 2019 and was President of the Campania TEST Interuniversity Consortium. Professor Senatore was and is responsible for various projects financed with Italian ministerial funds and European funds and industrial funds such as Ferrari, Porsche, Duplomatic, Fluid-O-Tech. His research group consists of 3 permanent persons and about 6 PhD students and Post Doc. His research activities, since the beginning of his career, are documented by around 250 scientific publications and monographic works.

Decarbonization in mobile machinery – from reducing the carbon emissions to emission-free drivetrains

Dr. Andreas Schumacher

Dr. Andreas Schumacher, Danfoss Power Solutions GmbH & CO OHG, aschumacher@danfoss.com

Abstract.

Here in Europe, the carbon emissions of components and machinery are getting more in focus. A lot of regulations are driving this, but also the market demand increases for reduced carbon footprint to also emission-free vehicles. As the use-phase is typically in mobile machinery the by far and outmost the biggest contributor to the CO2-footprint of a machine, reducing energy consumption is key. Significant contributions are coming surely from the typical prime energy source, the engine, but also from the drivetrain as well as the work hydraulics. To reduce the energy consumption of these functions, solutions can be applied with a three-level approach:

- The first level is based on the components.
- The next level is on (sub-)systems and software.
- The last level is on the machine and the prime energy source, where e.g. switching from diesel to battery-electric also leads to significant decarbonization.

The paper will show the impact on all three levels which can be done with Danfoss components in more detail. The potential shown will be backed up with measurement data. So it will become clear, that the journey towards zero emission vehicles is possible, it can start today on these different levels on the machines, also with very high impact on reducing the TCO of a machine as highly efficient components and systems not only reduce the CO2e emissions but also reduce operation costs.

Keywords. Datacenter design, energy efficiency of datacenter, energy efficient metrics, datacenter carbon footprint computation.

1. INTRODUCTION

In the current situation, especially in Europe, the carbon footprint of products and their usage is becoming increasingly important. Several drivers, from the regulatory site, reporting site and application requirements demand the labelling, publishing and reducing of the carbon footprint of products. The publicly funded research project Fluid 4.0 [1] develops methodologies to share among further product information also CO_2-footprint data of products [2].

Reducing carbon footprints is in mobile machinery also important. There are different regulatory drivers, requiring the report of CO_2 emissions during production and usage of components and complete machines, for example as part of the reporting obligations CSR-D/ ESRS, there as part of product or company carbon footprint reporting (PCF and CCF). Another level of reporting the product or company carbon footprint takes place, when a public sustainability commitment has been engaged. Good examples are here commitments with the Science-based Targets Initiative SBTi [3] or the Carbon Disclosure Project CDP [4]. An obvious consequence is when reporting the PCF of a product, that there is an intrinsic motivation of optimizing the footprint, meaning reducing the product emissions.

Another aspect leading to the need to reduce the carbon footprint of mobile machinery becomes imminent if external regulations require reduced emissions in specific application cases. Here, good examples are indoor operations like with areal lifts in buildings or farm machinery in stables. Or if emission reductions are prerequisites for working in specific areas, like construction sites in dense cities, requiring emission-reduced or even emission free machinery and equipment.

And last but not the least, the bigger-picture-based motivation for emission reductions of machinery is based on the aspect of doing the right thing for our climate. Reducing the emission of CO_2 is scientifically proven the right thing to do to limit the progress of climate change. As this applies for all emitting machines – and mobile machines often can reach big sizes with big power needs – improving the emissions of mobile machinery is a smart move for climate change prevention.

All these motivations to reduce the carbon footprint of a mobile machinery have the same baselining challenge: Where to start and what is an effective way to reduce emissions, especially in the use phase with all the challenges to determine use-phase emissions [5] ?

2. POWER AND LOSSES IN A TYPICAL HYDROSTATIC DRIVETRAIN

For gaining an inside of what impact the different components in typical mobile machinery drives have, the example of a standard hydrostatic drivetrain is being analyzed. **Figure 1** depicts such a drivetrain in a Sankey diagram, which is here, to represent the most common standard architecture, energized by a combustion engine, typically a diesel engine. The power of the engine as prime mover is distributed to the work functions (not shown in that figure) and to the drivetrain, represented with the hydraulic pump and motor to form the hydrostatic transmission. The transmission supplies the power via a gearbox to the wheels. For the sake of simplification, the wheels are not represented in Figure 1, so the usable energy to propel the machine is emitted at the gearbox, here.

Figure 1 also includes typical maximum efficiency values for the components in the drivetrain, starting from the engine with around 40% total efficiency in best points. With these given values, assuming all components are operated in their best points, from 100 *kW* input power only nearly 35 *kW* are usable at the gearbox output.

It also needs to be considered, that the maximum efficiencies are listed in Figure 1. That means, in other words, in normal operations, when engine and hydrostatic transmission

dynamically sweep through their operation and efficiency maps, lower component and system efficiencies are very likely.

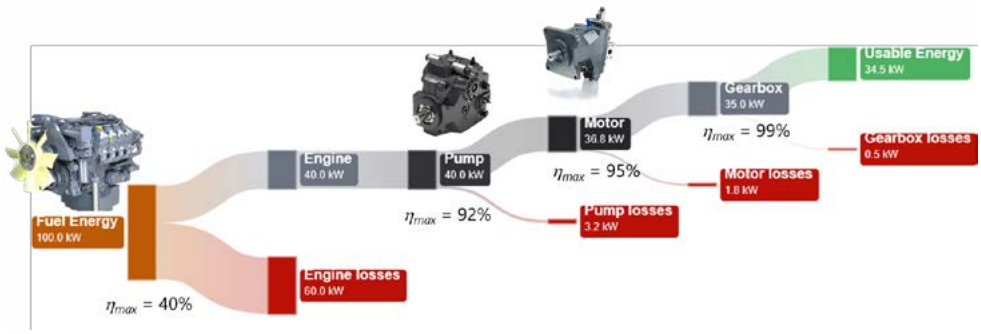

Figure 1: Power- and loss-flow in a standard hydrostatic drivetrain

Based on the illustrative losses of the individual components, Figure 1 makes it clear that going from engine to the wheels has the biggest impact, gaining reductions, but that is also the most complex path from the change-perspective. Hence, depending on the target one has in decarbonization, swapping the prime energy supply might lead to too complex solutions to begin with, especially taking into account that for some bigger mobile machinery the energy demand for a regular working day exceeds what alternative decarbonized energy sources can deliver, like batteries or hydrogen H_2. Their storage would become way too big to support the equivalent energy supply to diesel fuel.

Thus, it is very reasonable to analyze from wheels to the engine, excluding the gearbox and start with the hydrostatic motor. This also gives an estimation of what level of change is sufficient to realize the sought decarbonization level in the drivetrain.

3. DECARBONIZATION ON COMPONENT LEVEL

Starting the impact analysis as mentioned with a hydraulic motor, to derive a better understanding of what is the impact in efficiency and CO_2-emissions, two different types of hydraulic motors used in transmissions will be discussed in this chapter. A typical configuration of a hydrostatic transmission consists of a variable displacement pump in axial piston design paired up with a fixed motor.

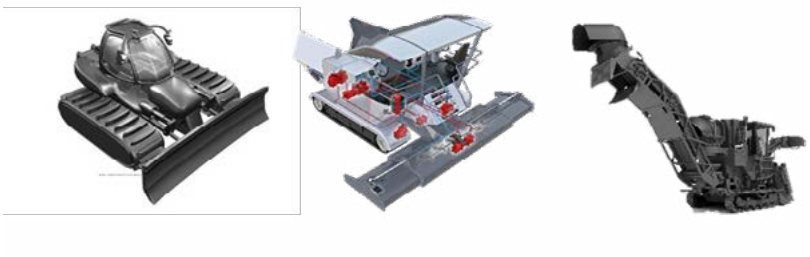

Figure 2: Power and loss-flow in a hydrostatic drivetrain [Source right image: Internet]

This configuration is often used in smaller machines where the cost impact has a high priority or also in more complex machines with a so-called dual path configuration – driving two tracks or wheels in a skid-steering architecture, demonstrated in **Figure 2**. These vehicles are not intended for high speeds and thus operate well with a fixed motor - compared to a variable motor.

To get a fair comparison, the vehicle example used here is a smaller crawler as shown in Figure 2 on the left side. In this setup, the comparison is made between version 1, consisting of a Danfoss S90MF075 swashplate-technology motor with 75 cm^3/rev as the predecessor and a Danfoss H1F080 bent-axis motor with 80 cm^3/rev as the new product with higher efficiency. But just the comparison of the peak efficiency is not giving satisfying information what might be achieved in normal machine operation. To overcome this, two typical operation conditions of the crawler are compared, which are:

- **Working:** Lower speed and high tractive force; approx. 5 *km/h* and ~75 *kN* tractive force. This represents the condition when the crawler moves material by pushing it forward.
- **Transport:** Highest speed and medium tractive force; approx. 13 *km/h* and ~40 *kN* tractive force, representing the machine returning to the starting point after pushing material to continue moving material or relocating to a different location for work.

As this comparison focuses on the impact of motor technology, the pump as well as the further drivetrain components are not shown in this comparison, it will be assumed that the difference in motor displacement is compensated by the gearbox driving the sprocket so that the same speeds and tractive forces are achieved on machine level.

The results of this comparison are shown in the next figure, **Figure 3**, where the resulting advantage of the new H1F is demonstrated in the bar chart of the predecessor-product S90MF. The gray bars are for the S90 motor, the red for the new H1F.

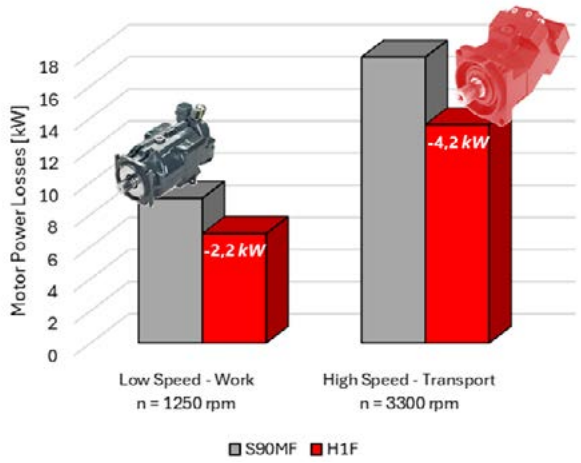

Figure 3: Results of the losses comparison S90 vs H1F-motor in two operation conditions

The diagram shows clearly that the new technology has an impact when analyzed in real operation conditions. The losses for the low-speed working conditions and in the higher-speed conditions are on a similar reduction level close to 25% lesser that using the older product with the swashplate technology – or in other words, the H1F saved 2,2 *kW* in the low-speed and 4,2 *kW* in the high-speed condition. To calculate the impact on the machine's CO_2-footprint, an approximation of the usage of the machine needs to be determined:

- Small Crawler with typical yearly 1000 *hrs* work, 300 *hrs* transport, and 8 *yrs* machine lifetime. That results in typical 10.400 *hrs* total machine lifetime
- In that load cycle, 17,6 *MWh* losses are avoided during Work and 33,6 *MWh* losses avoided in Transport conditions, so 51,2 *MWh* in total.
- Typical diesel engine with 215 *g/kWh* fuel consumption – this value is lower than the best point and thus represents variable load conditions with around 35% engine efficiency.

With these approximations and an emission factor of 2,9 *kg* CO_2e per liter diesel fuel, it can be calculated that the application of an H1F **avoids 38,3 *to* CO_2e** per machine life through a 2% weighted efficiency increase only compared to the S90MF – by just exchanging this single component in a drivetrain.

4. DECARBONIZATION ON SYSTEM LEVEL

If a higher decarbonization level is desired, the system level offers higher reduction potential. System level, that might either comprise of multiple components, making a hydraulic system or it can also take the control software into account. In this chapter, the key element leading to CO_2-reductions is the Danfoss Digital Displacement® Pump DDP. That pump is combining multiple smaller pump units in one housing. The pump units are based on a variable radial piston pump design whereas the variability is achieved by connecting and disconnecting the piston during its stroke to/from the outlet. The pistons of the pump can be actuated all individually, run on different pressure levels and they can also be completely deactivated (not connected), so that Power on Demand is possible without efficiency compromises. **Figure 4** depicts two of these pumps, whereas the left is the single DDP096 and the right is a double pump DDP1X0D. The principle of switchable radial piston design delivers very high efficiency also at part stroke and additionally features very high reaction times in changing the displacement. This allows loading the engine at high levels as stalling can be avoided through quick unloading through the pump.

Figure 4: Digital Displacement pump in single (DDP096) and double version (DDP1X0D)

This quick reaction of the pump being applied to an excavator can – with an adapted control software – deliver higher efficiency, as **Figure 5** is explaining. Normally, to prevent the engine from getting overloaded at sudden load-increase situations, the engine is not loaded to its maximum capability, some safety margin is left. That can be avoided with a DDP, the engine can be loaded higher, close to its maximum and thus also operate in areas with higher efficiency.

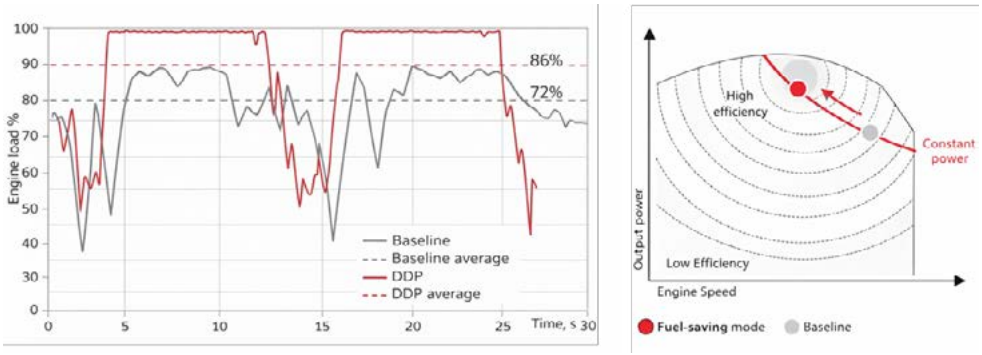

Figure 5: Adapting the control software to the quick reaction characteristics of the DDP

In the left part of Figure 5 the loading of the engine is depicted, in grey the unchanged baseline system with an average loading of 72% of the engine and in red the DDP pump system with adapted control software, where the average load can be increased up to 86%, due to quicker overload prevention. To demonstrate the effect onto the engine, the right diagram is an illustrative example of a fuel consumption shell diagram. The baseline, to reserve some reaction margin through lower loading, operates the engine at lower efficiency conditions (grey point), whereas the optimized system with the DDP moves the operation point of the engine through higher loadings to areas with higher efficiencies. In measurements, published in [6], 21% fuel saving was obtained, although in normal operation conditions, the practical fuel consumption reductions achieve between 10-15%, also dependent on the baseline system design.

The decarbonization potential is further increased when the hydraulic characteristics of the DDP are fully used – the independent use of the different pumping unit outlets. This will now be discussed by taking a classical open-circuit work-function system with a pump,

valves and cylinders as an example, like in an excavator boom. In typical hydraulic circuit designs in mobile machinery, an axial piston pump is combined with a proportional valve to actuate the consumer(s). Those systems are typically very prone to throttling losses, especially if multiple consumers with a different flow and pressure demand are supplied simultaneously.

To overcome these conditions, multiple solutions are possible. One is the direct drive of an actuator with a pump, including changing into closed circuit setup, if the drive needs to be reversable. That means, the actuator – a cylinder or motor – is directly coupled to a pump which controls the speed through changing its displacement – aka displacement controlled [7], [8]. Thus, that avoids the valve losses. The downside of this solution is higher installation costs as per consumer one pump is required.

Another solution, which will be discussed here further, is using the characteristics of the DDP. That pump can also be seen as an enhancement of the just described displacement-controlled principle through combining multiple smaller pump units in one housing. The system impact of an installation with these pumps is explained in **Figure 6**, where a classical architecture ("Baseline") on the left is compared with a DDP-architecture on the right ("System Architecture 2").

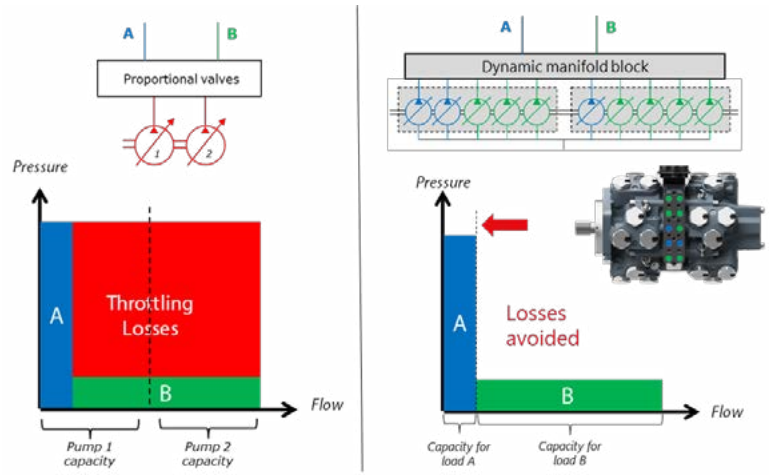

Figure 6: Results of the losses comparison S90 vs H1F-motor in two operation conditions

The baseline system consists of two pumps, delivering flow into a valve block out of which two consumers A and B are supported. The System Architecture 2 uses the double DDP pump with 10 pump units and a dynamic manifold block, out of which the same two consumers A and B are supported. For both systems, the flow and pressure demand is the same, consumer A demands a small flow at a high pressure and B demands a high flow at low pressure. In the classical system, as the flow demand of B is bigger than what only one pump can deliver, both pumps need to be combined and thus run also on the same pressure level – defined by the higher pressure demand from A. For B, the higher pressure needs to be throttled away by the valve block, resulting in the losses indicated by the red area in Figure 6. In the DDP system, with the dynamic manifold, two pistons (blue) will be combined to support the demands of A, the remaining 8 piston suffice the flow demand of B. As the pistons run pressure independently, the throttling losses of the classic system design will be avoided. To

estimate and measure the impact of System Architecture 2, [9] has made simulations and tests with an excavator. The outcome is – in short:

- The simulation of a digging cycle delivered that for a classical unchanged **baseline version** of an excavator a typical average **57*kW*** is transmitted from the engine into the hydraulic system (at engine/pump interface).
- The excavator with the **DDP** architecture consumes in same digging cycle **42,3 *kW*** at that pump/engine interface. That is 26% less than the baseline and is composed of a pump loss reduction of 4,4 *kW* (-60%) and 10,5 *kW* in the main control valve (-45%).
- **Measurements** show a realistic fuel consumption reduction of around **25 – 30%** in typical digging cycles. That validates the simulation results well and took also some further reduction potential into account that, due to lower loads, the engine runs in different, more efficient operation conditions.

The fuel saving potential equates roughly with the CO_2-emission reductions, but the detailed impact will be discussed in the next chapter, where also the decarbonization potential of an electrified system will be discussed.

5. DECARBONIZATION POTENTIAL OF E-POWERED MACHINES

Following the system comparison, where "Baseline" is the unmodified standard system of an excavator und "System Architecture 2" in the modified system with a DDP, the next step in analyzing the decarbonization potential is to compare different prime energy sources and their carbon emissions. The natural comparison is a diesel engine to electrification.

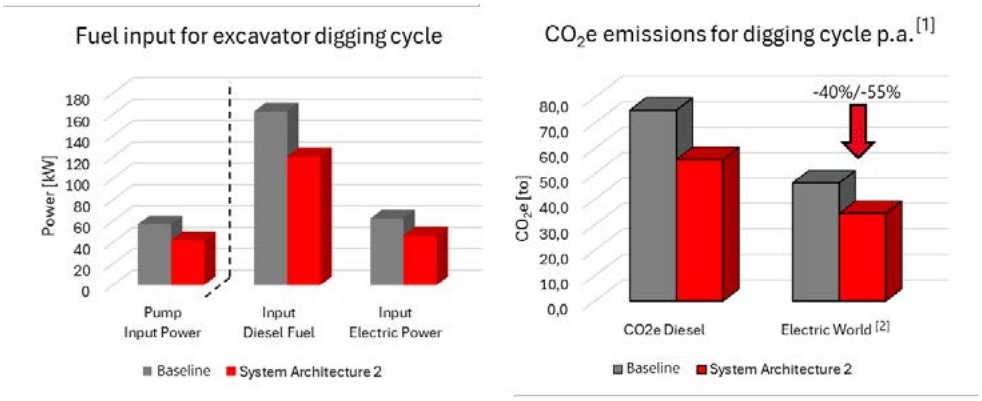

Figure 7: Comparing CO_2 emissions of diesel and electric systems in the excavator [1],[2]

Although there are other fuels available for reducing the CO_2-footprint like HVO, LPG or H_2, the most common alternatives are still diesel and electrification with batteries. Thus, for the above-mentioned excavator, the difference between these both will be further analyzed.

[1] Digging cycle per year based on an 8hrs shift and 220 workdays digging
[2] Source of grid emission factors (world/regions): 2024 IEA data

Figure 7 introduces the results of the comparison: Starting on the far-left side with the power at the engine/pump interface, 57 *kW* for the baseline and 42,3 *kW* for the modified system. To be able to realize a CO_2-comparison, the total fuel/electricity consumption needs to be estimated, which is also shown in the left diagram from Figure 7:

- **Diesel:** 163 *kW*/121 *kW* fuel power for Baseline/System Architecture 2 with 215 $^{g}/_{kWh}$ specific fuel consumption or 35% engine efficiency in the digging cycle. Based on this power consumption, System Architecture 2 could save up to 110 *to* CO_2e on a 10.000 *h* machine life.
- **Electric:** 63 *kW*/46 *kW* with using a Danfoss Editron PMI motor with an average 93% and Editron Inverter with an average 98% efficiency during the same cycle (no battery loading/unloading considered here to incorporate cable-powered machines, too)

The highest prime energy and emissions saving can be obtained if the DDP-system is combined with an electric system. The decarbonization potential of electrified systems significantly depends on the electric power generation. The right diagram of Figure 7 depicts that for a diesel engine 75 *to*/56 *to* CO_2e are emitted in a year's time, based on this digging cycle, versus 46 *to*/34 *to* CO_2e for the Baseline and DDP-system with electricity as prime energy – and the CO_2e calculation based on the IEA world grid factors [10]. While the power saving in an electrified System Architecture 2 is approx. $^{2}/_{3}$ over the diesel-driven baseline, the CO_2e emissions are only 55% lower – explained through the power mix in the world grid factors, as that also factors power generation with coal and gas into account. Still, this equates to a machine lifetime saving of around 230 *to* CO_2e in this use case.

The impact of the regional power generation and their CO_2e-factors is shown in **Figure 8**, only for System Architecture 2 (DDP-system).

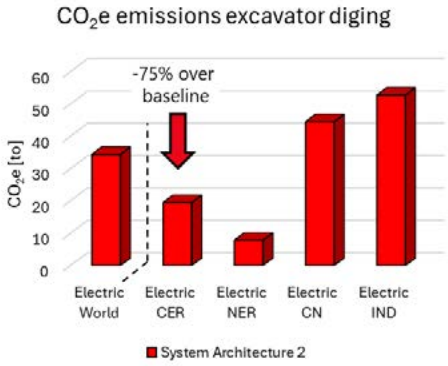

Figure 8: Regional power generation impact of CO_2 emissions

With the world grid emissions equivalent on the far-left side, the other bars in Figure 8 show big the power generation impact is. While in the Northern-European regions NER the renewables in the power generation dominate and thus the CO_2-emissions for the excavator with System Architecture 2 are very small, lower than 10 *to/year*, the same excavator with the same operation cycle would create only 20% less emissions than with a diesel engine in China and nearly the same emissions as a diesel excavator if used in India, as shown in

Figure 7 right part (all with System Architecture 2). This comparison shows that especially in electrification, which is often considered as zero emissions, the emissions during production do have a significant impact on the total emissions of a mobile machine in the use phase. A possibility to capture the information where the machines are used and store for further analyses might be using the emission and energy-reporting functionalities of an Asset Administration Shell, like developed in the Fluid 4.0 project [1].

6. SUMMARY AND CONCLUSIONS

In this paper, several steps towards decarbonization were discussed and presented, in ascending order of the impact. The smallest impact is achieved if only components of a system will be exchanged to higher efficient components. The example of swapping the S90 fixed swashplate motor to the new H1F bent axis fixed motor delivered in the given application a considerable positive potential of saving up to 10% of CO_2e over the machine lifetime. The next solution discussed is optimizing the system. In the given example, the DDP was the key element. It can contribute with its differentiating characteristics on the one side to a different engine control algorithm, allowing to optimize the engine operation points – accounting up to 25% CO_2e saving potential – and on top of that, on the other side, it allows a redesign in the hydraulic system which especially pays off in valve-based work function systems by reducing throttling losses. This would account for an additional efficiency increase in best case up to 30% in a typical excavator system.

If, in a possible last step, the diesel engine will be replaced by a battery-electric system, the impact is potentially even higher as electric systems have in a broad cycle average 90% efficiency to convert the electric energy into mechanical energy, where the engine efficiency is around 40% – only in its best point and in part-load conditions significantly worse. Nonetheless, an additional factor to determine the CO_2-footprint impact is how the electricity used is generated. In a worst-case scenario, like in India (according to the IEA), the energy mix eliminates the efficiency advantages of the electrification and creates a wash on CO_2-emission level, in a best-case scenario when the machine is used in the Northern European Region NER, the decarbonization potential is up to 90% compared to a diesel engine.

A step in between, not requiring changing the machine architecture as drastic as going to a battery-electric machine, would be the use of alternative fuels. A fuel which recently gains attention is HVO, Hydrotreated Vegetable Oil. It has the potential to reduce CO_2e emissions by up to 90% and has a high engine compatibility, but the availability in bigger masses is currently still a challenge, in addition to a higher price challenging TCO. Furthermore, LPG and CNG are also alternatives with lower CO_2e-emissions, but their advantage is compensated by the lesser efficiency of the gas engines and thus equates in a wash on emissions-level. Hydrogen/H_2 is also an emerging alternative, whereof the machine design for storage and depending on the technology used (combustion engine or fuel cell) is also subjected to a radical redesign in its architecture.

Closing the loop to the motivation of machine decarbonization, depending on the goal and the requirements a machine manufacturer wants to fulfill, several steps and their impact have been highlighted in this paper. It can be used as a guide determining what to do to achieve a certain level of decarbonization. Component swap could be sufficient for lower

decarbonization goals or gearing up to electrification to make the vehicle locally emission free, where required. The in Fluid 4.0 developed toolchain [2] for the Asset Administration Shells could be a tool to track the machine's emissions during their use-phase to gain further information about real-time and real-life decarbonization effects.

Danfoss Power Solutions offers products and solutions to accompany mobile machine manufacturers on their decarbonization journey in all steps towards reaching their goals, from application knowledge, components and systems as well as software solutions for classical hydraulic as well as electric machines. Simulative and test-based decarbonization estimation is part of the support, to make future machines ready for a sustainable future and a world worth living in it.

Abstract.

Climate change, increasing regulation, and heightened customer demand require transparent emissions calculations and sustainable product development. Currently, no standardized procedure to quantify use-phase greenhouse gas emissions of hydraulic components exists. On machine level emissions can be measured at the tailpipe or calculated, but the link to components is missing. This paper addresses this gap by developing and validating a methodology as baseline for further standardization. Using a wheel loader as a reference, two allocation approaches are derived for a hydraulic pump in a travel drive: First an approach based on the component's energy loss and second an extended approach that additionally accounts for primary energy supply efficiency. Meaningful comparisons across energy carriers such as diesel and electricity require qualitative emission results from machine level being reflected on component level. The proposed methodology provides, to the authors knowledge for the first time, such a framework for calculating use-phase greenhouse gas (GHG) emissions of hydraulic components. Further, it establishes the methodological foundation for assessing the impact energy carriers on component emissions and supports sustainability-oriented design decisions in fluid power systems. This work thus contributes to the creation of a standardized emissions assessment method that allows companies to promote sustainable products and differentiate themselves in the market through reduced energy losses and thus lower emissions.

Keywords. greenhouse gas emissions, use phase, hydraulic components, product carbon footprint, non-road mobile machinery, mobile working machines.

1. INTRODUCTION

Hydraulic machinery, including non-road mobile machinery (NRMM), is estimated to contribute nearly four percent to global greenhouse gas (GHG) emissions [1], thereby significantly influencing climate change. In response to increasingly stricter regulatory frameworks – such as the EU Green Deal [2] – industrial stakeholders are under growing pressure to implement credible emission reduction strategies. Compliance with these

All Open Access articles are peer-reviewed, distributed under the Creative Commons Attribution-Non Commercial 4.0 International

requirements is not only a legal obligation but also gaining economic importance, as companies seek to avoid penalties and strengthen their market competitiveness. Consequently, many companies are establishing strategic sustainability targets that rely on robust and comparable metrics, particularly for GHG emissions. Customers and investors are also increasingly demanding such transparency, making these metrics a key differentiator.

The concept of a "footprint" as a quantified measure of the ecological impact of human activities has gained significant traction across society. Given the urgent need for climate action, the quantification of GHG emissions has become highly relevant. The Product Carbon Footprint (PCF) refers to the total GHG emissions associated with a product across its entire life cycle, expressed in carbon dioxide equivalents (CO_2e). This measure encompasses all greenhouse gases, not only carbon dioxide. [3]

Several frameworks exist for calculating GHG emissions, including the Greenhouse Gas Protocol (GHG Protocol), DIN EN ISO 14067, and the Product Environmental Footprint (PEF). These frameworks offer standardized guidance for companies to systematically assess, quantify, and reduce GHG emissions [4], [5], [6]. However, while they provide general methodological scaffolding, they leave room for interpretation. To increase comparability and specificity, Product Category Rules (PCRs) have emerged [7]. These are often initiated by industry consortia to define more granular rules for specific product groups. Furthermore, more specific standards like DIN EN ISO 14083 (ISO 14083) can arise. This specific one focusses on emission accounting for supply chains [8]. Currently, no PCRs or specific standards exist for either NRMM or hydraulic components to the authors knowledge. Some companies have disclosed internal procedures for PCF calculation, yet these remain proprietary and are not standardized. The existing more specific standards are mainly used by companies for calculating cradle-to-gate GHG emissions and do not offer companies enough guidance to calculate use-phase emissions.

The present work addresses this gap by developing a methodology as baseline for further standardization in calculating use-phase GHG emissions of hydraulic components in NRMM, while accordance with existing standards is not the focus. The goal is to provide a methodology that enables companies to transparently assess and reduce these emissions of individual hydraulic components including comparison of application in NRMM using different energy carriers. Firstly, section 2 introduces a representative reference machine. Based on this, a method for calculating use-phase GHG emissions at machine level is illustrated. In the end of section 2 the research question is derived describing the challenge of emissions attribution to component level, especially with different energy carriers. In section 3 a methodological approach based on component's energy losses for assigning use-phase GHG emissions is developed, validated and discussed for an exemplary hydraulic component. In section 4 this approach is extended to include the primary energy supply to achieve consistent results between component and machine level emission calculations with different energy carriers.

2. GHG EMISSIONS OF REFERENCE WHEEL LOADER

2.1. Definition of the Reference Wheel Loader

To understand the relevant interdependencies and to ensure comparable emissions results, it is essential to first define system boundaries. A wheel loader serves as the reference machine in this study. Using a system perspective similar to [9], the wheel loader as a machine can

be structured into systems such as the primary energy supply, travel and implement drives, and auxiliary systems, shown in Figure 1.

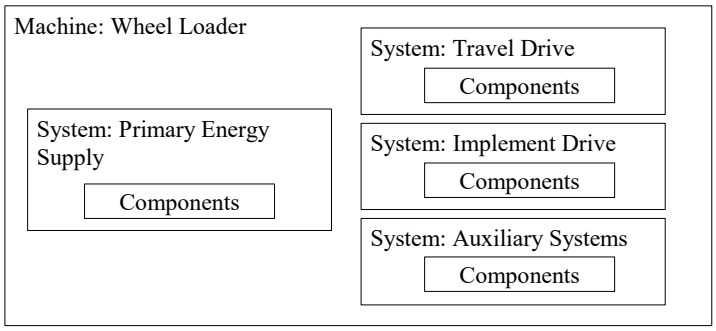

Figure 1: Structuring of wheel loader (based on [9])

The primary energy supply can be realized with various energy carriers, including diesel fuel, electrical energy, or hydrogen [9]. In this study, two configurations are examined:

- A diesel-powered wheel loader.
- A battery-powered wheel loader.

For the diesel variant, the primary energy supply consists of a fuel tank and an internal combustion engine on component level. In contrast, the electric version replaces these components with a battery, an inverter, and an electric motor. Other topologies for electric powertrains are not considered here to maintain conceptual clarity.

This study focuses on component level analysis of an axial piston unit (swashplate type) as pump within the hydrostatic travel drive system (closed circuit). The internal charge pump is excluded from the analysis for simplification. It is further assumed that the operating points of the hydraulic pump remain identical across both energy configurations.

2.2. GHG Emissions Calculation of Wheel Loader

Initially, the reference machine is analysed in both energy configurations. The methodology for calculating use-phase GHG emissions of the reference machine is based on established frameworks and industry practices in automotive and construction equipment sectors like [10].

The cited share of around 4 % of global GHG emissions coming from hydraulic machinery refers to emissions from diesel combustion [1]. These emissions can be measured at the tailpipe, but with the large variety of possible configurations of NRMM, this would lead to high measuring efforts being time- and cost-intensive. As an alternative, the GHG Protocol recommends calculating emissions via Activity Data and Emission Factors, as illustrated in Equation 2.1.

$$\text{GHG Emissions} = \text{Activity Data} \times \text{Emission Factor} \tag{2.1}$$

Activity Data quantify the extent of a process that emits GHG emissions (e.g. energy consumed). An Emission Factor denotes the GHG emissions per unit of activity, expressed in CO_2e. The chemical energy of combusted diesel fuel over an assumed reference lifetime represents the Activity Data of the diesel machine. Since measurement data of the amount

of fuel combusted are available from the diesel-powered wheel loader, it serves as the base case. From this, Activity Data for the electric variant are derived.

A usage profile was needed to obtain this measurement data. Unlike passenger cars, where standardized drive cycles like Worldwide Harmonized Light Vehicle Test Procedure (WLTP) exist, no standardized usage profiles are available for NRMM like wheel loaders [11]. Hence, a representative usage profile was used consisting of working and driving tasks as well as idling. Such a usage profile consists of typical cycles and their time shares within the overall operating period. This work provides no further details concerning the used cycles since they are subject to many parameters and therefore very individual.

During test drives with the wheel loader, the fuel consumption for each cycle was measured. Average values were calculated per cycle and weighted according to their time shares. Concluding, the average fuel consumption for the assumed usage profile of the wheel loader is 7.7 $\mathrm{l/h}$. With a density of 0.743 $\mathrm{kg/l}$ and a lower heating value of 42.5 $\mathrm{MJ/kg}$, according to [16], and an assumed reference lifetime of 10.000 h equates to 675.42 MWh, equaling the Activity Data of the diesel configuration ($\mathrm{E_{In,Diesel}}$).

A diesel engine efficiency of 40 % is assumed similar to [12] and [13]. In the electric configuration, the efficiency of battery, inverter, and electric motor is assumed to be 81 %. To provide the same useful energy, only around 49 % of the diesel input energy is required electrically equating to 330.96 MWh as Activity Data of the electric configuration ($\mathrm{E_{In,Electric}}$).

An **Emission Factor** is now needed to translate Activity Data into GHG emissions. If only tailpipe emissions were considered, the electric loader would appear emission-free. However, GHG emissions are also generated during electricity generation and supply. Hence, system boundaries must be distinguished [14]. For instance, [14] uses well-to-tank and tank-to-wheel which are also used by companies like Volvo Construction Equipment in their emission reporting [10]. ISO 14083 introduces the terms energy provision and operation for these boundaries [8]. ISO 14083 aims to define guidelines for quantifying GHG emissions from passenger and freight transport chains. The term GHG emissions from energy provision refers to the release of greenhouse gases during the production, storage, processing, and distribution of energy carriers for use in transport chains. GHG emissions from operation, on the other hand, refer to the release of greenhouse gases due to the operation of vehicles or locations. This enables ISO 14083 to also make statements about locations in logistics where the term tank-to-wheel would be inappropriate. At the same time, energy supply can serve as a direct substitute for well-to-tank and operation for tank-to-wheel in vehicles, which is why the terms used in ISO 14083 are used for this work. [15]

- Energy provision (well-to-tank) and
- Vehicle operation (tank-to-wheel).

The total use-phase GHG emissions for the diesel configuration ($\mathrm{GHG_{Machine,Diesel}}$) are calculated as:

$$\mathrm{GHG_{Machine,Diesel}} = \mathrm{E_{In,Diesel}} \times \left(\mathrm{EF_{Operation,Diesel}} + \mathrm{EF_{Provision,Diesel}}\right) \quad (2.2)$$

For diesel, Emission Factors from [16] are used within the framework of ISO 14083, which are also used here. According to [16], the Emission Factor for diesel combustion ($\mathrm{EF_{Operation,Diesel}}$) is 0.271 kg $\mathrm{CO_2e/kWh}$. An additional 0.081 kg $\mathrm{CO_2e/kWh}$ is released

during diesel supply chain processes ($EF_{Provision,Diesel}$). According to these Emission Factors, total use-phase GHG emissions from the diesel-powered wheel loader are

- 77 % from operation, and
- 23 % from energy provision.

With Equation 2.2 $GHG_{Machine,Diesel}$ calculates to 237.75 t CO_2e with the earlier calculated Activity Data and introduced Emission Factors, being the total of the left bar in Figure 2.

For the electric variant GHG emissions ($GHG_{Machine,Electric}$) are calculated as:

$$GHG_{Machine,Electric} = E_{In,Electric} \times EF_{Provision,Electric} \quad (2.3)$$

Since no emissions occur during operation, only the energy provision is relevant. The Emission Factor for energy provision ($EF_{Provision,Electric}$) in the German electricity mix is both region- and time-dependent. [16] provides a value for energy supply in the German electricity mix for 2022. The values change every year by a significant amount [17]. In this work, the 2024 factor published by the German Environment Agency (UBA) of 0.427 kg CO_2e/kWh is used [17]. This factor includes all processes mentioned earlier for energy provision. Not taking all the provision processes into account is one reason why varying factors may arise. Since the efficiency of the electric drivetrain is assumed with 81 % instead of the 40 % of the diesel drivetrain and with the different Emission Factors, $GHG_{Machine,Electric}$ equates to 141.32 t CO_2e. This results in total use-phase GHG emissions of the electric wheel loader being approximately 59 % of the diesel variant, a 41 % reduction in use-phase emissions, as shown in Figure 2.

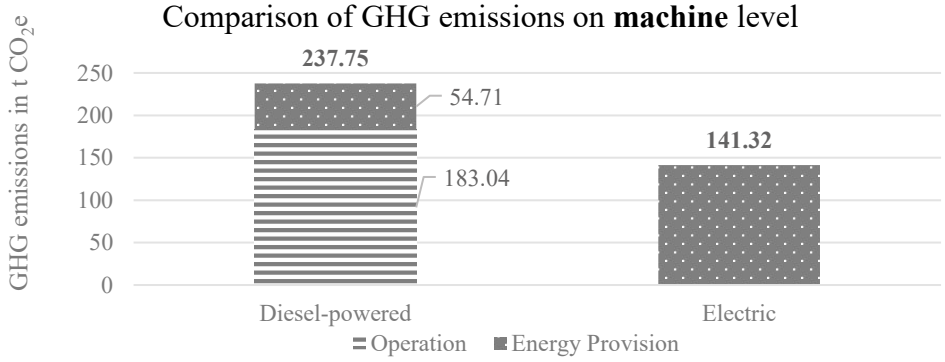

Figure 2: Comparison of wheel loader's use-phase GHG emissions for operation and energy provision with different energy carriers

Emissions from operation are depicted striped in white and grey and energy supply emissions are white dotted on grey background. While the electric loader produces no operational GHG emissions, the energy provision emissions are higher than those of diesel. Nonetheless, the overall emissions are significantly lower in the electric configuration under the given assumptions.

2.3. Research Questions

However, the presented approach offers no resolution at system or component level. While methods for assessing emissions from hydraulic components during production stages exist,

a methodology for evaluating their use-phase emissions remains absent to the authors knowledge. Even though the emissions of the use-phase on machine level are dominant, especially for diesel-powered machines [18]. Given that GHG emissions of hydraulic components cannot be measured, it remains uncertain how their use phase emissions can be quantified. However, for regulatory and customer requirements, companies must be able to disclose and ultimately reduce these emissions transparently.

As used for the machine level approach shown previously, this paper investigates how a component level approach can also rely on Activity Data and Emission Factors. As alternative energy carriers like electricity rise in importance, e. g. [12] [19], a key requirement is that qualitative emission trends at the component level must be consistent with those at machine level, when comparing different energy carriers. In order to attribute use-phase GHG emissions to hydraulic components the following research question must be answered:

How can use-phase GHG emissions of hydraulic components be determined, while allowing consistent comparisons across different energy carriers?

In the following, approaches to answer this question are developed, validated and discussed by focusing on the hydraulic pump of the travel drive of the wheel loader in two different energy carrier configurations.

3. FIRST APPROACH

3.1. Methodology

In the first step, the diesel-powered wheel loader is taken as a reference. Firstly, only GHG emitted during machine operation are considered. The activity that causes these emissions is characterized by energy flow, as illustrated in Figure 3.

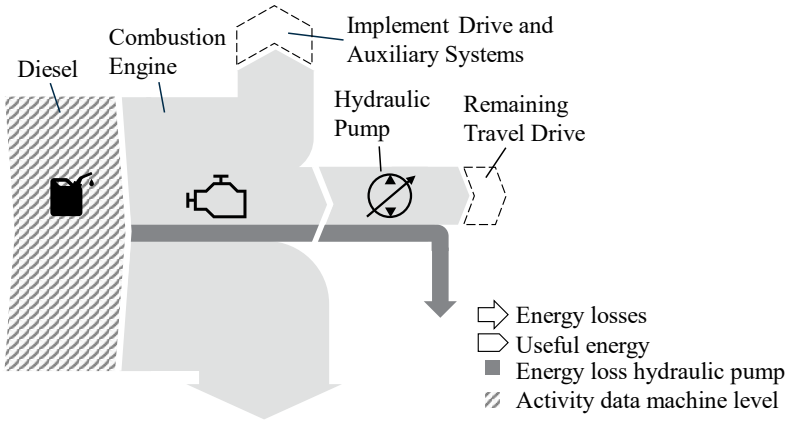

Figure 3: Sankey diagram of diesel-powered wheel loader

In this configuration, diesel serves as input energy. Through combustion in the internal combustion engine, chemical energy is partially converted into mechanical energy, while the remaining portion dissipates, indicated by the light grey arrow pointing downwards. The mechanical energy is distributed among the implement drive and auxiliary systems (indicated by the upward pointing arrow) as well as the travel drive (indicated by the arrow

pointing right), which includes the here focussed hydraulic pump. The pump transforms mechanical energy into hydraulic energy, whereby hydromechanical and volumetric losses occur [20], which are summarized as dark grey arrow.

The combustion results in GHG emissions, which are measurable at the tailpipe. As diesel is both an energy carrier and a source of emissions, the chemical energy supplied to the machine is directly proportional to the resulting GHG emissions. Accordingly, the supplied chemical energy (E_{In}) represents the Activity Data on machine level, depicted with a grey hatch, for use-phase emissions, as used in Equation 2.2.

The engine supplies this energy to downstream systems and components, which in turn dissipate part of it and pass the remainder along. The sum of energy loss from each component ($E_{Loss,Component}$) and the useful energy output, for working or driving tasks, (E_{Task}) equals the input energy:

$$E_{In} = \sum E_{Loss,Component} + E_{Task} \tag{3.1}$$

With Equation 2.2 this leads to Equation 3.2 with EF representing Emission Factors for energy provision and operation.

$$GHG_{Machine} = \left(\sum E_{Loss,Component} + E_{Task}\right) \times EF \tag{3.2}$$

Even though emissions are not directly measurable at a component, its energy demand has a causal influence on total emissions. Each component's energy loss contributes to the overall demand for energy supply, thereby to the amount of diesel burned in the combustion engine finally resulting in GHG emissions. This contribution is shown in Figure with the dark grey arrow being part of the grey hatched input energy. The component's contribution can be represented by a ratio of the component's energy loss to the machine's energy input. The first approach uses the same ratio for the component's contribution to machine level GHG emissions leading to:

$$\frac{E_{Loss,Component}}{E_{In}} = \frac{GHG_{Component}}{GHG_{Machine}} \tag{3.3}$$

Hence the machine's energy input is used as Activity Data for machine level emissions calculation, in this first approach the energy loss of a component is taken as its Activity Data for calculating its use-phase GHG emissions ($GHG_{Component}$), as shown in the following expression:

$$GHG_{Component} = E_{Loss,Component} \times EF \tag{3.4}$$

Therefore, the dark grey arrow in Figure depicts the Activity Data of the hydraulic pump.

This aligns conceptually with the delta approach described in the Product Environmental Footprint (PEF): Additional consumption compared to a reference is assigned to a product. Here, the losses represent the deviation from an ideal, loss-free component. An alternative would be to consider the total energy throughput of a component. However, this would include energy that is passed on to downstream components, leading to double-counting in the GHG balance of the machine. The sum of component emissions would then exceed the measurable tailpipe emissions of the machine. Therefore, the use of loss energy is preferable for accurate allocation.

The useful energy ultimately delivered by the machine (E_{Task}) also represents Activity Data and can be used to assign the remaining GHG emissions to the task (GHG_{Task}) like driving or working:

$$GHG_{Task} = E_{Task} \times EF \tag{3.5}$$

This approach pushes the idea to not only optimize components, rather holistically including the machine's task. The total machine emissions ($GHG_{Machine}$) can thus be partitioned into task and component emissions:

$$GHG_{Machine} = GHG_{Task} + \sum GHG_{Component} \tag{3.6}$$

Consequently, this enables a causal allocation of GHG emissions to components (e. g. the hydraulic pump) and functional processes (e. g. driving or working tasks).

In the second step, the same approach is applied to the electric variant of the reference vehicle. Importantly, the hydraulic pump's operating points are assumed to remain unchanged across both drivetrain configurations. Therefore, the energy loss (and thus the Activity Data) of the hydraulic pump is considered identical in both systems (see dark grey arrow in Figure).

However, just as with machine level, the electric system emits no operational GHG emissions, which could be measured like tailpipe emissions, the only relevant emissions stem from the provision of electricity. Accordingly, no emissions from operation could be assigned to a component and therefore only the Emission Factor for energy provision applies, just as on machine level.

Finally, the proposed answer by the first approach to the research question is Equation 3.4:

The GHG emissions of a component can be calculated by multiplying the average loss energy of the component over a usage profile for a reference lifetime as Activity Data with the respective Emission Factor for operation and energy provision for the energy carrier.

3.2. Validation

During test drives with the diesel-powered wheel loader, pressure, swivel angle, and shaft speed of the hydraulic pump were recorded across work cycles from the same usage profile as defined earlier. Using the pump's characteristic maps, volumetric and hydromechanical losses were determined. Losses from the integrated charge pump are disregarded. The power loss is integrated over each cycle and divided by the duration of the cycle to calculate the pump's mean power loss during the respective cycle. For each cycle in the usage profile this is then weighted by its time share to obtain the mean power loss for the specific usage profile. Multiplied by the assumed reference lifetime of 10.000 h, this yields for this specific example a total energy loss of 27.1 MWh ($E_{Loss,Pump}$) which is according to the first approach equivalent to the Activity Data of the pump.

Special consideration is required for overrun (regenerative) operation, e. g. during coasting. In such cases, no diesel is injected [21], hence no GHG emissions occur, although energy is dissipated. Concluding, only load operation is relevant for accounting emissions. To exclude this, fuel flow measurements are used to identify periods with 0 l/h diesel consumption, which indicate coasting. Only the losses during load operation are included in the Activity Data.

The same Activity Data are applied for both the diesel and electric configurations, as operating points of the hydraulic pump are assumed identical. Use-phase GHG emissions of the pump are then calculated for the diesel-powered wheel loader by values from Table 1 in Equation 3.7.

$$\mathrm{GHG}_{\mathrm{Pump,Diesel}} = \mathrm{E}_{\mathrm{Loss,Pump}} \times \left(\mathrm{EF}_{\mathrm{Operation,Diesel}} + \mathrm{EF}_{\mathrm{Provision,Diesel}}\right) \quad (3.7)$$

Table 1: Values for parameters in Equation 3.7

$\mathbf{E_{Loss,Pump}}$	$\mathbf{EF_{Operation,Diesel}}$	$\mathbf{EF_{Provision,Diesel}}$
27.1 MWh	0.271 kg CO_2e/kWh [16]	0.081 kg CO_2e/kWh [16]

For calculating use-phase GHG emissions of the hydraulic pump in the electric wheel loader Equation 3.8 is used with values from Table 2.

$$\mathrm{GHG}_{\mathrm{Pump,Electric}} = \mathrm{E}_{\mathrm{Loss,Pump}} \times \mathrm{EF}_{\mathrm{Provision,Electric}} \quad (3.8)$$

Table 2: Values for parameters in Equation 3.8

$\mathbf{E_{Loss,Pump}}$	$\mathbf{EF_{Provision,Electric}}$
27.1 MWh	0.427 kg CO_2e/kWh [17]

Figure depicts the resulting GHG emissions assigned to the hydraulic pump in each configuration.

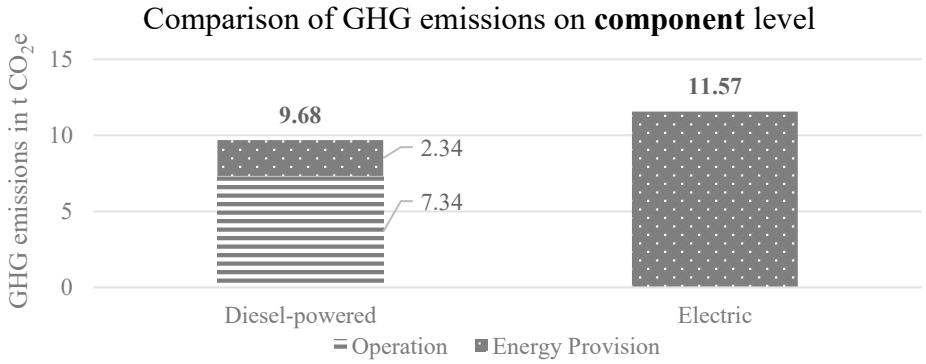

Figure 4: Comparison of hydraulic pump's use-phase GHG emissions for operation and energy provision with different energy carriers

Both bars show the GHG emissions assigned to the hydraulic pump. The left bar shows the hydraulic pump's emissions in the diesel-powered wheel loader, grey-white striped for operation and white dotted on grey background for energy provision. The right bar shows only emissions assigned to the hydraulic pump during energy provision, as no operation emissions occur in the electric wheel loader which could be allocated. However, the total use-phase emissions assigned to the hydraulic pump in the electric wheel loader are higher.

3.3. Discussion and Conclusion

The result contradicts the machine level finding that the electric variant emits fewer use-phase GHGs. To analyse this discrepancy, the ratio of GHG emissions from Equations 3.7 and 3.8 is formed:

$$\frac{\mathrm{GHG_{Electric}}}{\mathrm{GHG_{Diesel}}} = \underbrace{\frac{\mathrm{Activity\ Data_{Electric}}}{\mathrm{Activity\ Data_{Diesel}}}}_{\text{Ratio of Activity Data}} \times \underbrace{\frac{\mathrm{EF_{Provision.Electric}}}{\mathrm{EF_{Operation,Diesel}} + \mathrm{EF_{Provision,Diesel}}}}_{\text{Ratio of Emission Factors}} \tag{3.9}$$

This concludes that, independently of machine or component level, the ratio of GHG emissions from different energy carriers is equal to the ratio of Activity Data and the ratio of Emission Factors.

At machine level, as found in section 2.2, the electric variant requires 49 % less input energy, equalling a ratio of Activity Data between diesel and electric of 0.49. Though the ratio of Emission Factors, with values previously used, concludes that electricity has a 21 % higher total Emission Factor. Consequently, for the electric drivetrain in comparison to the diesel-powered less energy is required in total, but per unit of energy provided more GHG emissions are emitted. However, the higher efficiency outweighs the worse Emission Factor, leading to a 41 % reduction in total use-phase GHG emissions.

At component level, the Activity Data are assumed identical for both configurations. The ratio of Emission Factors still differs. Therefore, the ratio of Activity Data is not able to outweigh the ratio of Emission Factors like it did on machine level. This leads to higher assigned emissions for the hydraulic pump in the electric wheel loader, despite the machine emitting less overall. This inconsistency arises because the share of the hydraulic pump's energy loss relative to the machines total input energy ($\mathrm{E_{Loss,Component}}/\mathrm{E_{In}}$) increases due to higher primary energy supply efficiency and therefore less input energy needed:

- In diesel-powered wheel loader: 4 % of total input energy
- In electric wheel loader: 8.2 % of total input energy

Not only the share of the hydraulic pump's energy loss relative to the machines total input energy increases but according to Equation 3.3 a larger fraction of the machine's emissions is allocated to the hydraulic pump in the electric case. This leads to higher absolute component's emissions, despite the absolute machine's emissions being lower. The total GHG emissions of the component appear to grow solely because of being accounted for a larger fraction of the machine's emissions.

This reveals a key weakness of the first approach: It does not maintain proportional consistency across energy carriers. While suitable for comparing different components with everything else staying the same, therefore changing only Activity Data due to efficiency differences of the components, it leads to qualitatively misleading results when introducing other changes like comparing across energy carriers.

The first approach offers an answer to the research question and enables to allocate use-phase GHG emissions to a hydraulic component with minimalistic data input. As soon as more than one energy carrier is of relevance, it fails since misleading conclusions concerning impacts of different energy carriers can be made on component level. A second approach is required to resolve this issue and ensure component level emission assessments align with machine level trends, also with different energy carriers.

4. SECOND APPROACH

4.1. Methodology

In the first approach, the ratio of Activity Data between the two energy carriers remained constant, while only the ratio of Emission Factors changed. This simplification neglects a crucial interdependency: a change in energy carriers and Emission Factors inherently implies a change in the primary energy supply, which in turn alters the overall system efficiency and thus the machine's total energy input. By keeping the component's Activity Data constant between energy carriers, these upstream effects were not reflected. Consequently, the resulting component emissions did not scale consistently with the machine level emissions when switching energy carriers. Since components do not emit measurable GHGs themselves, their calculated GHG impact is always linked to the chosen energy carrier via the Emission Factor. When comparing different energy carriers, not only the Emission Factor but also the primary energy supply system changes. The first approach captured only the former, dismissing the latter. This led to only comparing Emission Factors when comparing component's emissions. Therefore, in the second approach, the Activity Data are extended to incorporate the influence of the primary energy supply efficiency.

While it would be most straightforward to base energy carrier comparisons directly on machine level energy inputs, this is often not feasible in practice. Component manufacturers typically lack access to complete machine level energy data and instead only possess information about the operating points and energy losses of their components. Furthermore, a methodology relying solely on machine level data would not support the practical need for component-specific GHG reporting. Therefore, the proposed method focuses on extending component level data in a way that remains applicable even without full system information.

Energy flows in the machine for each energy carrier configuration are shown in Figure .

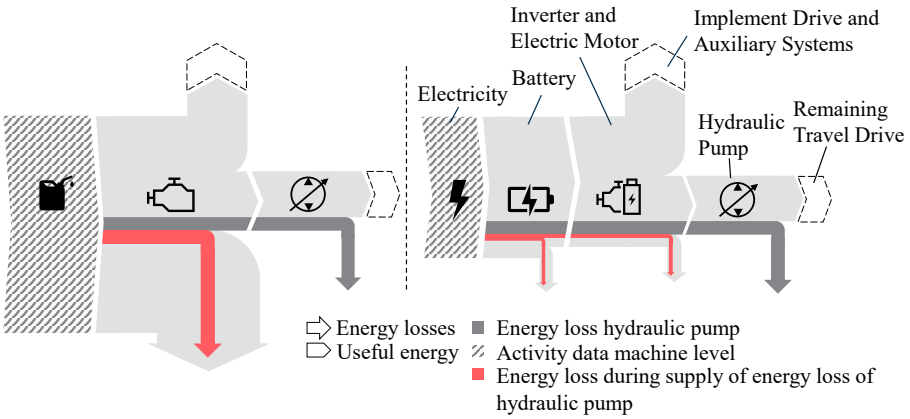

Figure 5: Sankey diagrams for electric and diesel-powered wheel loader

The dark grey arrow represents the hydraulic pump's energy losses, as used in the first approach. The first approach failed to account for the different efficiencies of the primary energy supply, leading to inconsistent results when comparing diesel and electric configurations. In the second approach, the Activity Data are therefore extended to include the energy required to supply the pump's losses, represented by the red arrows. These arrows

indicate the additional energy that must be provided – depending on the primary energy supply's efficiency – to compensate for the component's energy losses.

The adjusted Activity Data for the hydraulic pump are calculated by expanding the measured loss energy by the inverse of the primary energy supply efficiency ($\eta_{\text{PrimaryEnergySupply}}$), as expressed in Equation 4.1:

$$\text{Activity Data}_{\text{Component}} = \frac{E_{\text{Loss,Component}}}{\eta_{\text{PrimaryEnergySupply}}} \tag{4.1}$$

By incorporating these upstream losses, the Activity Data now reflect the full energetic impact of the component within its respective drivetrain, now including the 40 % efficiency of the diesel engine versus 81 % for the electric drivetrain.

The second approach extends the Activity Data in comparison to the answer of the first approach to the research question as follows:

Activity Data for components must include not only the energy losses occurring at the component itself, but additionally the energy losses at the primary energy supply when supplying these losses. To translate Activity Data into use-phase GHG emissions Emission Factors for energy provision and operation must be used.

4.2. Validation

In the following the same assumptions for efficiencies of the primary energy supply system are used as before. Component's Activity Data are now expanded according to Equation 4.1. This leads to 67.75 MWh as Activity Data in the diesel configuration and 33.46 MWh in the electric configuration. As a result, the ratio of Activity Data in Equation 3.9 on component level between the two energy carriers is 0.49, matching the ratio used at the machine level. The share of the pump's Activity Data relative to the machine's total energy input (Activity Data on machine level) becomes identical across energy carriers: 10 % for both configurations. The resulting emissions are calculated as in the first approach with the same emission factors but with the adjusted Activity Data and are shown in the center bar chart of Figure 6. Consequently, with Equation 3.3 the emission share attributed to the hydraulic pump aligns proportionally with the overall emissions of the reference machine. This resolves the mismatch observed in the first approach.

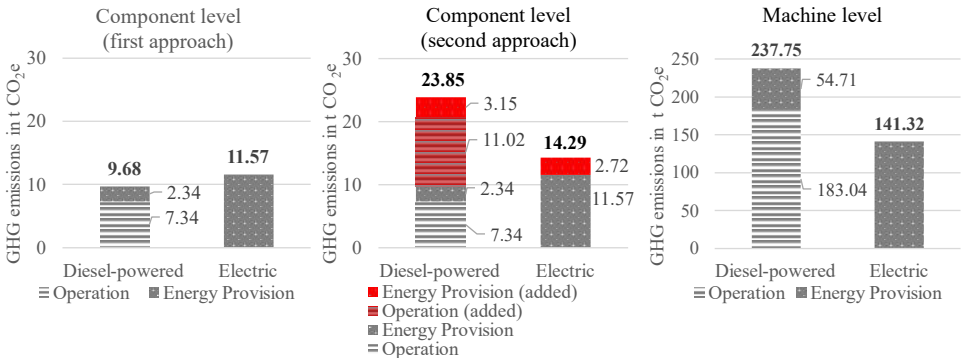

Figure 6: Comparison of use-phase GHG emissions of different approaches on component level and machine level

In Figure 6, the left bar chart shows the result of the first approach on component level for comparison. The center bar chart shows the result of the second approach on component level. The red-hatched section equals emissions linked to the red arrows in Figure 5. The red arrows represent additional energy from losses in the primary energy supply to supply the pump's energy losses, which are now included in the Activity Data of the hydraulic pump. The right bar chart depicts the total emissions of the machine as shown before in Figure 2.

Coming from the left bar chart the red hatched sections in the center bar chart add to GHG emissions of the hydraulic pump exactly so that the ratio of its emissions in diesel and electric drivetrain matches the ratio on machine level comparison. With the second approach, the pump in the electric drivetrain is assigned approximately 41 % fewer GHG emissions, consistent with the machine level analysis.

4.3. Discussion and Conclusion

In the first approach when the drivetrain becomes more efficient, total machine emissions decrease, yet the relative share of individual components in those emissions rises. In other words, a component appears "responsible" for a larger portion of a smaller total. Resulting in higher absolute emissions in comparisons, even though machine level comparisons show reduced emissions.

The second approach demonstrates that the consistency between component level and machine level GHG assessments critically depends on capturing all dependencies, including primary energy supply losses. By extending the Activity Data with the inverse of the primary energy supply efficiency, the second approach establishes a link between the component and the primary energy supply system. A change in energy carrier (for instance, from diesel to electricity) not only modifies the Emission Factor but also alters the efficiency of the primary energy supply system. These two effects are interdependent: the Emission Factor determines the environmental impact per energy unit, while the primary energy supply efficiency dictates how much energy must be provided to sustain component operation. Neglecting this link leads to incomplete or misleading comparisons. Using the second approach, the resulting emissions attributed to components scale proportionally with the overall machine behavior, thereby resolving the inconsistency observed in the first approach, allowing for a holistic and physically consistent comparison of different drivetrain configurations.

The second approach offers a practical compromise for real-world implementation. In industrial practice, complete machine data are often unavailable to component manufacturers. The proposed approach allows them to approximate realistic emissions by expanding known component level Activity Data with a representative efficiency factor of the primary energy supply. This ensures a balance between methodological rigor and practical applicability, enabling consistent use-phase emission allocation for reporting purposes.

5. CONCLUSION AND OUTLOOK

This study developed and validated a methodology for calculating the use-phase greenhouse gas (GHG) emissions of hydraulic components in non-road mobile machinery (NRMM). The work addresses a key gap in current sustainability assessment frameworks: while machine level GHG emissions can be quantified using established standards, no consistent procedure exists to attribute these emissions to individual hydraulic components, whose emissions cannot be measured.

Using a wheel loader as a reference machine, the machine level emission calculation was first established by combining Activity Data, defined as the total supplied energy, with Emission Factors for energy provision and operation. On this basis, two allocation approaches were derived and validated for a hydraulic pump in the travel drive, addressing the central research question:

How can use-phase GHG emissions of hydraulic components be determined, while allowing consistent comparisons across different energy carriers?

The first approach, based solely on the component's loss energy as Activity Data, provides a clear causal link between component efficiency and total machine energy demand. As long as only one energy carrier is relevant, it allows to report GHG emissions of hydraulic components with minimal effort. Alternative energy carriers are rising in importance though, creating the need for comparisons. This is where the first approach leads to inconsistent results, because it neglects the impact of the primary energy supply efficiency only taking the difference in Emissions Factors into account. Although the overall machine emissions decreased for the electric configuration, the pump appeared to contribute higher emissions due to the constant Activity Data definition. Thus, the first approach failed to maintain proportional consistency between component and machine level analysis.

The second approach resolves this inconsistency by extending the Activity Data to include losses in the primary energy supply system required to supply the component's losses. This adjustment ensures that both dependencies, the Emission Factor and the primary energy supply efficiency, are consistently reflected in the component level emission assessment. The approach thereby aligns component and machine results, enabling a physically consistent and holistic comparison between drivetrain configurations such as diesel and electric systems. It bridges the gap between machine level energy-based emission accounting and component level data availability, offering a robust foundation for sustainable design and emission transparency in fluid power systems.

Further concluding from the developed method, efficiency improvements, for example through optimized component operating points, directly translate into lower use-phase emissions within the operational boundary. Similarly, improvements in energy provision, such as the use of renewable electricity, further reduce emissions in the energy provision boundary, leading to two main levers to reduce use-phase emissions:

- Efficiency improvements
- Usage of "green" energy

The model neglects potential optimization of the hydraulic pump's operating points when comparing different primary energy supplies. Building on this, system optimization offers high potential for efficiency improvements. While this work mainly addressed reporting requirements for components, future research should aim to expand the method beyond energy carrier to system comparisons.

To extend the demonstrated method to other components in other machines measurement data, from real-world testing with a suitable machine-level operating profile, is needed to calculate the needed loss data. However, real-world testing introduces non-repeatable conditions, such as varying soil properties, weather, and operator behavior. To ensure reproducibility and comparability and to address high efforts in collecting measurement data for the high variance of NRMM a shift from real-world testing to a simulation-based approach will be required in future work.

In the long term, the methodology presented with the second approach can form the foundation for a standardized, modular, and simulation-supported emission-accounting framework for fluid power systems. By providing a consistent way to attribute use-phase emissions to individual hydraulic components, it contributes to greater transparency, supports the development of sustainable hydraulic designs, and thereby advances the decarbonization of NRMM and fluid power applications.

Biographies

Felix Ruthmann received the master's degree in mechanical engineering from the Karlsruhe Institute of Technology (KIT) in 2024. Since 2025, he has been pursuing a Ph.D. at the Institute of Mobile Machines (Mobima) at KIT in cooperation with Bosch Rexroth AG. His research focuses on calculating greenhouse gas emissions and therefore energy efficiency of hydraulic components and systems in non-road mobile machinery (NRMM).

Prof. Dr.-Ing. Marcus Geimer received the Diploma degree in mechanical engineering from the RWTH Aachen University, Germany, in 1990, and the Ph.D. degree from the Institute of Hydraulics and Pneumatics, today named the Institute for Fluid Power Drives and Systems, RWTH Aachen University. He started his industrial career in 1995 in the field of construction at the company Krupp Berco Bautechnik GmbH, Germany, where he was the Leader of the research group for hydraulic breakers. In 2000, he was with Bucher Hydraulics GmbH, Germany, where he led the construction and customer development for mobile hydraulics. Since 2005, he has been a Full Professor and the Director of the Institute of Mobile Machines (Mobima), Karlsruhe Institute of Technology (KIT), Germany. His research and teaching focuses on automation systems, drive concepts, hydraulics and simulation. In addition, he is Faculty Director of Mechatronics.

Prof. Dr.-Ing. Gerhard Geerling received his Diploma degree in mechanical/ aeronautical engineering from the RWTH Aachen University, Aachen, Germany in 1992. In collaboration with the Airbus Technology Transfer Center in Hamburg-Finkenwerder (THF) he received his Ph.D. from the Technical University of Hamburg (TUHH), where he worked as scientific system project engineer at the Institute of Aircraft Systems Engineering (FST) from 1993 until beginning of 1998. He started his industrial career in 1998 with Brueninghaus Hydromatik GmbH, at this time part of the Mannesmann Rexroth AG, nowadays integrated in the business unit Mobile Solutions (DC-MH) of the Bosch Rexroth AG. He has led various management positions at engineering, technology and innovation management, product and project management as well as marketing, technical sales and project procurement. Today he is the responsible Senior Sustainability Manager of DC-MH. Furthermore, he is an honorary professor at the Karlsruhe Institute of Technology (KIT), Karlsruhe, Germany, giving a lecture about the planning and design of hydraulic systems.

Ulrich Lenzgeiger received his Diploma degree in mechanical engineering from the Technical University of Munich, Germany in 2006. He started his industrial career at Bosch Rexroth AG in System Development, focusing on system integration and functional development for mobile machinery. From 2019 onwards, he has been a Senior Manager in System and Software Development, responsible for mechatronics, reliability, and vehicle system testing.

A Holistic Approach Towards Energy Efficient Excavators

Abstract

In the context of the need to reduce greenhouse gas emissions, the construction equipment industry is experiencing a transformative shift.

For decades, excavators have been designed to deliver high performance while maintaining cost-effectiveness. Hydraulic systems provide an easy way of energy distribution from the prime mover to the individual motion function. Robust components with high energy density have been a key factor. Energy efficiency has often been taken with lower priority.

By introduction of electric drives into general purpose machinery, energy consumption becomes a critical factor, especially in case of using batteries as a primary energy storage. At the same time new ways of energy distribution are provided.

A holistic approach will be demonstrated by utilizing architectural methods evaluating established and emerging technologies to identify innovative solutions that can optimize energy efficiency while considering economic viability.

Through a comprehensive analysis of technological advancements alongside their economic implications and commercial availability, this exercise will provide valuable insights for academia and industry stakeholders by driving the future of energy-efficient construction machinery.

Keywords: Energy efficiency, fuel consumption, carbon footprint, BEV, hydraulic systems

1. INTRODUCTION

This study focuses on motion system concepts for battery-electric medium-size excavators with an operating weight between 15 and 30 t. As a reference, a state-of-the-art diesel-driven 22 t crawler excavator is used. The goal is to identify, structure, and evaluate potential solutions for energy- and cost-efficient motion systems that are suitable for battery-electric operation.

Both academic concepts and industrial motion systems are considered. Using an architectural approach, all relevant system variants are mapped in a structured manner, enabling a systematic comparison in terms of energy efficiency, technical feasibility, and expected costs.

2. FUNDAMENTALS ON HYDRAULIC SYSTEMS FOR EXCAVATORS

A comprehensive review of hydraulic system concepts from academia and industry suitable for excavator applications reveals several fundamental system principles. Today's market is still dominated by throttle valve-controlled metering systems, while alternative concepts are emerging.

Valve metering systems remain highly attractive due to their excellent controllability at comparatively low cost. Power distribution is provided in a quite effective way. Energy efficiency is typically considered with lower priority.

In conventional internal combustion engine (ICE) driven machinery, this drawback has been tolerated because the energy density of fossil fuels is high, and fuel costs have been in an acceptable range.

With the rising of battery-electric construction machinery, the need for more energy-efficient motion systems is more urgent than ever. Batteries are costly and have limited energy density. Simply replacing the diesel engine with an electric motor without changing the hydraulic architecture results in limited operating time per charge due to the low overall efficiency of conventional motion systems. Just increasing the battery capacity is constrained both by cost and by the limited installation space in the machines.

At the same time, electric drives open new possibilities. Battery-electric machines can employ multiple electric motors on board, enabling advanced hydraulic and electro-hydraulic architectures that directly support more efficient motion systems.

When energy efficiency is prioritized, it becomes evident that inherent system losses must be minimized. Besides throttling losses at individual control functions, pressure compensation losses between functions play a significant role in hydraulic systems. Energy recuperation is rarely used in current excavator applications, even though a medium-size excavator typically comprises 5 to 10 main working functions, frequently operated simultaneously.

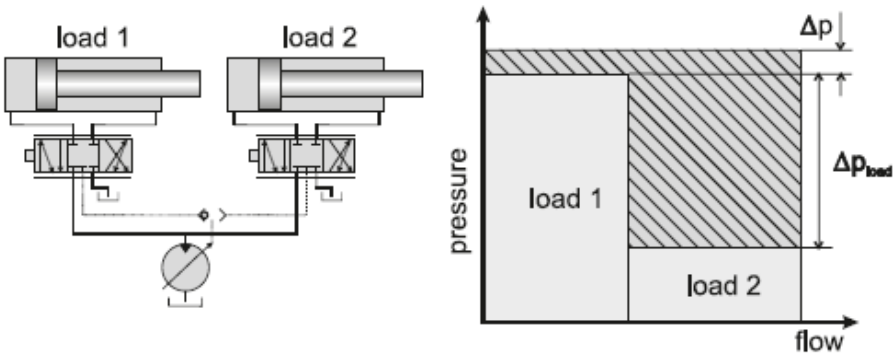

Figure 2.1. Typical single-circuit load-sensing hydraulic system [1]

Higher efficiency can be achieved by using multiple hydraulic circuits supplied by dedicated pumps or by employing more sophisticated architectures that systematically reduce throttling and compensation losses.

2.1. Paths Towards Throttle-Free Hydraulic Control

Two main technological paths towards throttle-free hydraulic control can be identified:

- the Common Pressure Rail (CPR) hydraulics path
- the Displacement Controlled Hydraulics (DCH) path,
  or rather known as Pump Controlled Hydraulics (PCH)

In Common Pressure Rail hydraulics, the system employs a plurality of nearly constant pressure rails, typically supported by hydraulic accumulators. This architecture inherently provides the possibility of energy recovery. A combination of discrete valves and hydraulic transformers is used to control the actuators. For linear actuation, multi-chamber cylinders can be applied to enable advanced flow and pressure management [1]. Hydraulic transformers can appear in both technological paths, but in this study, they are primarily allocated to the Common Pressure Rail approach.

In Displacement Controlled Hydraulics, a linear actuator is directly driven by the displacement of dedicated hydraulic pump unit. The actuator speed is controlled by the pump flow, without interfering throttle elements. Speed can be adjusted via pump rotational speed and/or variable displacement, while the motion direction is determined by the direction of the hydraulic flow.

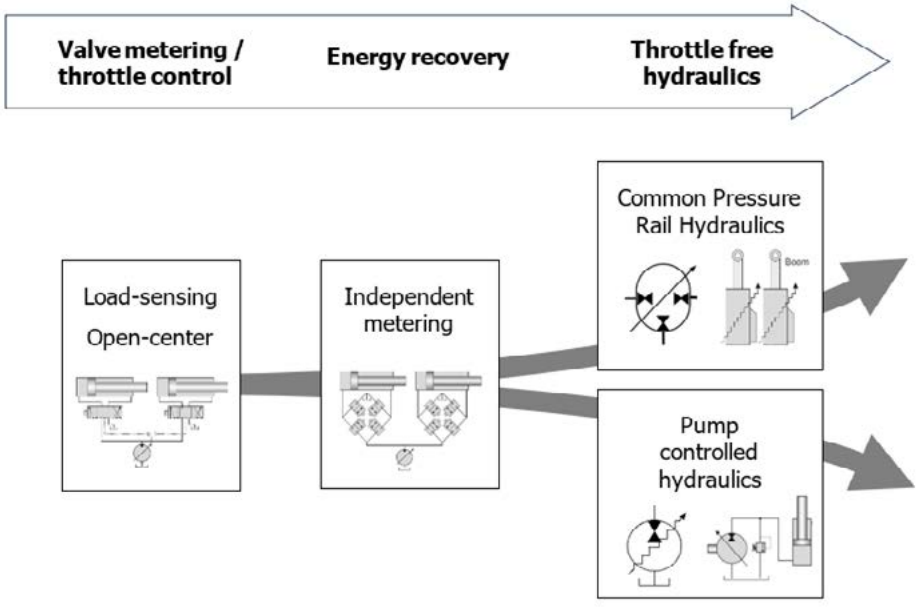

Figure 2.2. Possible paths towards throttle-free hydraulic control

The above-shown basic system principles can be combined in various ways or complemented by additional elements, resulting in hybrid architectures that further optimize efficiency, controllability and cost while the CPR and PCH principles are rather diverging.

3. ARCHITECTURAL APPROACH

The excavators' motion and control system can be clustered into its basic elements. Following the energy flow from the supply side via distribution & control towards the actuation of the working functions.

Those basic elements could be either commercially available components out of the shelf, parts under development or even theoretical ideas from academia.

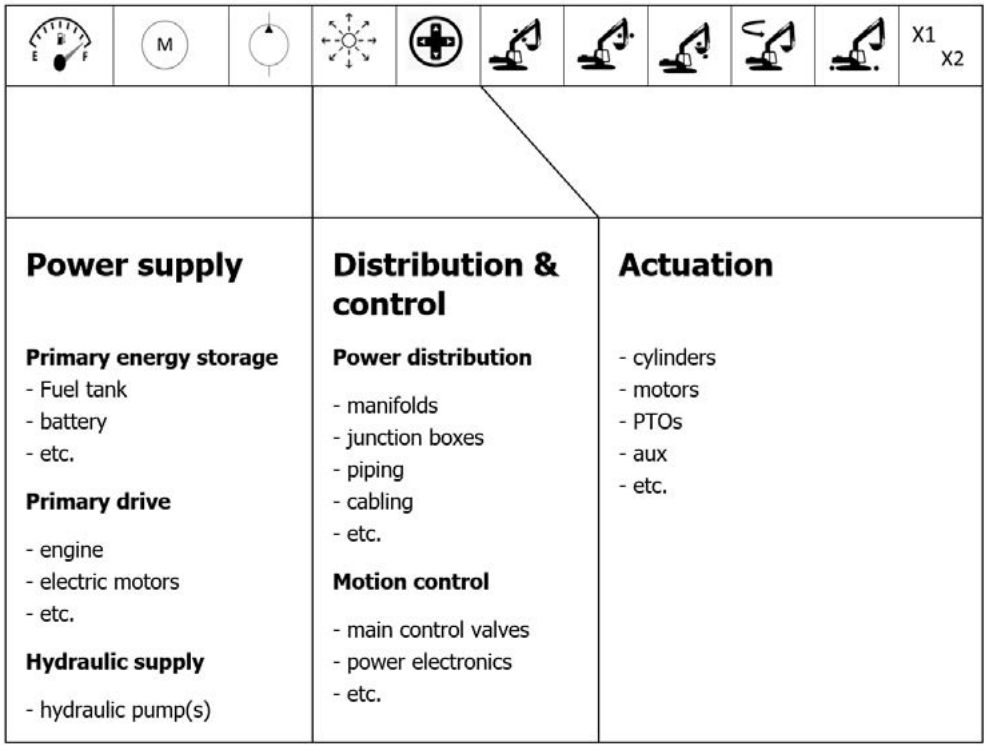

Figure 3.1. Architectural approach

3.1. Concept Creation

The excavator's motion and control system is decomposed into its basic architectural elements along the energy flow: from the energy supply (prime mover and energy storage), through the energy distribution and control subsystems, to the actuation of the individual working functions. These basic elements may be:

- commercially available off-the-shelf components,
- components under industrial development, or
- conceptual solutions proposed in academic research.

This architectural decomposition allows systematic generation and comparison of motion system concepts by combining compatible elements into complete system configurations.

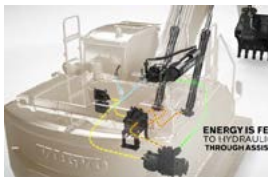
Figure 3.2. Concept matrix

3.2. Concept Selection and Evaluation



By combining the different architectural sub-components, a broad variety of motion system concepts for medium-size excavators is generated. In parallel, a streamlined power and loss calculation methodology is developed to quantify the potential energy efficiency of each concept under representative duty cycles. The outcome is a comparative assessment of motion system cost versus input energy reduction for the entire excavator. This provides an overall picture of the trade-offs between efficiency, complexity, and economic viability.

Several of the investigated concepts are already commercially available in the construction equipment industry. Others have been analysed in more depth using simulation or experimentally validated on demonstrator machines. Battery-electric excavators in particular act as a strong driver for the adoption of more efficient motion systems, as they directly benefit from reduced energy demand via smaller batteries, lower charging requirements, and improved total cost of ownership.

3.3. Advanced Hydraulic Systems - Commercially Available

As a brief excursus a few examples on already commercially available advanced hydraulic motion systems:

Single function IMVT

Open-Center system combined with independent metering for boom-down energy recuperation.

Commercially available for medium and large excavators.

+ limited complexity
+ cost efficient
+ robust and proven technology

- limited energy efficiency

Full-scale IMVT

Full scale independent metering valve technology

Commercially available for large excavators.

+ significant energy efficiency improvement
+ limited impact on general machine layout

- system complexity

CPR System

Common Pressure Rail system with Digital Valve Actuators and Secondary Controls.

Commercially available for large excavators

+ high energy efficiency improvement
+ supply system downsizing

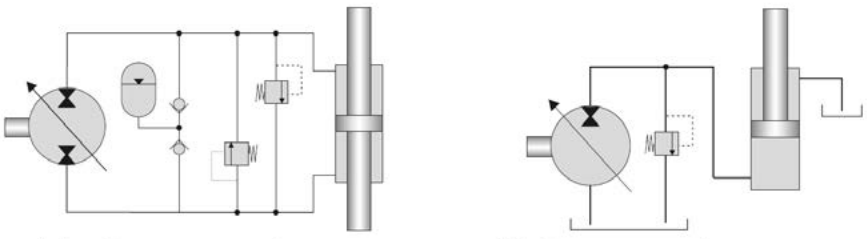
- complex motion control
- increased system costs

Figure 3.3. Commercially available products with advanced hydraulics

4. HYBRID SYSTEM APPROACH

As electric construction machinery is emerging, the range of possible motion and control systems is expanding. Inspired by industrial robotics, one might consider driving all functions with electric motors or electro-mechanical actuators (EMA). For rotary functions like swing of the upper carriage of an excavator or the traction drives, it comes rather naturally to directly apply those with electric propulsion.

Excavators digging attachment, however, must provide high forces and high speeds while being robust against mechanical shocks and dynamic overload in a rough terrain. Meeting all these requirements simultaneously with purely electro-mechanical actuators becomes challenging [3]. In addition, packaging constraints, component masses, and costs must be carefully considered.



This raises also the question of energy efficiency: Will electro-mechanical solutions automatically outperform hydraulics?

In an EMA-based system, all propulsion and recuperation power flows through the electro-mechanical drive chain, and therefore experiences the associated losses:

- Bearing and mechanical transmission losses
- Electric motor losses
- Power electronics and conversion losses
- Energy storage system (ESS) losses

Considering an excavator working function with high recuperation potential, such as the boom, offers a useful benchmark. Up to 50 % of the required lifting capacity may be due to the dead weight of the structure and its attachment. This justifies a more complex and potentially more expensive motion system, as the benefits in terms of reduced primary energy storage demand and lower energy consumption (and thus total cost of ownership) can outweigh the additional system cost.

In contrast to EMA, Electro-Hydraulic Actuator (EHA) systems allow various different layout concepts that can be tailored to the specific use case [1][5].

(a) *Pump control in a closed circuit arrangement.*

(b) *Pump control in an open circuit arrangement.*

Figure 4.1. Two basic EHA system examples

For example, open- or closed-circuit layouts can be chosen (figure 4.1). Depending on the application, either plunger-, synchronous- or differential cylinders may be the favored choice. Whereas differential cylinders dominate in construction machinery. With the differential flow one of the challenges for EHA systems needs to be considered. Those cannot be simply driven by conventional pumps or pump-motors without further valve technology and storage devices. This will add cost and complexity on one hand, but also provides opportunities to increase the system's efficiency. If a pressurized reservoir in form of a hydraulic accumulator is built-in, this could offer the chance for short term energy buffering or counter-balancing a load.

For an excavator's boom dead weight compensation, a power-split concept (as illustrated schematically in Figure 4.2) can be highly advantageous in terms of energy efficiency. The static load component can be compensated in the hydraulic domain using hydraulic accumulators, while the electric drive primarily provides speed and directional control. Consequently, the power throughput in the electric subsystem is reduced, lowering conversion losses. A significant share of the energy flow remains within the hydraulic domain, and overall efficiency of the specific motion function of up to 80 % can be achieved.

Optimizing and partially decoupling a single motion function not only reduces the power consumption of that particular function. The remaining (hydraulic) motion system also benefits through reduced supply and compensation losses, thereby improving the efficiency of the entire machine significantly.

Considering the above-mentioned aspects, a hybrid system approach for an electric driven excavator could be drawn as shown in figure 4.2.

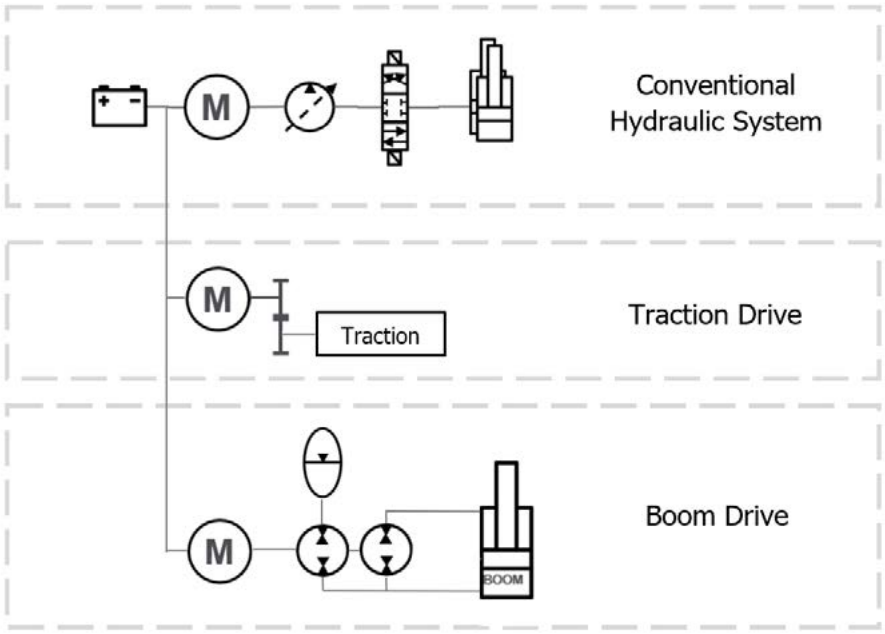


Figure 4.2. Hybrid motion system approach

A hybrid system, as illustrated above, emerged as a promising conceptual result of the architectural approach. The corresponding analysis indicates both a significant improvement in energy efficiency and a considerable economic potential.

The system was simulated and subsequently implemented in a demonstrator machine. As shown in figure 4.3, a substantial reduction of the total input power of approximately 27% was achieved in the dedicated load cycle, although other applications may show different figures. The energy portion of the boom function was reduced by about 10%, which lies within the expected range, while the energy efficiency of the remaining functions improved by approximately 17% in parallel. This can be explained since in conventional hydraulic systems, the boom drive constitutes the most dominant function and typically causes considerable compensation losses for the other functions used in parallel, such as arm, bucket, and swing. By decoupling the boom function, the compensation losses of the remaining functions are significantly reduced.

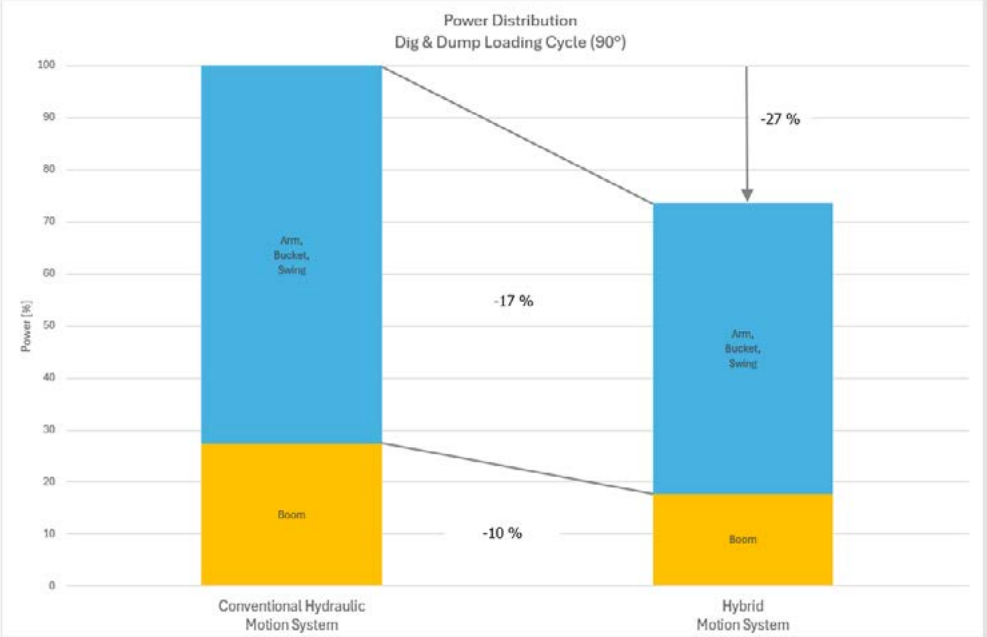

Figure 4.3. Comparison of the power distribution of a dig & dump loading cycle

5. CONCLUSION AND OUTLOOK

The study has been carried out by a cross-functional, international project team within Volvo Construction Equipment. The objective was to derive a motion system technology roadmap for construction machinery, with a focus on excavators and their transition towards electrification.

Technologies and concepts from both academia and industry were evaluated using an architectural approach. Several solutions have been implemented on demonstrator machines or selected as candidates for series development. The analysis confirms that there is no universal, one-fits-all solution that simultaneously delivers maximum performance at minimum cost. In the hydraulic domain in particular, a wide variety of technical solutions exist, suited to different applications and boundary conditions.

As one example a hydraulic hybrid system approach has been showcased in this study to demonstrate that it could be advantageous to optimize only one single machine function by a rather complex system. Nevertheless, there was a substantial benefit for the rest of the hydraulic system as compensation and supply losses are significantly reduced.

However, by systematically applying architectural methods and smartly combining appropriate elements, viable pathways towards significantly higher energy efficiency can be defined. These pathways support the development of economically attractive, energy efficient construction machinery and provide a structured foundation for future research and industrial implementation.

Innovative self-sufficient clamping system for machine tools

Johannes Gattinger, Marc Summer, Markus Grossauer, Markus Schwimmer

WEBER-HYDRAULIK GmbH, johannes.gattinger@weber-hydraulik.com

Abstract

In the course of optimizing milling processes, automatic workpiece clamping plays an essential role for a high degree of automation. Hydraulic workpiece clamping offers additional advantages, such as good integrability due to the high power density and the generation of variable clamping forces. The aim of this work is to develop a hydraulic, retrofittable, universal pressure supply for automated clamping fixtures. This clamping system should work without hydraulic and electrical interfaces. An integrated pressure accumulator in the closed system can be charged by the spindle of the machine tool via a separable coupling. This provides hydraulic energy for building up and maintaining the clamping force. Other functions, such as reducing the clamping force and opening or closing the clamping jaws, can be performed either manually by the operator or by actuating the corresponding valves with the machine spindle. The clamping force can be monitored wirelessly via Bluetooth using the integrated pressure sensor.

Keywords: hydraulic clamping, retrofit, automation, closed hydraulic system, interface-free clamping system.

1. INTRODUCTION

When optimizing milling processes, a high degree of automation is usually aimed for, and automatic workpiece clamping plays an important role here [1]. In addition to the good automation capability of the clamping process, hydraulic workpiece clamping offers additional advantages such as good integrability due to the high power density and the generation of variable clamping forces [2]. Apart from enabling automation through hydraulic clamping systems, further general advantages are also expected with manual workpiece clamping. While mechanical clamping fixtures are tightened manually with a suitable tool and defined torque, clamping with hydraulic clamping fixtures can simply take place by switching a valve. This could increase productivity through faster part change processes in order to achieve a high Overall Equipment Effectiveness (OEE) [3, 4, 5]. Another positive effect on the OEE is that quality can be increased through repeatable clamping force, which can also be monitored and documented using integrated pressure sensors [6].

All Open Access articles are peer-reviewed, distributed under the Creative Commons Attribution-Non Commercial 4.0 International

State-of-the-art technology for the pressure supply of hydraulic clamping devices are clamping units integrated in the machine tool. If pallet changing systems are used, appropriate interfaces must be provided for automatic coupling of the hydraulic and, if necessary, electrical connections. Today, many milling machines are equipped with hydraulic clamping units as standard, but retrofitting existing machines is expensive and therefore rarely done.
The aim of this work is to develop a universal pressure supply for hydraulic clamping devices. In order to ensure optimal retrofitting capability and robustness, this clamping system should not require any hydraulic and electrical interfaces. The main focus here is on the question of whether it is possible to drive the pump of the clamping system via the machine spindle using a separable coupling, requiring as little time as possible.

2. CONCEPT AND DESIGN

The basic concept of the clamping system presented here is based on the idea of generating, accumulating and supplying the hydraulic energy directly at the clamping devices in the clamping tower. This enables hydraulic clamping to be carried out directly on the pallet, eliminating the need for an interface to the machine. Each pallet therefore has a self-sufficient clamping unit. All power transmission to the unit is to take place via the machine spindle. This primarily means the drive of the hydraulic pump and also any valve switching operations. This allows the main objective of avoiding hydraulic and electrical interfaces to be achieved. In addition, this design allows the clamping system to be extremely compact and cost-effective, since no additional electric motor is required to drive the pump. The machine spindle drives the hydraulic pump of the clamping system by rotating. A separable coupling is used for this purpose, with one hub acting as a spindle tool that connects to a corresponding hub in the clamping system. The coupling is designed to eliminate the need for precise angular alignment between the machine spindle and the clamping system hub. Even if the machine spindle could, in principle, couple at a defined rotational angle, this approach is avoided because it would increase complexity and error susceptibility. More importantly, it allows for a functionality where the exact position of the clamping system's coupling hub is not always known. It should be possible for the pump to be operated independently of the machine tool, for example, to enable the operator to reload hydraulic energy when changing parts in the pallet station. An additional coupling hub is designed for this purpose, which can be inserted into a cordless screwdriver. After manual operation of the pump by the worker using a cordless screwdriver, the angular position of the coupling hub of the clamping system is undefined. In order to make safe coupling possible for the machine tool, an approach is pursued in which, on the one hand, the highest possible probability is achieved that the coupling parts slide into each other regardless of their angular position and do not collide and block on the end face when they are pushed together axially and, in addition, axial compensation is made possible during coupling so that the coupling parts can move out of the way when they are pushed together. A curved-tooth gear coupling from KTR is selected for this purpose, in which the teeth are sharpened on the end faces, making it less likely that flat end faces will collide. In addition, the sleeve of this special coupling is fixed on the pump-side hub, but can move axially on the hub by 4.5 mm. An O-ring is integrated into the sleeve/hub combination as a resilient element to press the sleeve into its initial position and allow elastic displacement (Figure 2.1). To engage, the spindle must now rotate slowly as it moves axially towards the coupling of the pump. Due to the

continuous rotation of the hub on the spindle with the possibility of elastic displacement of the coupling sleeve on the pump-side hub, the coupling parts can slip into each other. The pump-side hub is also rotated from the point of engagement and the spindle can move to the axial end position. As soon as the coupling process is complete, the spindle can drive the pump at maximum pump speed in order to generate the hydraulic power.

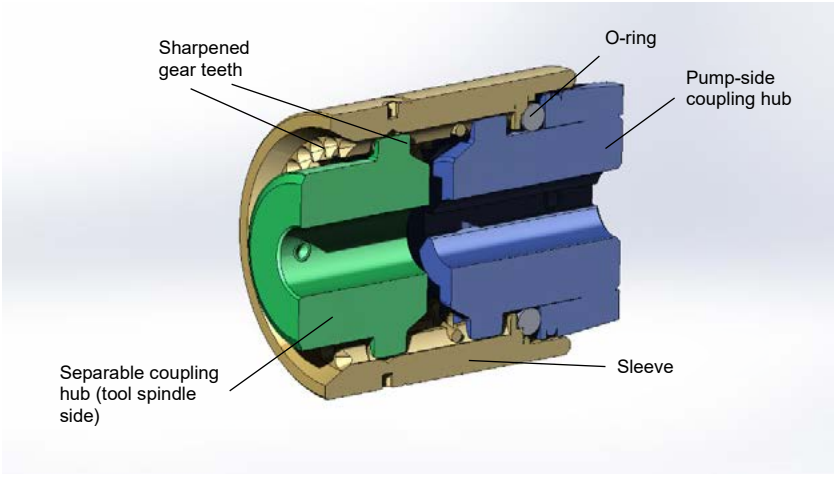

Figure 2.1. Separable coupling

In the unlikely event that the hub does not slide into the sleeve because something is jammed or the teeth actually meet exactly with the end faces and do not slide into each other due to the rotation, the machine has a force monitoring device on the spindle, which prevents a crash by switching off in the latter instance.

A hydraulic accumulator is integrated to enable the clamping jaws to be operated outside the machine during workpiece changes. This accumulator is loaded when the pump is driven by the tool spindle and must be dimensioned so that it is possible to carry out several clamping operations without having to reload in between. This system design (Figure 2.2) with accumulator also makes it possible to maintain the clamping pressure reliably over a long period of time. The accumulator size and preload pressure must be selected so that the maximum clamping pressure to be achieved can be safely maintained over a long period of time, despite internal droplet leakage. In addition, there must be sufficient oil volume in the accumulator to be able to carry out several clamping operations. However, a compromise can be made here in that the full clamping pressure does not have to be reached when clamping the workpiece. When clamping, it is sufficient if the workpiece is held securely in position. The final clamping pressure can then be built up in the machine by the machine spindle before machining begins. On the other hand, the accumulator would have to be disproportionately large. The accumulator design is calculated using the formula for the polytropic change of state of nitrogen with n=1.4 [7]. This results in a calculated available oil volume of 370 ml for the 1 l accumulator with 70 bar gas pre-charge between the maximum pressure of 250 bar and the assumed minimum clamping pressure of 100 bar to be achieved during clamping of the workpiece.

Since the required clamping force can vary greatly depending on the application and component and is often not known precisely [8], but is sometimes simply clamped with the maximum available clamping force, the clamping system is designed so that a standard maximum clamping pressure of 240 bar can be achieved. In order to reliably provide the required maximum clamping pressure over a long period of time, a higher pressure of 250 bar must be maintained in the accumulator. At the same time, however, the maximum pressure limits of the clamping device must not be exceeded, which is why the clamping pressure is regulated by pressure reducing valves. This has the additional advantage that the clamping pressure required for the respective application can be easily adjusted.

The clamping system is also equipped with valves for reducing the clamping force for fine machining. The circuit is designed so that it is possible to switch between high and low clamping pressure without having to build up pressure again via the pump. It is possible to switch from high pressure to low pressure and vice versa. To ensure that this can be done without leakage, a combination of a pressure reducing valve and a pressure relief valve is selected for the low-pressure supply, as shown in Figure 2.2. The switchover is performed by a mechanically operated 4-way, 2 position valve, which can be switched manually or with a movement of the machine spindle (Figure 2.3). The clamping system is designed so that several clamping jaws can generally be operated on the clamping tower. In the application example, there are 4 clamping jaws, each of which is controlled individually via manually operated 3-way, 2-positions valves. This allows the operator to easily clamp and release when changing parts by simply turning the valve switch.

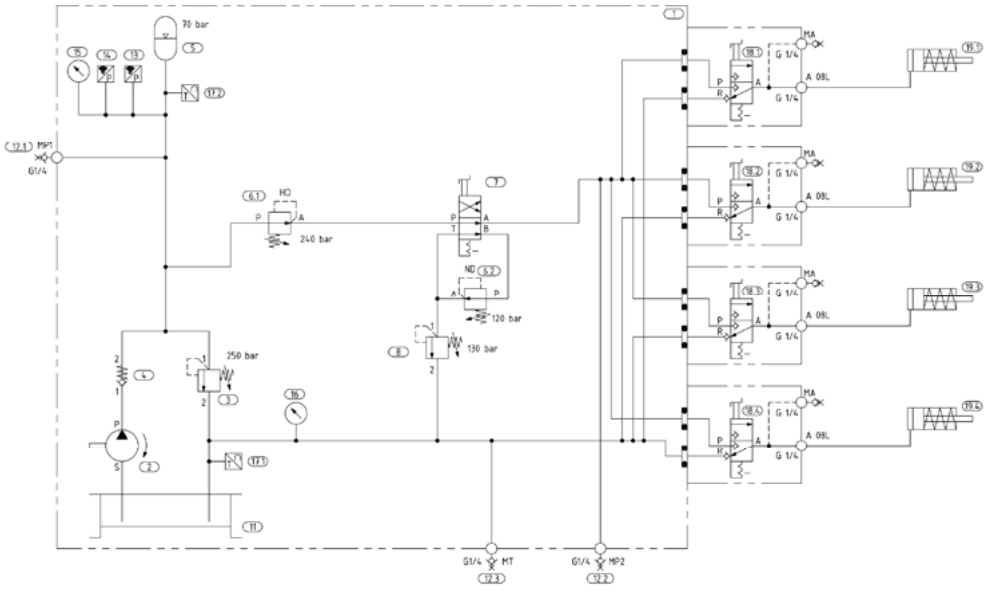

Figure 2.2. Hydraulic circuit diagram of clamping system

Single-acting hydraulic vices with an effective area of 25 cm² are used as clamping jaws. This results in a maximum clamping force of 60 kN at a maximum pressure of 240 bar. The maximum clamping stroke is 4.5 mm, but is additionally limited mechanically to 2 mm in

order to prevent the operator's body parts from becoming trapped during clamping as far as possible. This results in a required oil volume of 5 cm³ per vice, respectively per clamping operation. This means that approximately 74 clamping operations are possible within the limits of 250 bar (fully charged accumulator) and 100 bar (selected lower clamping pressure limit during workpiece insertion).

An external gear pump with a displacement of 2.1 cm³/rev is selected as the hydraulic pump. At 3000 rpm, this allows a calculated reloading time of 0.2 s, assuming that each of the four vices has been relaxed and clamped once. With the selected pump, speeds of up to 6000 rpm would even be possible, resulting in a calculated reloading time of 0.1 s.

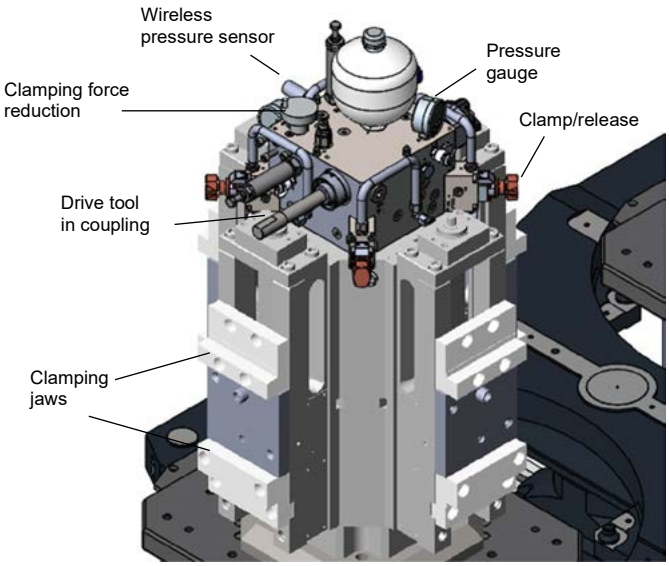

Figure 2.3. Clamping system on pallet tower

The oil tank is flanged to the bottom of the hydraulic manifold and seals hermetically with the manifold. This is necessary to protect the oil from moisture and dirt ingress from chips and cooling lubricant. The tank has a nominal volume of 2.4 l and is filled with 0.8 l of oil. The required exchange volume is 0.6 l. This results in an approximate pressure of 0.73 bar absolute in the tank for an isothermal change of state at maximum oil extraction (accumulator fully charged), which is still acceptable for proper suction by the pump.

Since reliable fixation of the workpiece is relevant to safety, pressure monitoring must be implemented during the machining process [9]. In order to keep complexity low and avoid interfaces, the focus is on wireless pressure monitoring. This also ensures seamless pressure monitoring over a longer period of time in the pallet station. One option for wireless clamping force transmission, as investigated by Denkena, would be to integrate strain gauges on the clamping jaws and transmit the data wirelessly via a CAN master on the pallet to the machine control system via an industrial PC [10]. However, such a solution requires a relatively large amount of electrical energy at the clamping tower. Since no electrical interfaces are desired here, a solution using battery-powered pressure sensors with a wireless

interface (Bluetooth) is implemented. Two relatively new wireless sensors available on the market, the PEW-1000 from WIKA and the M5600 from TE Connectivity, are being tested.

A pressure gauge is integrated so that the operator can easily check the available pressure at any time when changing workpieces. In addition, temperature sensors, another pressure gauge on the tank, and additional measuring connections have been provided for validation purposes.

3. RESULTS

When testing the coupling process, it becomes apparent that the strategy of allowing the coupling sleeve to deflect via the O-ring does not work. The stiffness is too high and the resulting travel too low, so that when the front sides of the coupling teeth meet, the machine's sensitively adjusted force monitoring system is triggered. This means that the coupling process must be carried out very slowly. On the other hand, it can be seen that the basic approach of allowing the coupling sleeve to deflect while the spindle rotates toward the coupling is effective. This is more important than the geometrically adapted front faces of the teeth, as these do not completely prevent a collision. It is therefore assumed that the special geometry of the coupling is not necessary if sufficient deflection is provided. With the current design and the cautious coupling process, coupling takes approx. 14 s. A measurement of the accumulator charging process shows that charging from 160 to maximum pressure at 1000 rpm takes approx. 3.5 s (Figure 3.1). This means that the time required for coupling significantly outweighs this and should be improved.

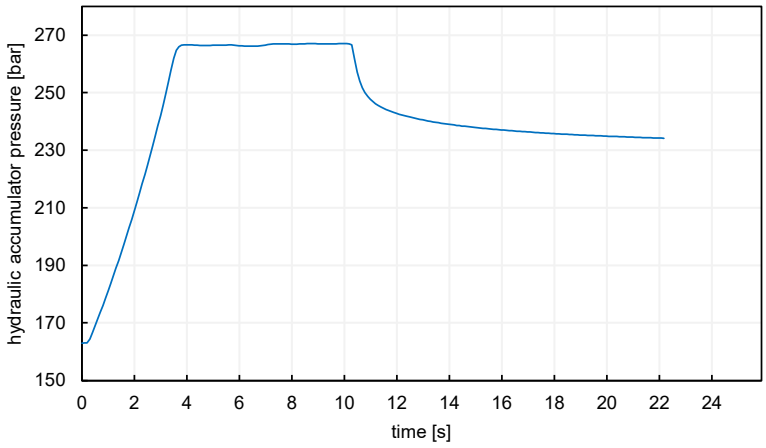

Figure 3.1. Time-controlled charging over 10 s at 1000 rpm

It is also noticeable that the pressure drops rapidly by approx. 30 bar at the end of the charging process. This is attributed to the hysteresis of the pressure relief valve. This effect can probably be avoided if the pressure connection of the pressure relief valve is not connected between the check valve and the accumulator, but between the check valve and the pump. It would also be helpful if the maximum pressure or setting pressure of the relieve valve were not so close to the maximum clampinig pressure. This would also give more

reserve capacity in terms of the stored oil volume above the maximum clampinig pressure, which would mean that it might not be necessary to reload after every insertion process. Currently, only 2.3 clamping procedures between 250 bar and 240 bar storage pressure are calculated to be possible. In reality, even a single cycle of release and clamping results in a pressure drop from 240 bar to approx. 225 bar, as all channels are briefly connected to each other when the 3-way, 2-position poppet valve is switched, resulting in additional oil loss to the tank. If the required clamping pressures are more precisely defined, the pre-charge pressure of the accumulator can also be set more advantageously, so that even at higher pressures a better ratio between the amount of oil available and the pressure difference is possible.

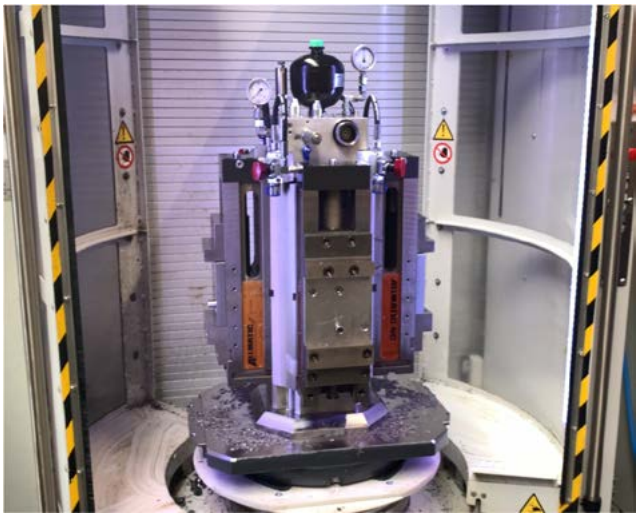

Figure 3.2. Clamping tower with installed clamping system

During validation, the following experiences were recorded with regard to time savings and operational convenience compared to mechanical clamping. In terms of time savings, an improvement of approx. 5 to 10 seconds per workpiece change was observed with a standard 4-sided clamping tower, but this alone does not lead to a profitable amortization period. From an ergonomic point of view, the hydraulic clamping device does lead to an improvement in the process. This effect is sometimes enhanced if the devices are located outside the comfortable working area when changing workpieces, or if the workers are below average in terms of size or strength, which in turn leads to further time savings.

During charging, it can be observed that negative pressure builds up in the tank, but not to the expected extent. When driving the pump, the pressure in the tank quickly drops to approx. 0.85 bar absolute and then does not drop further while the pump continues to fill the accumulator. Therefore, a leak in the tank is suspected. The tank is a welded steel tank that seals radially to the flange via an O-ring on a collar on the manifold, which is the most likely location for a leak. Since the tank is located below the manifold and thus within the clamping tower, and therefore in a fairly protected area, the risk of contamination and moisture entering the hydraulic system is relatively low.

The general suitability of the Bluetooth pressure sensors was demonstrated. Pressure recordings were possible using the manufacturers' application software, and in some cases measurement data could also be exported as CSV files. Measurement and transmission intervals vary and can be parameterized within certain limits. According to the data sheet, the sensors can also communicate with application-specific controllers via standard protocols, but this was not tested.

4. SUMMARY AND CONCLUSION

In summary, it can be stated that the principal functionality of the intended concept is in place. There is further potential for optimization, particularly with regard to the drive shaft coupling. This can be improved in terms of design to enable faster engagement of the tool spindle and thus reduce the loading time, which is directly included in the machining time per pallet. Furthermore, the integration of the wireless sensor for clamping pressure monitoring into the machine control system remains to be completed. This would also enable a pressure-controlled loading process, which would optimize the loading time to the necessary duration compared to time-controlled loading. The root cause of the tank leak needs to be identified and rectified. Alternatively, a second accumulator with a very low gas pre-charge could be utilized as a tank. It is recommended that a further optimization be made by switching to hydraulically vented pressure reducing valves. The pressure reducing valves used are atmospherically vented, which poses a general risk of contamination in this operating environment.

Abstract.

Performance degradation under temperature rise conditions is a persistent challenge in the motion clamping system of injection molding machines, where unmeasurable variations in oil viscosity led to pump efficiency loss and positioning accuracy deterioration. To address this issue, this study proposes a platform-assisted approach for system performance modelling and control optimization. A digital platform integrating data acquisition, simulation analysis, and data review is developed to enable unified analysis of measured operating data and model predictions. Using the temperature-dependent viscosity effect as a representative case, a data-driven inverse identification method is implemented through platform-based parameter mapping and implicit indicator extraction, allowing an engineering-oriented redefinition of leakage characteristics in the pump flow model and explicit incorporation of the viscosity-temperature relationship into system modelling. Based on the established model, a pump flow compensation channel is introduced into the original position-based PID control architecture to provide feedforward correction for temperature-induced flow degradation. Experimental results under multiple operating conditions demonstrate that the proposed method significantly improves positioning accuracy and control consistency. The study provides an effective modelling and control optimization framework for performance degradation driven by unmeasurable latent variables in electromechanical-hydraulic systems.

1. INTRODUCTION

In recent years, digital twins and digital prototypes have attracted increasing attention in both industry and academia, with digital technologies emerging as a key driver for overcoming existing limitations and enabling transformative upgrades [1]. In equipment

All Open Access articles are peer-reviewed, distributed under the Creative Commons Attribution-Non Commercial 4.0 International

manufacturing in particular, digital technologies—leveraging production data as a central link—have introduced new models and methods across all stages of production, significantly advancing the industry toward higher efficiency, intelligence, and sustainability [2, 3].

Electromechanical-hydraulic (EMH) systems are the core driving units of industrial equipment, with their performance directly determining functional value across the entire life cycle. FIGURE 1.1 shows the key stages from development to decommissioning, among which the performance tuning stage plays a pivotal role in optimizing the preliminary prototype into a high-performance product. However, the multidisciplinary coupling of EMH systems introduces substantial challenges in both forward design and reverse debugging of industrial equipment [4].

Figure1.1. Equipment Lifecycle and Performance Debugging Phase

1.1. Industry Status and State of the Art

First, the dynamic responses of multidisciplinary components are inconsistent, and complex parameter matching makes it difficult to accurately predict operating performance at the design stage [5]. Meanwhile, nonlinear factors such as friction and inertial loads increase uncertainties in debugging, compromising system stability and responsiveness [6]. Moreover, conventional debugging relies heavily on manual experience [7], with limited data integration, poor documentation, and weak knowledge reuse, which constrain efficiency and global optimization [8]. Therefore, introducing digital technologies, virtual debugging, and intelligent methods is essential to optimize the process, shorten the cycle, and ensure accurate and efficient EMH system debugging [9].

Currently, research on digitalization and platform construction is emerging across equipment design, debugging, manufacturing, and operation and maintenance [10–13]. Within debugging, studies focus on assembly debugging, which verifies functional integrity, and performance debugging, which optimizes operational performance. In various industries, digital technologies have partially addressed key challenges, including variable operating conditions [14], conflicts between development cycle and quality [15], high costs [16], equipment discreteness [17], complex and error-prone design processes [18], and strongly time-varying performance indicators [19]. However, for complex EMH equipment, application cases remain limited, and substantive support is lacking.

This study focuses on the EMH system of an injection molding machine (IMM) and addresses the demand for motion accuracy optimization of the motion clamping system (MCS) by proposing a performance tuning–oriented digital system architecture. The proposed architecture consists of a physical layer (PL), a simulation layer (SL), a data relay layer (DRL), and a visualization layer (VL), and establishes a data visualization workflow for system diagnosis and optimization based on high-fidelity multidisciplinary models. The PL corresponds to the actual IMM system. The DRL enables real-time acquisition and updating of multiple key operating variables using a limited number of sensors. The VL serves as the human-machine interface, providing the display of diagnosable variables and supporting performance analysis. The SL implements virtual sensing through multidisciplinary simulation to characterize both dynamic and static system behaviours, conduct coupled multidisciplinary analyses, and virtually estimate implicit parameters that are difficult to measure directly. In this way, the proposed architecture reveals both explicit and implicit factors affecting system performance, thereby improving system tunability and motion accuracy.

2. OVERALL DESIGN OF SYSTEM ARCHITECTURE

2.1. Overview of the MCS of the IMM

The research object—MCS of an IMM—is a core unit of plastic forming. It must travel about 1 m within 1 s, maintaining millimeter-level positioning while withstanding high-speed motion of mold components weighing several tons. The system operates via motor-driven hydraulic pumps that actuate the MCS. System configuration and motion accuracy are shown in FIGURE 2.1. Scatter plots indicate that actuator motion raises hydraulic oil temperature and positioning errors. High inertia, rapid response, and strict precision requirements pose severe challenges to conventional commissioning methods.

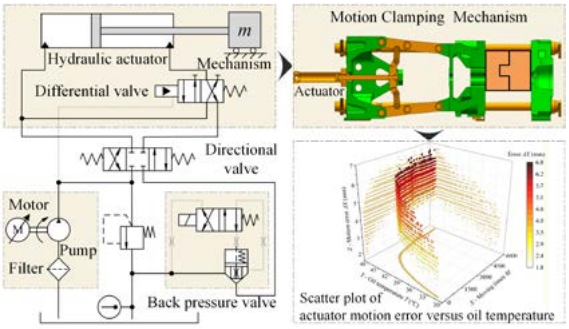

Figure 2.1. The EMH System of IMM and Its Existing Problems

2.2. Requirement Analysis

Based on the overview and current challenges of the MCS, the logical relationships of the requirements in the context of digital upgrading are illustrated in FIGURE2.2 and can be summarized as follows:

(1) High-precision simulation models: Digitalization requires high-fidelity models that accurately map physical entities. Incorporating external, inertial, and frictional forces enables faithful reproduction of the platen's dynamics. Such models allow analysis of operational deviations, and support improvements in motion accuracy and stability.

(2) Feature data support: The MCS requires a data acquisition system to collect and process key state data, enabling the simulation model to accurately depict equipment operation.

(3) Visualization platform: The platform integrates simulation models with the data acquisition system, providing intuitive display of real-time states, trends, and implicit variables to enhance system transparency, while offering interactive interfaces for functional expansion and optimization analysis.

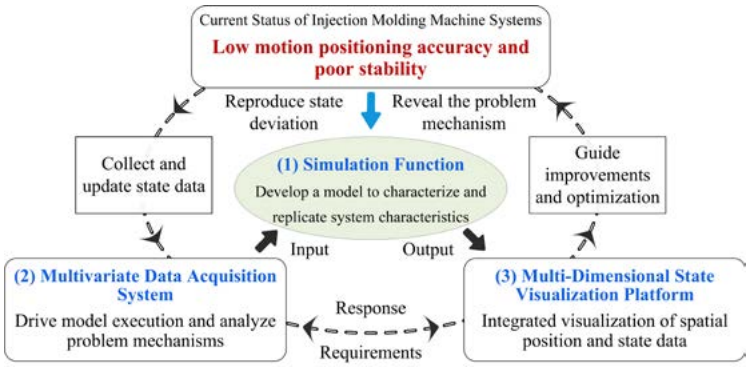

Figure2.2. Digital Technology Application Requirements for the MCS of the IMM

2.3. Architectural Design

Based on the aforementioned logical relationships of requirements, a digital application scheme is designed, encompassing both functional hierarchy design and technology framework design.

(1) Functional Hierarchy Design

This study follows an application-driven and incremental digitalization paradigm, rather than pursuing a fully instantiated, end-to-end global digital twin in a single step. Based on the current state and requirements of the MCS, the digital upgrade should adopt a four-level architecture: physical entity, system model, multi-source data acquisition system, and visualization platform. The following sections define each level and its objectives.

① PL: The MCS provides geometric and state data, forming the dynamic basis of the digital architecture. This layer includes components and sensors for data acquisition.

② DRL: This layer collects and manages multi-source data between the physical entity and digital space, serving as the core medium for their interaction. It includes transmission systems, protocols, and databases to enable efficient data transfer, storage, and management.

③ SL: Integrating the physical system's geometric and state models with its operational logic, this layer creates a virtual representation of the entity. Using data from the DRL as constraints, it replicates EMH system operation, serving as the core of digital applications.

④ VL: Serving as the interface between the physical entity and simulation model, this layer manages data acquisition, simulation execution, and comparative analysis of physical and simulated states. By identifying optimization parameters, it enhances the application of high-precision SL models, providing intuitive support for performance analysis and optimization.

(2) Technical Architecture Design

The above four functional levels establish a digital application framework for the MCS, centered on a high-precision simulation model. On this basis, it is necessary to further develop operational logic and implementation standards to form a complete digital technology architecture, which can guide system application and deployment. This technology architecture is shown in FIGURE2.3.

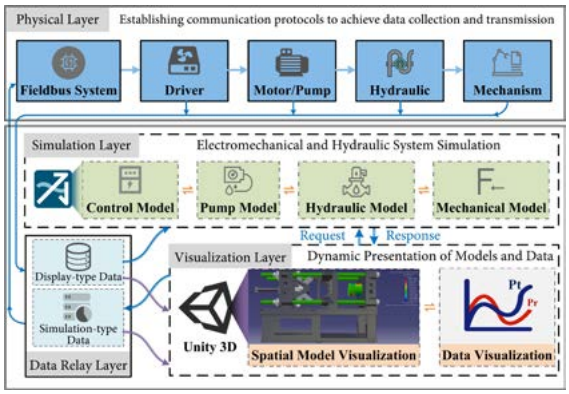

Figure 2.3. Digital Application Technology Architecture of the MCS

Based on this technology framework, the system operates as follows: During the operation of the MCS, the VL monitors system performance and collects state data for computation in the SL and for visual display. The acquired data and simulation data are synchronously stored in the DRL, supporting dynamic comparison and subsequent analysis on the VL. By linking all layers through data, the framework drives the high-precision simulation model to reproduce motion deviations in the MCS. The state variables in the model are abstractly represented on the VL, and through explicit comparison of observable states and implicit calculation of latent states, the system's operational mechanisms are revealed, providing guidance for optimizing motion positioning accuracy in the MCS.

3. DIGITAL PLATFORM DEVELOPMENT

This section builds a performance optimization digital platform for the MCS based on the proposed digital application technology architecture. By integrating multidisciplinary simulation, data flow processing, and visualization technologies, the platform enables the digital upgrade of the debugging process.

3.1. SL Construction

Multidisciplinary co-simulation is essential for the study of EMH systems. By characterizing the interactions among multiple physical fields, it reveals the system's dynamic behaviour and coupling effects, providing theoretical support for optimization. In this study, a hierarchical modelling strategy is employed to construct the SL for the MCS.

(1) Mechanical Structure Model

As the actuator of the system, the MCS is required to achieve precise positioning, rapid dynamic response, and continuous coordination across multiple motion stages during operation. However, latent factors such as component deformation, coupled inertial effects,

and friction exert a significant influence on its dynamic performance. To address these issues, this study proposes a symmetric recursive method based on Newton–Euler dynamics and introduces a deformation allocation strategy grounded in the ratio of component stiffness coefficients. By exploiting measurable displacement variables, unmeasurable parameters, including coupled inertia and structural deformation, are inferred, enabling the construction of explicit dynamic models for sub-stages. This framework facilitates virtual sensing and thereby enhances the observability of the motion process.

In addition, an equivalent friction modelling approach is adopted to provide a unified representation of friction effects arising at multiple positions and governed by different friction mechanisms. A position–pressure dual-parameter identification and switching logic is further developed, enabling the establishment of a dynamic model that spans the entire operational process of the mechanism. Experimental results demonstrate that the accuracy of each stage-specific sub-model exceeds 90%, while the overall model accuracy remains stably above 97% under continuous multi-cycle operating conditions, thereby achieving high-fidelity dynamic simulation of the MCS throughout its full process. Detailed procedures and analyses of the related study can be found in Ref. [6].

(2) Hydraulic-Electro-control Model

The electrohydraulic control subsystem is characterized by numerous components and complex parameter coupling. During the research process, model development is often constrained by practical factors such as industrial confidentiality arising from market competition, non-standardized designs, and the difficulty of directly measuring fluid parameter characteristics, which together pose significant challenges to accurate modelling. To address these issues, this study integrates multiple approaches: characteristic curves relating rotational speed to volumetric efficiency and torque based on performance and efficiency samples for the pump; component disassembly, inspection, and dimensional measurement of spool geometry and spring stiffness for the directional control valve; and black-box principle-based validation for the back-pressure valve. By fully accounting for multidisciplinary coupling, as well as nonlinear effects such as temperature, viscosity, and friction, electrohydraulic control subsystem models of the MCS are established.

(3) Integrated Model

Since the MCS couple mechanical, hydraulic, and electrical domains, this study develops an integrated EMH model based on existing subsystems. By coupling these models, a unified multi-domain dynamic simulation platform is established. Here, the electro-control model issues motion commands to the hydraulic model, which simulates pressure and flow and drives the mechanical structure. As the actuator, the mechanical structure feeds back displacement, velocity, and acceleration, enabling the electro-control system to adjust parameters accordingly. The approach, model, and results are shown in FIGURE3.1.

3.2. DRL Construction

Based on the proposed technology architecture, this section elaborates on the construction of the DRL from three aspects: data acquisition, data storage, and data-driven applications.

(1) Data Collection

Data acquisition should be based on the EMH mechanism model of the MCS, in order to identify key parameters and thereby determine the types of data required. These data encompass three aspects: mechanical, hydraulic, and electro-control, as detailed below:

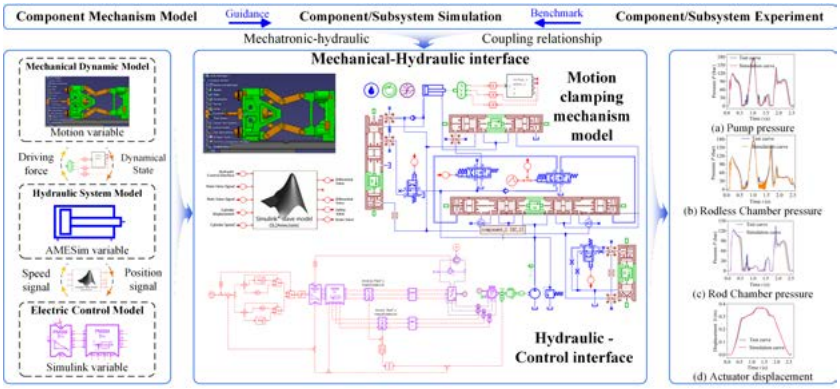

Figure3.1. EMH Combined Simulation Model of the MCS

(1) Mechanical part: Focus on monitoring the displacement-acceleration mapping relationship between the input and output ends of the MCS, as well as the deformation of tie bars, in order to calculate the clamping force and analyse the effects of inertia, friction, and deformation on the system.

(2) Hydraulic part: Monitor the inlet and outlet pressures and flow rates of each hydraulic component to evaluate the effects of hydraulic losses, cavitation, and pressure build-up processes on system performance. Meanwhile, a combined pressure–temperature sensor is installed at the return port of the hydraulic oil tank to enable real-time monitoring of the oil temperature, thereby revealing the intrinsic relationship between temperature rise and performance degradation.

(3) Electro-control part: Monitor motor speed, torque, and solenoid valve enabling signals to analyse the impact of signal delays on system performance.

Considering the diversity of data types, the dispersion of measurement points, and the stringent requirements on transmission cycle and sensitivity, this study employs a fieldbus motion control unit based on the EtherCAT communication protocol as the master-slave transmission device, enabling efficient acquisition and integration of multi-source data. In addition, the Modbus TCP protocol is used to facilitate data and command interactions between the fieldbus system and the host computer platform. Ultimately, a multi-source data acquisition and interaction system is established, in which the fieldbus system serves as the relay, with EtherCAT and Modbus TCP protocols operating collaboratively, as illustrated in FIGURE 3.2.

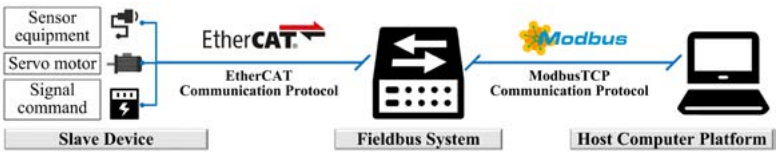

Figure 3.2. Multi-Source Data Acquisition and Interaction System

The real-time performance of data updates is a key indicator of system performance. In this study, the system communication delay was measured to be approximately 50 ms. Compared with the 2.3 s cycle of continuous motion tests and the production operation cycles exceeding 10 s, this delay has a negligible impact on the performance of the digital platform, thereby ensuring the reliability of real-time data interaction.

(2) Data Storage

Efficient data storage and management directly affect the operational efficiency of the digital platform. In this study, system data are categorized into display data and simulation data, and hierarchical storage is implemented using MySQL, with Navicat employed for management.

① Visualization Data: This includes system test and simulation data, encompassing system state parameters such as actuator displacement, clamping force, and component pressures and flow rates, and is primarily used for monitoring and result visualization.

② Simulation Data: This involves the modelling parameters of individual components and the system simulation model, such as spool diameter and damping, which serve as inputs for model computation and simulation analysis.

To enable convenient "one-click simulation" functionality and support comparative analysis of multiple data types, this study integrates a MySQL database communication interface within the Python simulation scripts, allowing for automatic storage and visualization of simulation results. To address the comparative debugging requirements of step-type components, a component parameter modification window was added (see Section 4), supporting parameter adjustment and simulation analysis for components of different specifications, thereby enhancing the flexibility and specificity of performance tuning.

(3) Data Drive

The key to achieving digital-assisted debugging of the MCS lies in the platform's ability to call and drive multi-source data and simulation models, transforming simulation results into visualized optimization guidance and gradually realizing virtual debugging. As shown in Figure 3.3, this study connects the multidisciplinary simulation software AMESim via a software interface, utilizing Python scripts to drive simulation execution while interacting with the database. The specific process is as follows:

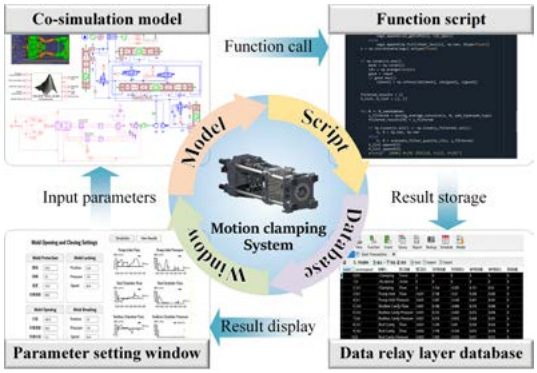

Figure 3.3. Platform-Driven Integrated Simulation Framework Logic

① Parameter Modification: Users adjust component parameters via the platform interface, and the modified data are written to the database through data communication.

② Simulation Execution: The script calls the AMESim simulation model, retrieves the updated parameters from the database, and drives the simulation computation.

③ Data Storage: During simulation, the model dynamically references parameter variables from the database, and upon completion, the results are stored in the database.

④ Visualization Display: The platform retrieves the simulation results and presents them intuitively through the Unity interface, enabling full-process visual interaction for parameter adjustment, simulation execution, and result review.

It is worth noting that the proposed DRL is designed to be protocol-agnostic. Given the widespread use of EtherCAT and Modbus TCP in industrial environments, these protocols are adopted in this study, while the relay layer abstracts raw data into unified data objects. This design enables higher-level industrial communication standards, such as OPC UA, to be integrated as gateway or middleware solutions without affecting the proposed modelling and control optimization approach.

3.3. VL Construction

The VL, serving as the carrier for both the SL and the DRL, not only supports the MCS and integrated data management but also acts as the interface for the digital platform's functional output. This section describes the construction of the VL from three aspects: functional positioning, architecture, and operational logic.

(1) Platform Functionality Positioning

Within the context of achieving virtual equipment commissioning, the platform's functional positioning encompasses three core functions:

① Status Monitoring: Utilizing a 3D model of the IMM in combination with data communication technology, the platform synchronously mirrors the physical system, dynamically presenting the operational process and spatial states of the MCS.

② Virtual Commissioning: Leveraging the simulation model and measurable parameters of the EMH system, the platform maps unmeasurable variables to potential system performance, thereby enhancing transparency in system debugging.

③ Data Management: The platform provides efficient and intuitive data query and analysis capabilities, supports historical data retrieval, and integrates comparative analysis of experimental and simulation data to reveal underlying patterns in system parameter variations, offering a foundation for optimization decisions.

(2) Platform Architecture

Based on the functional positioning, the DRL includes display data and simulation data. Display data are connected to the data acquisition system through experimental data communication, enabling data integration and storage. Simulation data rely on software interfaces to establish communication between the SL and scripts, supporting co-simulation of the MCS, storing computation results, and facilitating comparison between experimental and simulation data.

The status monitoring function maps physical entity data to the experimental data layer via data communication, ensuring synchronous updates between the VL and the PL and enabling intuitive monitoring of system states. The virtual simulation function allows parameter adjustments through the platform and visualizes simulation results, providing support for system optimization. The data management function integrates experimental and simulation data, facilitating data comparison, trend analysis, and optimization decision-making on the platform, thereby enhancing the tunability and optimization capability. The development environment and tools used in this study are listed in TABLE3.1.

Table3.1. Digital Platform System Development Environment and Tools

Item	Describe
Operating System	Window10
Programming Language	C#, Python2.7.15
Open-Source Tool	Numpy, Matplotlib
Database	My SQL8.0, Navicat
Visualization Tool	Unity3D, 3Ds Max, Xchart

4. PLATFORM-ASSISTED MODELING AND CONTROL OPTIMIZATION

This section presents the functional modules of the platform developed based on the aforementioned architecture and, taking the MCS performance degradation induced by oil temperature rise shown in FIGURE 2.1 as a case study, verifies the effectiveness of the proposed technical architecture in system diagnosis and performance optimization.

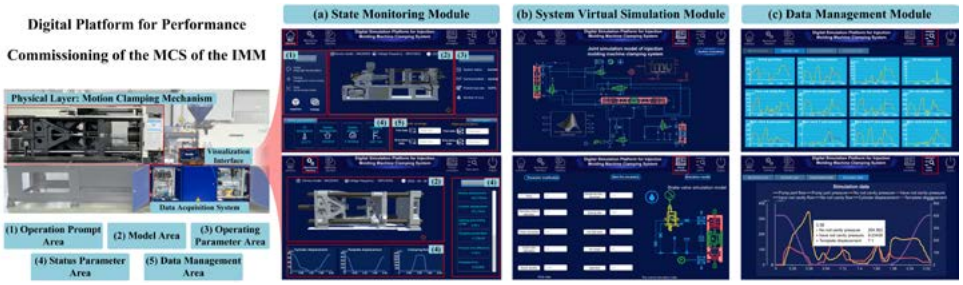

Figure 4.1. Digital Platform Interface of the MCS of IMM

4.1. Platform Functions

The platform takes the MCS as the research object and, through multi-level modelling as well as parameter interaction and analysis, realizes visual representation of system operating states, online evaluation of key parameters, and closed-loop support for the design and commissioning processes, thereby providing a unified tool environment for performance degradation diagnosis and validation of optimization strategies. The overall interface of the platform is shown in FIGURE 4.1.

(a) *State Monitoring and Visualization Function*

The platform integrates state monitoring functions at the system, mechanical, and hydraulic levels. Through the coordinated visualization of three-dimensional models and parameter panels, the operating state of the equipment is presented in an intuitive manner. During system operation, key parameters such as oil temperature, platen displacement, system pressure, and clamping force are updated in real time and synchronously displayed with the motion process. At the mechanical level, the platform directly reflects state variations of the MCS, while at the hydraulic level, dynamic schematic diagrams illustrate hydraulic circuit switching and actuator actions. This enables comprehensive perception of the multi-physical states of the EMH system, providing an intuitive basis for operating condition assessment and anomaly identification.

(b) *System- and Component-Level Virtual Simulation Function*

The platform adopts a hierarchical virtual simulation architecture, enabling parametric simulation and result analysis at both the system and component levels. Based on the system

model, users can adjust key component parameters and trigger corresponding simulation calculations, with the simulation results fed back to the platform in real time for performance evaluation. This functionality establishes a rapid mapping between variations in component parameters and the dynamic response of the system, providing an efficient virtual validation approach for structural design, parameter matching, and performance tuning.

(c) *Data Management and Comparative Analysis Function*

The platform incorporates a unified data management module that enables centralized storage, retrieval, and comparative analysis of experimental and simulation data. Users can access historical data by operating cycle and perform synchronized comparative visualization of multiple categories of system parameters to reveal performance differences under varying operating conditions or parameter configurations. By supporting visualization of multiple physical quantities across multiple coordinate axes, the platform significantly enhances data interpretation efficiency, providing robust data support for system performance degradation analysis and optimization decision-making.

4.2. Optimization Support Based on the Digital Platform

Conventional performance tuning of the MCS in IMM primarily relies on an offline trial-and-error process driven by human experience. This process typically takes directly measurable explicit performance indicators, such as cylinder displacement error and system pressure response, as references, and compensates for performance degradation caused by changes in leakage characteristics, evolution of friction behaviour, and deterioration of actuator dynamic response during long-term operation by repeatedly adjusting parameters including control loop gains, pressure thresholds, or servo pump speed limits. However, this tuning approach is essentially an experience-based correction method relying on outcome feedback, and its effectiveness is highly dependent on the subjective judgment of the operator. In particular, for key influencing factors that are difficult to measure online, their effects can only be indirectly reflected through system-level performance degradation, making it challenging to distinguish whether observed performance variations originate from improper control parameter settings or from the evolution of component intrinsic characteristics under varying operating conditions. As a result, a clear causal mapping between parameter adjustments and system responses is lacking. Owing to these limitations, traditional manual tuning is often characterized by long commissioning cycles and poor reproducibility of parameter settings, and it provides limited support for subsequent mechanism analysis, model refinement, and performance optimization.

This study takes the empirically observed phenomenon of system performance degradation induced by variations in hydraulic oil temperature as the starting point. By combining theoretical derivation and analysis with the mapping capability of a digital platform, a quantitative relationship is established between the viscosity-temperature characteristics of the hydraulic oil, the leakage behaviour of the gear pump, and the corresponding flow equations. On this basis, explicit characterization of pump efficiency variations and the development of a corresponding compensation model are achieved.

As the core driving unit of a servo pump-controlled system, the hydraulic pump plays a decisive role in overall system performance, and its internal leakage is one of the primary factors leading to performance degradation, which is commonly characterized by the pump volumetric efficiency. Owing to the compact structure of gear pumps, the dynamic microscopic clearances and the associated leakage paths that vary with operating conditions

are difficult to measure directly using conventional methods. Therefore, this study adopts an experimental data–driven parameter inverse identification approach to systematically test and model the efficiency characteristics of the pump under different oil temperature, pressure, and rotational speed conditions. Specifically, based on the developed digital platform, multi-condition experimental data and the corresponding simulation results are managed in a unified manner and visualized synchronously. By aligning and analysing key variables such as pump outlet flow rate, pressure, and rotational speed, and by minimizing the discrepancy between experimental measurements and model outputs, the key parameters related to internal leakage in the flow rate equation are inversely identified. In this way, a quantitative mapping between pump performance indices and theoretical model parameters is established. Consequently, the flow rate equation of the engineering-oriented internal gear pump can be redefined as:

$$Q_{\mathrm{a}} = v_{\mathrm{c}} n_{\mathrm{p}} \cdot \left[1 - \frac{C_{\mathrm{leak}} \cdot \Delta p}{\mu(T) \cdot v_{\mathrm{c}} n_{\mathrm{p}}} \right] \tag{4.1}$$

where, Q_{a} denotes the actual output flow rate, v_{c} is the constant displacement of the pump, n_{p} represents the actual rotational speed of the pump, Δp is the pressure difference between the high-pressure and low-pressure chambers, μ(T) denotes the dynamic viscosity of the hydraulic oil as a function of temperature, and C_{leak} is the fitted leakage coefficient.

The volumetric efficiency of the pump can then be defined as:

$$\eta_{\mathrm{v}} = \frac{Q_{\mathrm{a}}}{v_{\mathrm{c}} \cdot n_{\mathrm{p}}} = 1 - \frac{C_{\mathrm{leak}} \cdot \Delta p}{\mu(T) \cdot v_{\mathrm{c}} n_{\mathrm{p}}} \tag{4.2}$$

Equation (4.2) indicates that the pump's flow delivery capability is primarily influenced by the combined effects of rotational speed n_{p}, hydraulic oil viscosity μ(T), and pressure differential Δp. Among these factors, the temperature-dependent evolution of oil viscosity is difficult to measure directly and represents a key source of uncertainty affecting the accuracy of pump volumetric efficiency estimation. To address this issue, the digital platform was employed to uniformly collect and manage system operating data for the hydraulic oil used (ISO VG 46) under varying temperature conditions. A parametric model of the relationship between oil viscosity and temperature was then developed, yielding an exponential viscosity-temperature empirical correlation, as shown in FIGURE 4.2 When this viscosity-temperature model is explicitly embedded in the controller, the current oil viscosity can be continuously estimated based on real-time readings from a temperature sensor, and, in combination with Equation (4.2), the pump volumetric efficiency η_{v} can be calculated and compensated online.

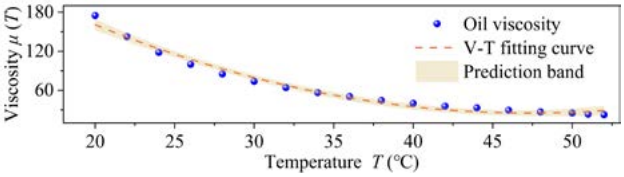

Figure 4.2. Viscosity-temperature fitting curve of hydraulic oil

4.3. Platform Performance

By integrating the oil viscosity–temperature model into the controller, this study introduces a pump flow compensation channel based on the viscosity-temperature model on top of the

original system's position-based PID controller, aiming to mitigate system positioning accuracy degradation caused by oil temperature rise. The corresponding framework is illustrated in FIGURE 4.3.

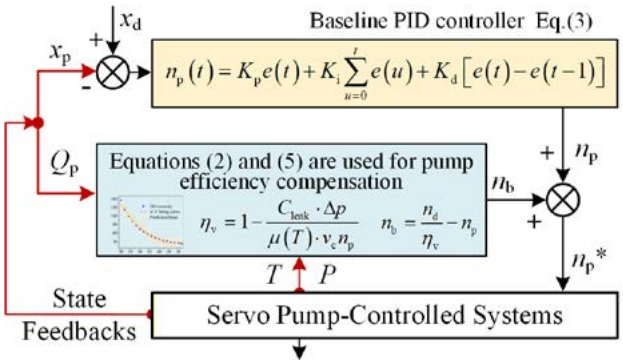

Figure 4.3. Pump Flow Compensation Strategy Based on the Platform-Fitted V-T Model

PID control is a classical method for servo pump-controlled systems. In the original system, position-tracking errors are constructed based on discretely sampled position signals, and the control law can be expressed as:

$$n(t) = K_p e(t) + K_i \sum_{u=0}^{t} e(u) + K_d \left[e(t) - e(t-1) \right] \tag{4.3}$$

where, e(t) denotes the tracking error, K_p, K_i, and K_d are the controller tuning parameters, and n(t) represents the controller output. The tuning parameters are set based on engineering practice and remain fixed.

Using the volumetric efficiency η_v estimated from the viscosity–temperature model, the compensation channel adjusts the pump command to offset the effects of leakage. Specifically, when the baseline PID controller requests a desired displacement x_d (or n_d), the compensation channel proportionally amplifies the speed command so that the actual flow Q_p closely matches the ideal demand $Q_d = n_d \cdot v_c$. The corresponding compensation flow Q_b can then be obtained as the reciprocal of the pump efficiency:

$$Q_b = Q_p^* - Q_p = \frac{Q_d}{\eta_v} - Q_p = \frac{Q_d \cdot \mu(T) \cdot v_c n_p}{\mu(T) \cdot v_c n_p - C_{leak} \cdot \Delta p} - Q_p \tag{4.4}$$

where Q_p* is the compensated flow, such that $Q_p = \eta_v \cdot Q_p^* = Q_d$.

Equivalently, the speed command of the servo motor can be scaled by the reciprocal of the efficiency to obtain the compensated speed n_b as:

$$n_b = n_p^* - n_p = \frac{n_d}{\eta_v} - n_p \tag{4.5}$$

where n_p* denotes the compensated rotational speed.

As illustrated in FIGURE 4.3, this channel functions as a parallel feedforward path, taking the baseline output n_p along with the current temperature T and pressure differential Δp as inputs to the compensation module, which outputs the gain-corrected command n_b. When η_v<1, n_b increases the pump speed appropriately to compensate for the flow deficit.

4.4. Performance Evaluation

To validate performance, multiple representative operating conditions were designed, under each of which 4,000 motion cycles were executed and data were collected for more than 4 hours in total. This design sufficiently captures the slow-varying characteristics of oil temperature during long-term operation, thereby verifying the general applicability and superiority of the platform and the proposed method under different conditions. The operating conditions were defined by varying actuator stroke and velocity, including a typical application condition with a 378 mm stroke, a short-stroke condition of 290 mm, a long-stroke condition of 406 mm, and a high-speed motion condition under the same long-stroke configuration. The detailed parameters of each condition are listed in TABLE 4.1, where the stroke and speed were set as percentages of the maximum hydraulic actuator stroke specified in the test standard [20]. Under the same temperature range, the tuning results obtained for different operating conditions are shown in FIGURE 4.4.

Table4.1. Detailed Experimental Operating Conditions

Scene	Distance (mm)	Velocity percentage	Purpose
1	378	80%	Frequent
2	190	70%	Short distance
3	406	70%	Long distance
4	406	99%	Speediness

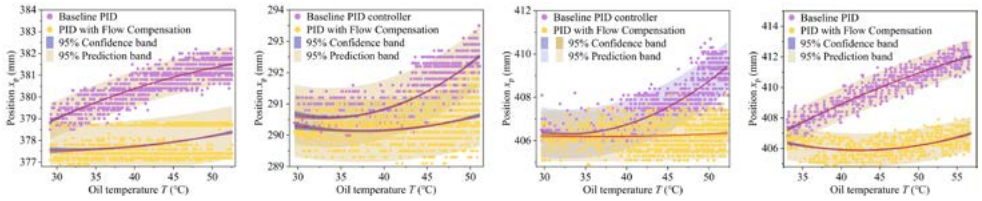

Figure4.4. Comparison of optimization effects for MCS. (a) Common operating condition. (b) Short-stroke condition. (c) Long-stroke condition. (d) High-speed condition

A cost function is constructed with the objective of minimizing the displacement tracking error to evaluate the optimization performance, and its magnitude of the real system under long-term operating conditions. The formulation is given as follows:

$$J = \sum_{k=1}^{N} \frac{\left(x_{\mathrm{p}} - x_{\mathrm{d}}\right)^2}{N} \tag{4.6}$$

where x_{p} denotes the actual terminal displacement of the system in the k-th experiment, and x_{d} represents the desired terminal displacement.

Table 4.2. The minimum cost values before and after optimization

Type	Common Operating	Short-Stroke	Long-Stroke	High-speed
J_{b}	7.61	2.32	3.75	18.33
J_{c}	0.45	0.37	0.41	0.44
R	94.1%	84.1%	89.1%	97.6%

With the minimization of the cost function J as the optimization objective, the minimum cost values corresponding to all tested configurations obtained from the displacement

tracking error data are summarized in TABLE4.2. Compared with the cost function of the baseline system J_b, the optimized cost function J_c achieved using the digital platform is reduced by 94.1%, 84.1%, 89.1%, and 97.6%, respectively, demonstrating a significant improvement in system tracking accuracy.

5. CONCLUSION

This study addresses the issue of performance degradation in the MCS of IMM under temperature rise conditions by proposing a digital platform–supported approach for performance modelling and control optimization. By developing a platform that integrates data acquisition, simulation analysis, and data review, unified analysis of system operating data and model predictions is achieved. Focusing on the reduction of pump efficiency and deterioration of system positioning accuracy caused by temperature-dependent oil viscosity, the approach employs the digital platform for parameter mapping, inverse identification, and implicit indicator extraction to realize an engineering-oriented redefinition of pump leakage characteristics and explicitly incorporates the viscosity-temperature model into system modelling. On this basis, a pump flow compensation channel is introduced into the original position-based PID control structure to implement feedforward correction for the effects of oil temperature variation. Experimental results demonstrate that the proposed method significantly improves system positioning accuracy under multiple operating conditions, providing an effective interactive control optimization strategy for performance degradation driven by unmeasurable latent variables in EMH systems. Moreover, the proposed digital platform architecture and modelling methodology are designed with strong engineering scalability and system-level compatibility, enabling seamless alignment with both existing and emerging industrial digitalization standards. This provides a solid foundation for future integration with standardized communication frameworks, digital twin architectures, and collaborative simulation environments.

Abstract.

Downsizing of hydraulic power units means installing the same hydraulic power within a smaller footprint or increasing hydraulic power within the same footprint.

To achieve this, knowledge and influencing the condition of the hydraulic fluid and the tank flow are crucial. The condition of the hydraulic fluid depends primarily on dispersed contaminations by air bubbles, water droplets, and dirt particles. All of these should be separated in the reservoir, which can be significantly improved through suitable flow guidance. The resulting improved fluid condition contributes to significant resource savings over the entire product life cycle, thus generating tangible economic and technological advantages.

The difficulties in implementation lie, on the practical side, mainly in the strong influence of the system's operating conditions, such as pressure and flow rate curves, and on the modeling side, due to the complex properties of hydraulic fluids, which also vary across the entire spectrum of fluid classes. Both challenges often prevent generally valid statements and therefore require a multitude of CFD simulations for various systems and even the same systems under different load situations.

We combine the solution to the resulting high demands on the model quality and the performance of the numerical method in bTrack, our in-house solver for dispersed flows. In this presentation, we provide an overview of the physical and numerical fundamentals of bTrack. We start with simple equations of motion and extend these continuously with algorithms capturing more complex phenomena like collision, breakup and coalescence. We also present and discuss coupling strategies between the disperse and continuous phase implemented in bTrack. The performance and efficiency of the models are presented and discussed using various application examples for bubble, particle, and droplet flows in tanks.

1. INTRODUCTION

The hydraulic industry faces increasing pressure to reduce the footprint and weight of hydraulic power units while maintaining or increasing performance. This downsizing trend is driven by demands for improved energy efficiency, reduced material costs, and enhanced system integration in mobile and industrial applications. A critical component is the hydraulic reservoir, which traditionally has been sized conservatively to ensure adequate fluid conditioning, heat dissipation, and contaminant settling. Significant reservoir size reduction is only feasible if fluid quality can be maintained despite reduced residence times and settling volumes. Hydraulic fluid condition is strongly determined by three types of dispersed contaminations: entrained air bubbles, emulsified water droplets, and solid dirt particles. Air enters through turbulent mixing at free surfaces, and suction-side leakage; water through condensation and seal leakage; and particles through external ingress and internal wear.

These dispersed contaminants cause numerous detrimental effects on hydraulic system performance and durability. Entrained air reduces the effective bulk modulus, leading to spongy system response, reduced positioning accuracy, and increased noise and vibration as well as oxidation and Diesel effect. Water contamination accelerates fluid degradation through hydrolysis, promotes corrosion of metallic components, reduces lubrication effectiveness, and catalyzes oxidation processes. Solid particles cause abrasive wear on precision surfaces, leading to internal leakage, reduced efficiency, and component failure.

The extent of air and water contamination strongly depends on both fluid properties and operating conditions. Air solubility in hydraulic fluids follows Henry's law, making gas absorption and release pressure-dependent phenomena. This can be illustrated by a carbonated mineral water bottle: when sealed under pressure, carbon dioxide remains dissolved; upon opening, pressure drops and gas bubbles form and rise. Similarly, hydraulic fluid returning from high-pressure zones to the atmospheric reservoir experiences pressure reduction, causing dissolved air to nucleate into bubbles requiring separation. Water solubility and emulsion stability are likewise influenced by temperature, pressure, and fluid additive packages, with mineral oils, synthetic esters, and water-glycol fluids exhibiting drastically different behaviors.

Successful reservoir downsizing through improved contamination control offers substantial lifecycle benefits. Reduced reservoir volume directly translates to lower fluid inventory, decreased system weight, and smaller footprints – critical advantages in mobile hydraulics where space and weight constraints are severe. Improved fluid quality extends component life by reducing wear rates, increase maintenance intervals by slowing fluid degradation, and enhances system reliability through consistent performance. Economically, these improvements reduce both initial investment and total cost of ownership. Environmental benefits include reduced fluid consumption and lower energy requirements from improved system efficiency. Furthermore, high fluid quality enables tighter manufacturing tolerances

in hydraulic components, permitting higher operating pressures and power densities – reinforcing downsizing objectives.

Effective downsizing requires accurate prediction of fluid flow patterns and contaminant separation efficiency within reservoirs. The reservoir must facilitate air bubble and solid particle separation while providing adequate deaeration surface, appropriate flow velocities to prevent particle resuspension, and sufficient residence time for settling. Computational Fluid Dynamics (CFD) enables optimization of reservoir designs, flow guidance structures, baffle arrangements, and inlet/outlet configurations without costly prototyping. However, reservoir flows present significant modeling challenges. The flow is inherently three-dimensional and highly unsteady, driven by turbulent structures and time-varying boundary conditions reflecting realistic operation. During typical operation, volume flow rates entering the reservoir vary by orders of magnitude depending on actuator movements, valve switching, and pump displacement changes. These transient conditions continuously alter the flow field, affecting particle trajectories and separation efficiency in ways not captured by steady-state simulations. Additionally, the wide range of hydraulic fluid types – from mineral oils to water-based fluids – each with distinct density, viscosity, surface tension, and foaming characteristics, prevents universal design rules.

Several numerical approaches exist for modeling dispersed multiphase flows. The Euler-Euler approach treats both phases as interpenetrating continua, solving conservation equations for each with interphase exchange terms. This method is computationally efficient at high volume fractions but requires closure models for interfacial forces and cannot easily track individual particle characteristics. The Euler-Lagrange approach treats the continuous phase as a continuum while tracking individual particles or bubbles as discrete entities moving according to Newton's equations. This method naturally accommodates polydisperse size distributions, enables direct implementation of collision, breakup, and coalescence models, and provides detailed particle trajectory statistics. For dilute to moderately dense dispersed flows – typical of hydraulic reservoirs where volume fractions generally remain below 10% – Euler-Lagrange offers optimal balance between physical fidelity and computational efficiency.

We employ a three-dimensional CFD approach combining Eulerian description of the continuous phase with Lagrangian tracking of dispersed contaminants. This framework captures complex, transient three-dimensional reservoir flow structures while resolving trajectories of individual air bubbles, water droplets, and solid particles. Lagrangian tracking naturally accounts for size-dependent separation, enables physically sound particle-particle and particle-wall interaction models, and facilitates bubble coalescence and breakup submodels. Two-way coupling ensures dispersed contaminants appropriately modify continuous phase momentum and turbulence fields, essential for accurate prediction at higher concentrations. This methodology is implemented in our in-house solver bTrack, developed and validated specifically for dispersed flows in hydraulic systems. bTrack is well matured and has been used in the analysis and optimization of hydraulic power units of Bosch Rexroth since more than a decade. Since the

Figure 1: mycro logo

beginning, it has been an essential part of the myCro Downsizing toolbox [1] and is today a further growing key factor of its success contributing to both customer-specific ETO applications as well as Bosch Rexroth Standard HPU solutions.

2. METHODOLOGY

The continuous fluid phase is described by the incompressible Navier-Stokes equations for mass and momentum conservation:

$$\nabla \cdot \mathbf{u} = 0$$

$$\frac{\partial}{\partial t}\rho \boldsymbol{u} + \boldsymbol{\nabla} \cdot (\rho \boldsymbol{u}\boldsymbol{u}) = -\boldsymbol{\nabla} \mathrm{p} + \boldsymbol{\nabla} \cdot \left(2\mu_{eff}\boldsymbol{S}\right) + \rho\, \boldsymbol{g} + \boldsymbol{S}_{b,mom}$$

with $\boldsymbol{u}$ the fluid velocity, p the pressure on the Euler grid, $\boldsymbol{S} = \frac{1}{2}[\nabla \boldsymbol{u} + (\nabla \boldsymbol{u})^T]$ the deformation rate tensor. The momentum source term $\boldsymbol{S}_{b,mom}$ are caused from the bubbles and it is nonzero only in case of two-way coupling. The density is the pure liquid density $\rho = \rho_l$ and assumed constant, throughout. The viscosity is the liquid viscosity $\mu_{eff} = \mu_l$ in case of a laminar flow. These equations are solved on a 3D domain with Cartesian coordinates. Turbulence is modeled using RANS or LES approaches.

The bubble velocity is computed by solving an ordinary differential equation for the linear momentum considering different forces on the bubble. Generally, these forces may be divided into fluid dynamic forces (e.g. drag, pressure, virtual mass, and Saffman forces) and field forces (gravity, electrostatic forces, etc.). The new bubble position is then obtained in each Lagrange time step by integrating the bubble velocity so that the equations read

$$\frac{d\boldsymbol{x}_b}{dt} = \boldsymbol{u}_b$$

$$m_b \frac{d\boldsymbol{u}_b}{dt} = \boldsymbol{F}_D + \boldsymbol{F}_L + \boldsymbol{F}_{vm} + \boldsymbol{F}_p + \boldsymbol{F}_g + \boldsymbol{F}_{coll}$$

where $\boldsymbol{x}_b$ is the bubble position vector, m_b the bubble mass and $\boldsymbol{u}_b$ the bubble velocity vector. The forces on the right-hand side are drag force, lift force, virtual mass force, pressure gradient force, and gravity, respectively. For solid particles, it may be required to account for their rotation by additionally solving an equation of the angular momentum. Due to the extremely small mass of bubbles and their behavior during collisions, this is typically not considered.

The drag force results from the flow around the particle and can be expressed with the following equation

$$F_D = \frac{3}{4} m_b \frac{\rho_l}{\rho_b} \frac{C_D}{D_b} (\boldsymbol{u} - \boldsymbol{u}_b)|\boldsymbol{u} - \boldsymbol{u}_b|$$

where C_D is the empirical drag coefficient, and D_b is the bubble diameter. Because the drag force is one of the most important forces for disperse flows the right choice of the drag coefficient is crucial. There are several correlations proposed in literature, e.g. [2].

The lift force is caused by a shear flow around the bubble. It acts perpendicularly to the direction of the flow and can be expressed as proposed by [3].

$$F_L = C_L m_b \frac{\rho_l}{\rho_b}[(\boldsymbol{u} - \boldsymbol{u}_b) \times (\nabla \times \boldsymbol{u})]$$

where the lift force coefficient depends on the deformation of the bubble or droplet and can be expressed by the correlation of [4].

The virtual mass force accounts for the additional work that the bubble performs to accelerate or decelerate the surrounding fluid and can be written

$$\boldsymbol{F}_{vm} = C_{vm} m_b \frac{\rho_l}{\rho_b}\left(\frac{\mathrm{D}\boldsymbol{u}}{\mathrm{D}t} - \frac{d\boldsymbol{u}_b}{dt}\right)$$

like proposed by [5]. The virtual mass force coefficient is typically modeled constant.

The sum of the pressure force and the gravity force can be expressed as [6]

$$\boldsymbol{F}_p + \boldsymbol{F}_g = m_b \frac{\rho_l}{\rho_b}\frac{\mathrm{D}\boldsymbol{u}}{\mathrm{D}t} + m_b \boldsymbol{g}\left(1 - \frac{\rho_l}{\rho_b}\right).$$

The collision force can be incorporated using hard-sphere or soft-sphere collision paradigm. All given equations are relying on choosing the respective coefficients carefully. Most of the coefficients from literature assumes ideal isolated lab conditions or deal with water or purified fluids. Due to the strong influence of the fluid properties and the deviation to hydraulic fluids an arbitrary error in prediction is introduced. To avoid these, the used relevant coefficients are based on experiments with hydraulic fluids.

Numerical Framework

The bTrack solver is an in-house tool designed for disperse multiphase flows in hydraulic systems, operating standalone or two-way coupled with ANSYS Fluent using first and second-order time integration. The solver is fully parallelized using MPI and written in Python and C, leading to both great flexibility and high performance. The software architecture is modular and designed to intercept and influence the operation at all relevant points during simulation to maximize flexibility during model development. Setup, monitoring and output files follow common open-source standards. Setup creation is simplified via a simple UI reducing input errors. The output format is also chosen to work seamlessly with Paraview. bTrack can be fully controlled via a command line interface, which makes it very suitable for parameter studies and automation.

In case of two-way coupling interpolation schemes from disperse to continuous phase and vice-versa are required. Besides robust and well validated schemes for interpolation of volume fraction to the Cartesian grid and undisturbed liquid velocity to each Lagrangian particle we also developed and validated interpolation schemes reducing computational effort.

Modelling turbulence in multiphase flows can be computational expensive due to the interplay between the turbulent continuous flow and the disperse phase, because it could demand a fully two-way coupled approach. To limit the effort while retaining the accuracy carefully modelling the effects is important. bTrack incorporates models for bubble induced turbulence to modify turbulent characteristics of the continuous phase and an advanced random walk model to take turbulent fluctuations into account for bubble motion calculation. bTrack relies on local fluid and flow properties by default, so that multiphase

flows with spatial and/or temporal varying properties like density, temperature, viscosity, etc. can also be simulated. Based on local flow properties bTrack can simulate bubble coalescence, deformation and breakup. As a foundation of coalescence and collision an efficient detection kernel based on Sweep-and-prune algorithm is implemented. An overview about the features can be found here [7, 8].

3. RESULTS

Within this chapter we present several reservoir flows where the capabilities of bTrack can be shown. Figure 2 shows a typical reservoir flow. The flow inside is highly transient caused by two aspects: boundary conditions and flow instabilities. The typical load cycle of an application leads to a time dependent flow and pressure profile at each inlet or outlet of the reservoir. Unsteadiness and magnitude of flow rate and pressure lead then to flow instabilities inside the reservoir. Our experience has shown that capturing these effects is crucial in many applications. mycro optimized reservoirs are intended to work even with large oil volume changes, so called working or pendulum volume, inside the reservoir. To capture all relevant effects a multiphase simulation is often necessary. In figure 2 bTrack is used to calculate bubble motion and behaviour of different sizes within the oil volume, while the oil and air phase and their interface are simulated via a Volume-of-Fluid approach. bTrack can not only output all raw data but can compute many relevant characteristics and statistics during simulation. This saves disk space and speeds up post processing.

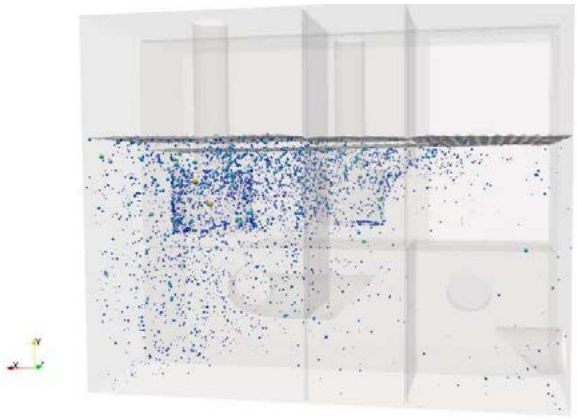

Figure 2: Transient multiphase flow

In figure 3 a bTrack water droplet simulation is shown. The droplets enter the reservoir through one of the pipes mounted from the top. The flow in this example is from the top to the bottom. Of main interest here is the accumulation of water droplets leading to puddle depending on the different vertical reservoir sections. Due to the Lagrangian approach of bTrack the motion and position of each droplet can be calculated in detail. Using statistical methods, the locations and extensions of puddles can be predicted. These predictions were in good agreement with experimental

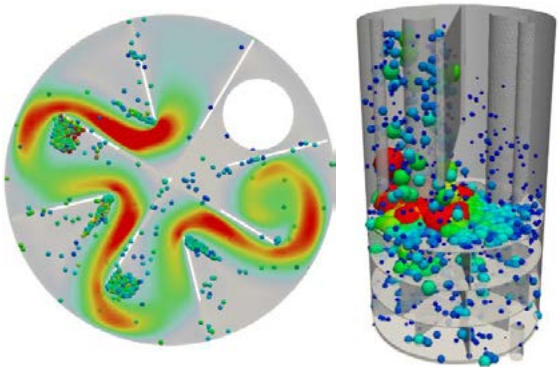

Figure 3: bTrack droplet simulation

investigations. The knowledge of the motion and position of disperse pollutions, like droplets, bubbles or particles are used in application dependent reservoir design.

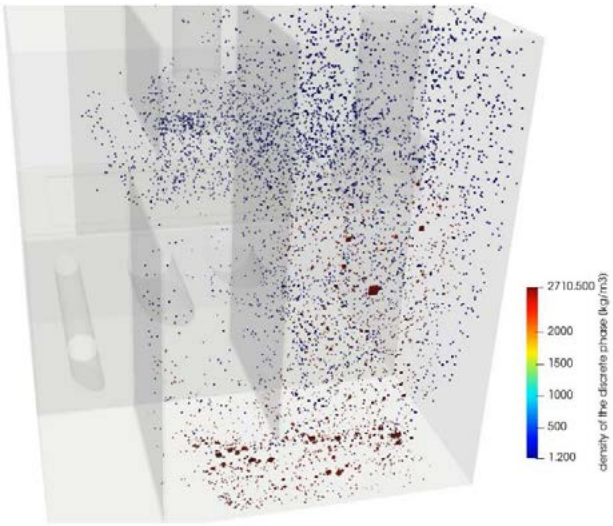

Figure 4: bTrack calculates multiple disperse phases

Figure 4 demonstrates how bTrack can handle multiple disperse phases at the same time, which enables for multi objective optimization of contaminant separation. In the given application metal particles in red are settling at the bottom, while air bubbles in blue rise to the oil surface. Both phases are influencing the velocity of continuous phase, the oil flow. This fact impacts the settling and rising times and are important for reservoir design and sizing. Each disperse phase can be described with their own properties, their own physical models and model constants. This allows for very accurate predictions and saves time.

Although the separation and settling takes place in the reservoir the flow inside is heavily depending on the application. One of these applications is shown in figure 5. If necessary bTrack is not limited to flows inside the reservoir. Disperse flows in suction and return lines can also be regarded in the same simulation, because disperse phase models, e.g. for bubble size, are taking local flow properties like pressure, temperature, density, volume fraction, etc. and numerical parameters like CFL number into account. This means that one description of a disperse phase can be valid for a wide range of flow conditions.

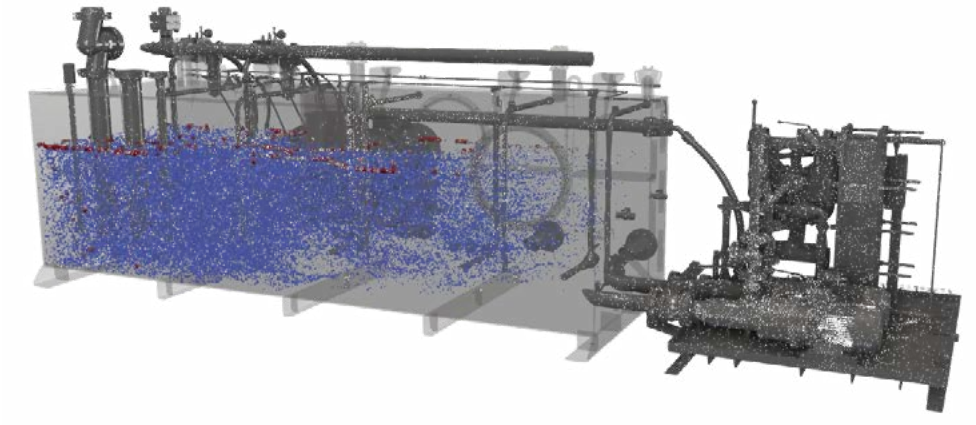

Figure 5: bTrack can capture flow in return and suction lines

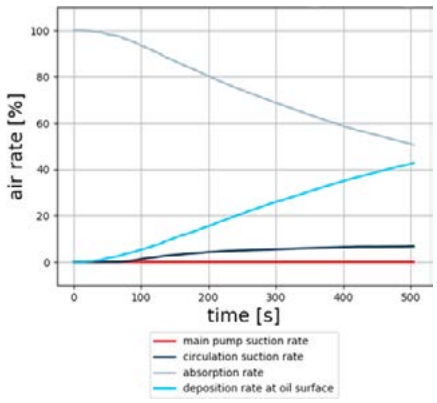

Figure 6: Air rate statistics

Detailed statistics like the air rates shown in figure 6 are calculated by default in bTrack and used for competitive design studies as well as in the analysis how robust a design is under changing fluid, ambient or operating conditions. These statistics are done for test bubble size spectra derived from several inhouse air release experiments for different hydraulic fluids. Application specific bubble size spectra are the foundation of reliable prediction.

Mycro reservoirs must fulfill highest standards and pass bTrack simulations with most conservative bubble size spectra.

4. CONCLUSION AND OUTLOOK

In this work we presented the capabilities of our three-dimensional in-house solver bTrack for simulation of disperse multiphase flows. bTrack is used since more than one decade in analysis and optimization of hydraulic power units and is integral part of mycro, the downsizing toolbox of Bosch Rexroth. The huge amount of implemented models, the modular architecture and robust and performant numeric schemes makes it suitable for a wide range of applications. Experimental campaigns to derive new models, integrate new fluids and improve numerics are continuously carried out, to improve accuracy and reduce computational effort.

Abstract.

SMS group GmbH presents a hierarchical health tree condition monitoring system specifically engineered for brownfield industrial hydraulic installations, where brownfield installations refers to the process of upgrading, expanding, or re-purposing existing facilities, for example by integrating online monitoring technologies or modern control systems. Based on SMS group's long-term OEM and service experience in the metal industry, this paper presents a framework to encode expert knowledge into an automated monitoring architecture that avoids the extensive labelled datasets required by many machine-learning approaches. The framework aggregates sensor data and operational parameters into a single, transparent Health Index, providing intuitive, real-time feedback for both maintenance and production crews. A novel, aggressive multiplication logic ensures that any component degradation is immediately reflected at the system level, preventing the failure-masking effects of conventional aggregation schemes.

The solution was developed and validated on a 1970s-era rolling mill, designed by SMS group GmbH. The implementation required only a minimal set of strategically placed sensors and a few hours of planned downtime for installation. The results confirm robust fault detection under realistic industrial conditions, thus leading to a significant reduction in unplanned downtime and a significant resource efficiency improvement. Furthermore, the system is able to quantify gradual degradation trends - a practical foundation for future predictive maintenance programs in challenging brownfield environments.

1. INTRODUCTION

Complex servo-hydraulic systems have been installed widely in rolling mills since the early 1970s to control the rolling force respectively the roll gap among other functions. With the demand for higher product quality and output, an increasing number of hydraulic functions were introduced into rolling mills, many of which were retrofitted into existing plants. This longevity, however, creates a fundamental tension: while the core machinery endures for decades, its components—comprised of countless moving parts—are inherently subject to continuous wear.

To increase overall equipment effectiveness (OEE) and product quality, a well-maintained hydraulic system is key. The above-mentioned brownfield hydraulic systems, which have grown organically over decades, present a formidable challenge for modernization. They are complex, hydraulically coupled networks of components from various eras, operating under immense pressure to maintain non-stop production.

This research builds upon an SMS group GmbH patent titled 'Method for monitoring the condition of a hydraulic system of a metal forming plant and condition-monitoring device' [1]. The scientific and technical realization of this patented concept was driven by a unique trilateral collaboration: SMS group GmbH, as the original equipment manufacturer (OEM) with decades of service experience, providing the foundational equipment know-how and an operator of a brownfield SMS plant contributing the critical perspective on real-world customer needs. This combined industrial expertise was then scientifically processed by the Chair of Fluid-Mechatronic Systems (TU Dresden), allowing to develop the methodology and implementation described in chapter 4 and following.

The central question this work addresses is how to bridge the gap between sophisticated maintenance experience and the need for digital, systematic monitoring in an environment where resources are severely constrained. Our answer is rooted in the formalization of decades of hands-on experience from maintenance and commissioning experts within the SMS group GmbH. This deep, practical knowledge is the essential ingredient to translate the complex, often tacit, operational experience from a customer's production environment into a systematic, digital assessment. Prevailing condition monitoring paradigms often prove unsuitable for this context. Approaches rooted in machine learning and artificial intelligence frequently require vast amounts of labelled fault data. This prerequisite fundamentally clashes with the reality of economically viable brownfield systems for two reasons: first, fault states are by necessity rare, making such data inherently scarce; second, their root causes are often obscured by complex system-level interactions that defy simple generalization. This data scarcity and ambiguity often result in “black box” models that are met with distrust by experienced maintenance crews [2]. While valuable for algorithmic development, solutions demonstrated on laboratory test rigs under controlled conditions often fail to translate to the operational volatility of a real factory floor.

Indeed, sophisticated approaches like hierarchical health index frameworks have been successfully implemented in data-rich sectors like semiconductor manufacturing [3]. However, these successes are typically enabled by extensive sensor networks and dedicated data science teams capable of managing complex statistical aggregation methods, such as the Analytic Hierarchy Process (AHP). This creates an economic and logistical barrier that is insurmountable for most legacy brownfield plants. Furthermore, these methods often

involve complex weighting debates and can mask critical single point degradations through averaging.

As the SMS group GmbH, we are proud to introduce an elegant approach to implement condition monitoring for existing hydraulic systems: a hierarchical framework designed specifically for resource-constrained, expert-driven environments in brownfield applications of the SMS group GmbH. With this method, we are able to elevate operation of old plants to a new level of availability. For the rolling mill, a reliable operation of the hydraulic system is of absolute importance. Therefore, this paper describes the approach to assessing “Operational Production Health” rather than monitoring single component wear. An 80% worn pump, for example, may still provide 100% production health if it reliably meets the system’s current operational demands. Our methodology enables the direct encoding of decades of maintenance expertise into intuitive, transparent operational boundaries. Through a principle of aggressive bottom-up multiplication, any deviation from these expert-defined boundaries at the lowest level immediately impacts the overall system health score. This deliberate choice prevents the masking effects common in weighted aggregation schemes [3], where a single critical failure can be statistically obscured by a majority of healthy components. By ensuring that one bad item "pulls down" the entire branch, we allow the operator to view the tree in a folded state without fear of missing a hidden fault, thereby reducing cognitive overload and allowing for focused troubleshooting only when necessary.

For a more detailed evaluation of the machine condition, the system can also provide further data on individual component wear. This is important for maintenance planning and will be further developed and described in future publications.

This work presents the design, implementation, and results of this framework on a 1970s-era rolling mill hydraulic system. We demonstrate that with the strategic addition of only a few sensors, a comprehensive, scalable, and trustworthy condition monitoring system can be built. The primary contributions are:

- A methodology for capturing and digitalizing expert knowledge without programming.
- A hierarchical aggregation model based on multiplication that ensures transparency and prevents failure masking.
- A clear distinction between component wear and production health, tailored for brownfield systems.
- A practical, module-by-module implementation strategy that minimizes risk and investment.

The following sections will detail the state of the art, present the methodology, describe its implementation and results, and discuss the implications of this approach for the sustainable operation of aging industrial assets.

2. STATE OF THE ART AND RELATED WORK

The field of condition monitoring is vast, but its application to brownfield hydraulic systems require navigating a specific set of challenges. Following established taxonomies, monitoring approaches can be broadly categorized as model-based, signal-based (including

data-driven methods), and knowledge-based. The existing literature can be reviewed through this lens to highlight the specific gap our work addresses.

2.1. Data-Driven and Model-Based Approaches

Condition monitoring approaches are often categorized as either model-based, requiring deep system knowledge, or data-driven, relying on historical process data [4]. Data-driven condition monitoring, particularly using machine learning, represents the most active area of research. The typical workflow involves detecting anomalies, diagnosing their location, and predicting the severity of the damage [5]. However, the success of these methods is critically dependent on the availability of large, comprehensive, and accurately labelled datasets. This prerequisite is a major obstacle in the context of brownfield industrial plants, where historical fault data is sparse or non-existent [6]. Researchers have explicitly acknowledged this "lack of data problem" as a fundamental hurdle, showing that classifiers trained only on simple, single-site damage data struggle to reliably identify more complex, multiple-site fault scenarios [7]. Much of the research is conducted using public benchmark datasets generated on laboratory test rigs, such as the widely used hydraulic system dataset from Helwig et al. [8]. The reviewed study predominantly utilizes machine learning and signal processing techniques. Although effective for pattern recognition, these approaches lack a physical basis, rendering them highly sensitive to noisy or anomalous measurements that may not reflect actual failures or performance degradation.

While invaluable for comparing algorithms, these datasets cannot capture the environmental noise and unique failure modes of a specific industrial installation. More complex "Big Data" frameworks [9], while powerful, assume a level of data velocity and IT infrastructure that is simply not present in the target environment.

Model-based approaches, such as those using Unscented Kalman Filters, offer an alternative by comparing sensor readings to the output of a mathematical system model. They can achieve excellent results in detecting and isolating faults with minimal sensor sets in real industrial machines [10]. However, their primary drawback is the significant upfront effort required to develop an accurate physical model, which is prohibitively complex for an organically grown system with components from different manufacturers and decades of undocumented modifications. Our work positions itself as a hybrid, knowledge-based approach, using data but relying on expert-defined rules rather than statistical models.

2.2. Hierarchical Health Indices

The concept of aggregating multiple sensor inputs into a single, hierarchical health index is an established practice for managing complex assets. Lee et al. developed a comprehensive Equipment Health Index (EHI) framework for the semiconductor industry, which successfully enables real-time monitoring of thousands of machines. It uses a hierarchical equipment structure which relies on statistical process control charts at the leaf level and uses AHP for weighted aggregation. This introduces a layer of statistical complexity and necessitates expert consensus on weighting factors, a process our methodology deliberately avoids.

Similarly, Yuan et al. proposed a Fuzzy Analytic Hierarchy Process (FAHP) to evaluate the health of gas insulated switchgear in power plants [11]. This method also leverages a

hierarchical structure and incorporates expert knowledge to define the hierarchy and pairwise comparison matrices. While this validates the use of expert input, it again depends on a complex, weighted aggregation logic that can obscure the impact of a single critical failure and is less intuitive for maintenance personnel without a background in fuzzy logic.

2.3. The Research Gap and Our Contribution

While the literature provides powerful tools for component-specific monitoring and sophisticated frameworks for data-rich environments, a critical gap remains. There is no established methodology that unifies decentralized expert knowledge into a single, transparent system health indicator for brownfield hydraulic systems under severe resource constraints. Existing hierarchical methods rely on complex statistical or weighted aggregations that are ill-suited for production environments where a single failure can halt operations and where trust in the system is paramount.

Furthermore, many data-driven approaches implicitly shift a significant burden onto domain experts: the selection and engineering of relevant features. This is a time-consuming task that experts are often unwilling or unable to perform, creating a bottleneck. Moreover, statistical models are notoriously brittle; their performance degrades when the system's behaviour changes due to modifications or new operational patterns, a common occurrence in brownfield plants, leading to false alarms and a loss of trust.

This paper closes this gap by presenting a framework that is:

1. **Expert-Driven at its Core:** It directly translates operational experience into deterministic rules.
2. **Transparent by Design:** It uses multiplication, avoiding opaque weighting schemes.
3. **Resource-Efficient:** It is built for minimal sensor additions and leverages existing infrastructure.
4. **Pragmatic:** It is scalable and deployable module-by-module without disrupting production.

By doing so, we provide a reproducible template for monitoring the vast number of aging, critical systems that will not be replaced but must be made smarter.

3. METHODOLOGY: THE HEALTH TREE FRAMEWORK

The health tree framework is engineered to overcome the specific challenges of monitoring brownfield industrial systems. The developed methodology rests on three foundational pillars: a deterministic bottom-up aggregation logic that prevents failure masking, a novel interface for capturing expert knowledge without programming, and a hierarchical structure that mirrors the physical plant, eliminating abstract complexity, as shown in Figure 1.

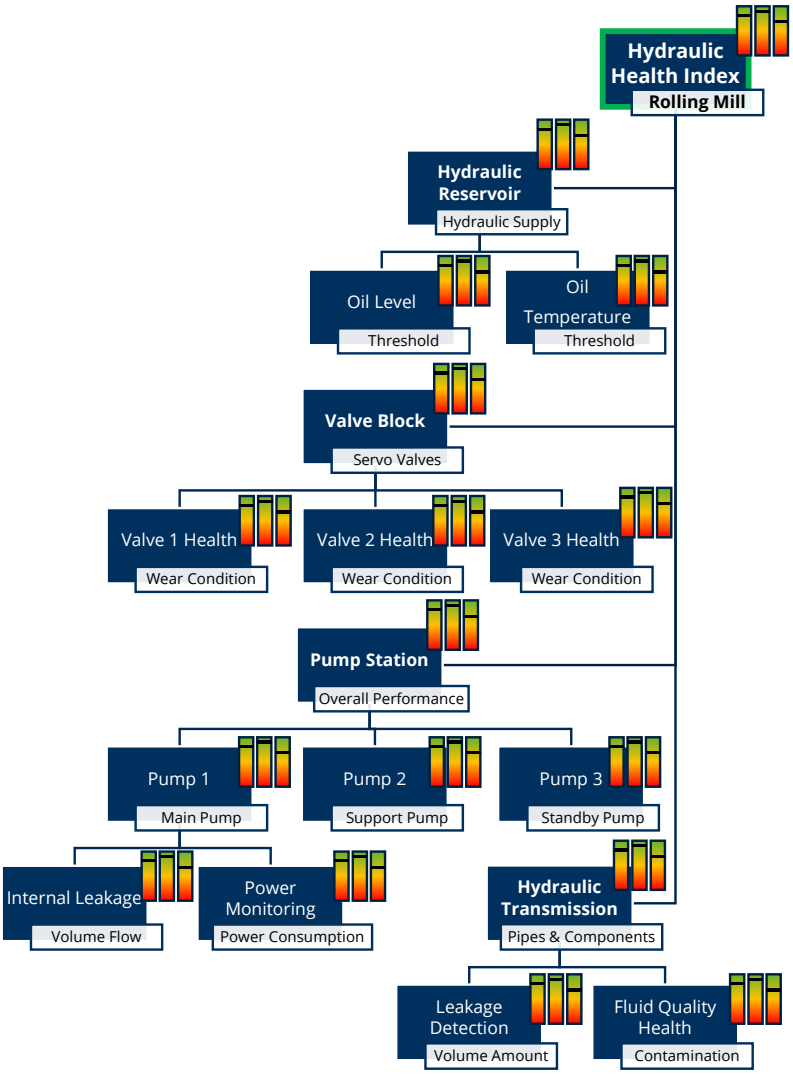

Figure 1 The health tree Framework for the Rolling Mill Hydraulic System (excerpt). This figure shows the root node (Overall System Health Index), branching into major subsystems (Pump Station, etc.), which in turn branch into individual component health indices

3.1. Hierarchical Structure Without Weighting Debates

The framework's main structure, shown in Figure 1, is not an abstract model but a direct digital representation of the physical plant architecture. This hierarchical tree is immediately intuitive to plant personnel who work with the physical system daily.

Level 1 (Leaves): Represent individual sensor inputs or calculated values, each with its expert-defined health function.

Level 2 (Branches): Represent physical components or subsystems, such as a complete pump station or cooling circuit.

Level 3 (Root): Represents the entire hydraulic installation. Its health, the System Health Index (SHI), is the product of all its underlying branches.

Crucially, this structure contains no weighting coefficients. This design choice deliberately eliminates the subjective, political, and often endless debates about whether the pump station is "more important" than the cooling system. The philosophy is absolute: if any single component's condition poses a risk to production, the overall system health must reflect that risk. This deterministic structure ensures that every SHI value is fully traceable. So, any Level 1 harm will be fully recognizable at Level 3 – the SHI.

3.2. Expert Knowledge Capture Without Programming

The core innovation that makes this framework practical is the method for defining the health functions f(s). The challenge was to create a digital representation of the nuanced, often unwritten rules that an expert with decades of experience uses to judge a system's health. To achieve this without requiring any programming skills, the solution was to replace traditional coding with a visual design paradigm. Instead of requiring engineers to write code, we developed an intuitive graphical user interface (GUI) where experts can directly "draw" their experience. The process is simple and powerful:

Graphical Threshold Definition: An expert sketches the acceptable operating region for a parameter directly onto a chart displaying its ranges, comparing it with live or historical data.

Real-Time Visualization: As the expert draws the curve, the resulting mathematical transformation and its effect on the health index are immediately visualized.

Decentralized and Autonomous Work: This tool empowers specialists to work independently. The pump expert defines pump leakage boundaries based on decades of observation, while the cooling systems expert defines temperature limits derived from past summer emergencies.

One-Click Code Generation: Once satisfied, a single click generates the complete, production-ready code for that health function.

This methodology mitigates the persistent challenges of compartmentalized expertise and complex system integration. It provides a structured process to transform valuable, undocumented operational knowledge into a scalable and digital asset, independent of the maintenance staff's programming capabilities.

3.3. Bottom-Up Health Index Through Multiplication

The framework employs a radical bottom-up construction with an multiplication logic at every aggregation step. The process is executed in three stages:

Leaf Node Assessment: At the lowest level of the tree, an individual measurement channel is transformed into a normalized Health Index (HI). All raw sensor data is collected and stored in an on-premise database. A leaf node does not always represent a raw sensor signal but rather a meaningful diagnostic parameter s, which is often the result of pre-processing:

> **Direct Sensor Values:** The parameter s is a direct, unprocessed signal, such as oil temperature.
>
> **Calculated Values:** Simple conversions, such as converting a tank height sensor reading (mm) into a tank volume (Liters).
>
> **Synthesized Parameters:** Complex metrics derived from multiple inputs, such as the heat exchanger efficiency calculated from temperatures and flow rates.
>
> **State-Dependent Metrics:** Values evaluated only when the system is in a specific state, such as assessing a valve characteristic during quasi-stationary periods.

The subsequent transformation of this parameter s into a normalized Health Index (HI) between 0 (complete failure) and 1 (perfect health) is performed by the expert-calibrated function $f(s)$.

Branch Node Aggregation: The health indices of all channels belonging to a single component or subsystem (a "branch") are aggregated into a single subsystem HI. Instead of averaging, we use the multiplication operator:

$$\boldsymbol{HI_{subsystem} = \Pi\,(HI_1, HI_2, \dots, HI_n)} \qquad \text{Equation 3-1}$$

This approach is deliberately chosen to compound the negative effect when multiple issues arise within the same subsystem. It ensures that the severity of the alert escalates when multiple concurrent faults are present, reflecting a more critical state. A pump unit with two moderately degraded parameters is considered less healthy than a unit with only one, a nuance that a min ( ) operator would miss.

While multiplication is the standard for assessing production readiness, it is important to note that alternative aggregations (e.g., weighted averages for specific sub-goals) are possible and can be configured in coordination with the plant operator.

System-Level Aggregation: Finally, the health indices of all subsystems are aggregated into the single, overall System Health Index (SHI), again through multiplication:

$$\boldsymbol{SHI_{system} = \Pi\, HI_{subsystem}} \qquad \text{Equation 3-2}$$

This consistent use of multiplication acts as a logical AND operator at every level. This approach is crucial for production assurance, ensuring any degradation at any level is immediately and unambiguously reflected in the final score.

4. IMPLEMENTATION STRATEGY

The successful modernization of an operational brownfield system hinges on the pragmatism of its implementation. Deploying a new monitoring framework in a live industrial environment, without interrupting production and on a constrained budget, requires a strategy that prioritizes immediate value, minimizes risk, and builds trust with the existing maintenance crews. Our approach was founded on two core principles: first, maximizing the diagnostic potential of existing infrastructure, and second, deploying the system in self-contained, value-driven modules. This stands in contrast to all-in-one solutions or model-based approaches which can require extensive upfront system modelling before any results are delivered [10].

4.1. Leveraging Existing Infrastructure

Our primary objective was to achieve maximum insight with minimal hardware intervention. This principle of using a small, targeted number of sensors is based on several strategic considerations:

- **Suitability for Brownfield Plants:** It allows for the maximum utilization of signals that are already available.
- **Rapid Deployment:** A minimally invasive approach enables installation and commissioning without production downtime.
- **Reduced Complexity:** Focusing on a few key indicators with clear diagnostic value is more effective than managing a deluge of data points.
- **Ensuring generalization:** The methodology is designed to be applicable across multiple plants and system configurations.

An audit of the plant's existing instrumentation revealed about 50 signals already installed for basic control but unutilized for condition monitoring. These included pressure transmitters, temperature sensors, cooling circuit on/off-signals, and position feedback sensors. While this provided a strong foundation, four new sensor types were added to close key diagnostic gaps:

1. Ultrasonic flow meters were installed on each pump leakage drain pipe. This enables a direct comparison of in-production pump performance against datasheet limits, a measurement typically only possible on a test rig [12].

2. Multiple temperature sensors were mounted on the main cooling unit to calculate the thermal power being extracted, providing direct insight into the thermal health of the system.

3. A particle counter was integrated into the main return line for continuous tracking of oil contamination, a validated method in industrial hydraulics [13].

4. A high-resolution oil level sensor was installed inside the reservoir to precisely track the system's total oil volume, making it a highly sensitive tool for detecting small, persistent external leaks.

This philosophy of using a small number of strategically placed sensors is supported by other research where system-level properties have been successfully modelled using common control signals [14]. The additional hardware investment for this upgrade was in the low

single-digit percentage range of the original plant investment, a stark contrast to the costs of production stops and emergency maintenance that can accumulate over a year.

4.2. Module-by-Module Deployment

To manage risk and foster adoption, the health tree was rolled out incrementally, module by module. The first module implemented was external leakage monitoring. Using data from the new high-resolution level sensor, it identified a small leak that had previously gone unnoticed, immediately proving the system's value and building trust. Following this, the cooling system health module was activated, using existing temperature sensors and a mass flow calibration from a non-persistent flow meter to track heat exchanger efficiency. Subsequently, modules for pump and valve health were deployed, providing continuous performance data.

A practical method for assessing pump condition involves comparing the measured drain flow with predefined baseline values derived from theoretical nominal flow calculations. The optimal conditions for monitoring the case drain flow are those under which the flow reaches its maximum, specifically:

- Dead head (nearly zero delivered flow rate)
- Constant nominal speed
- Constant nominal pressure

The case drain flow of axial-piston variable displacement pumps is a key indicator for evaluating internal leakage and overall pump efficiency. Monitoring this flow allows for early detection of wear-related degradation, particularly when manufacturer-provided leakage data is unavailable.

The servo valves play an important role within the gap and force control system. Three indicators have thus far been evaluated as health indices for each servo valve within the valve block and cylinders: null bias shift (NBS), signal deviation, and rated flow rate.

1. Null bias shift (NBS): This parameter reflects the tendency of a valve to drift from its neutral position as a result of variations in temperature, supply pressure, or internal leakage occurring in downstream components. In such situations, correction of the electrical current or adjustment of the mechanical null screw is required to re-establish the precise neutral point. Any deviation in the null position introduces errors in closed-loop systems, particularly in positional servomechanisms or pressure control applications, and is especially critical in zero-lapped valves.
2. Signal deviation: In electrohydraulic cylinders controlled by servo valves, control accuracy is determined by the dynamic relationship between the command signal (setpoint) and the feedback signal (measured response). Signal deviation is therefore defined as the difference between these two signals.
3. Rated flow rate: Assessing the actual flow characteristics is essential to compare the rated flow specified in the manufacturer's datasheet with the experimentally measured flow rate. Two degradation trends may be observed. An increase in the rated flow over time indicates spool wear, which enlarges the effective cross-sectional area of the spool ports. Conversely, a decrease in the rated flow signifies increased internal leakage in downstream components.

5. RESULTS FROM SEVEN MONTHS OPERATION

The ultimate measure of any industrial monitoring system is its tangible impact on plant availability, maintenance efficiency, and operational stability. Over a seven-month period of continuous operation, the health tree framework has transitioned from a pilot project to an indispensable tool for the maintenance team. Its success can be measured across four distinct areas: a direct comparison of system response, the technical detection of incipient failures, the cultural transformation of maintenance practices, and the resulting economic benefits.

5.1. Comparative Baseline and System Response

A comparison of system behaviour over two consecutive 7-month intervals provides the clearest evidence of the framework's impact. In the period before live monitoring, retrospective analysis of historical data shows that the System Health Index (SHI) dropped to as low as 8% during fault events. This extremely low score reflects the late discovery of issues where degradation was allowed to progress to a catastrophic state before manual detection.

In the subsequent 7 months with the active health tree, the SHI never fell below 70%. This stark difference is not due to a lack of faults, but rather the system's ability to trigger alarms early - typically when health drops from 100% to the 85-90% range. This enables proactive decisions long before a critical state is reached, effectively "flattening the curve" of degradation.

Notably, the number of fault-initiating events was of a similar magnitude in both periods; the crucial difference lies in the system's ability to make degradation visible in real-time.

Crucially, this multiplication logic does not lead to a permanently low system score (e.g., three 80% healthy pumps resulting in ~50% system health), as might be feared in a purely wear-based assessment. This is because our "Health Index" measures production readiness, not just physical wear. A pump with 80% remaining physical life can still be assigned a hight Health Index like 98% if its performance is fully sufficient to ensure production targets. This distinction allows the system to remain sensitive to critical deviations without generating constant, low-level alarms for functional but aging components.

For this comparison, the historical baseline was retrospectively calculated using the identical leaf functions $f(s)$ as the live system.

5.2. Detected Anomalies and Prevented Failures

The system’s ability to provide early warnings was validated on multiple occasions:

Leakage Prevention:

The early detection of an external leak, identified by the “Leakage Health” module prevented a potential emergency shutdown. More importantly, it averted product quality issues that arise from hydraulic oil contaminating the cooling water or emulsion—a subtle degradation that, without monitoring, is often discovered days later during quality control checks.

Heat Exchanger Performance:

As ambient temperatures rose, combined with maintenance work on the plant’s water management system, the “Cooling Health” index showed a progressive decline. This

visualized the decreasing efficiency of the main heat exchanger due to warmer inlet cooling water, allowing the team to proactively adjust production schedules.

Valve Health Verification:

The in-situ determination of valve characteristics via the "Valve Health" module showed a strong correlation with a manual valve measurement performed during a machine shutdown. This confirmed the system can support the definition of maintenance intervals and potentially justify component replacement without requiring external characteristic measurements.

5.3. Transformation of Maintenance Culture

Perhaps the most significant impact of the health tree framework transcends technical metrics. It has transformed the daily workflow and mindset of the maintenance crew.

Team members report a marked reduction in stress associated with unexpected failures. The system typically provides a 4- to 12-hour advance warning of developing issues, shifting the team from a reactive, firefighting mode to a proactive, planning mode. This newfound predictability allows for better coordination with production planning and provides maintenance managers with clear, data-backed justifications for necessary interventions.

One senior technician summarized the change perfectly: "For 20 years, I knew something was wrong from the sound, but I could never explain it to management. Now the health score system shows exactly what I hear, with numbers they understand."

The system has not replaced human expertise; it has amplified it.

5.4. Economic Impact

The economic benefits became apparent through a fundamental shift in operational efficiency:

The primary value is realized through avoided ad-hoc emergency deployments, the ability to conduct planned interventions, and the significant reduction of risks to both product quality and overall plant availability. While concrete monetary figures vary depending on the production context, the swift transition from reactive to proactive maintenance has generated a clear and positive financial impact.

As plant personnel universally acknowledge, the true value lies in the unquantifiable benefits of risk mitigation and enhanced stability for the entire production process.

6. 6. DISCUSSION

The health tree's effectiveness stems from a series of deliberate methodological choices that directly address the operational, cultural, and economic realities of aging factories.

6.1. Why Aggressive Multiplication Works

The framework's consistent use of multiplication for aggregation is a deliberate departure from conventional methods. It avoids the failure-masking flaw of weighted averages while also capturing the compounding risk of multiple concurrent faults—a nuance lost when only considering the single worst value (a min() operator). A focused on system optimization might tolerate averaging, but this fundamentally fails for production assurance.

Production in a rolling mill is often binary—either the product meets strict quality specifications, or it does not. The health tree's multiplication acts as a deterministic logical AND operator at every level, ensuring that any degradation threatening production readiness is immediately and unambiguously reflected in the final score.

While this multiplication deliberately maps production readiness, alternative aggregations (e.g., weighted averages for specific sub-goals) are possible and can be configured on a project-specific basis with the plant operator. However, transparent multiplication remains the standard for ensuring overall production security.

6.2. The Role of Localization: Awareness before Pinpointing

A key aspect of this resource-efficient strategy is the focus on awareness over precise localization. The primary goal is to make developing problems visible to the expert team early. Maintenance crews with years of plant-specific knowledge are highly effective at pinpointing the physical source of a fault once they are alerted to its existence. Providing a general but robust early warning, therefore, delivers the highest value by leveraging this existing human expertise. A more granular, sensor-intensive localization is technically feasible but economically complex and is reserved for future expansion stages.

6.3. Scalability Through Methodology, Not Standardization

The framework is designed to be scalable across different facilities, not through rigid standardization of thresholds, but through the replication of its core methodology. Each new plant implements the same proven approach:

1. **Map the physical plant architecture** to a logical tree structure.
2. **Audit available sensors and identify** critical diagnostic **gaps**.
3. **Implement a data pre-processing layer** to convert raw signals into meaningful diagnostic parameters.
4. **Empower local domain experts** to define operational boundaries independently for each leaf node's diagnostic parameter.
5. **Aggregate health indices** from the bottom up using the deterministic multiplication logic.
6. **Visualize** the results through intuitive, hierarchical dashboards.

This approach allows the specific health functions and thresholds to remain entirely plant-specific, respecting the autonomy and empowering the expertise that exists at each individual site.

6.4. Limitations and Future Development

The current implementation, while successful, also illuminates clear paths for future enhancement. The framework's modularity is one of its greatest strengths. One limitation is that the operational boundaries are static. Future versions could implement dynamic thresholds that adapt to the specifications of the product currently being manufactured. Furthermore, a key future development is the implementation of a prognostic layer at the leaf node level. This would involve extrapolating the observed degradation trend to provide

an estimated operational time window before a critical threshold is breached, analogous to a ‘range indicator’ in a vehicle.

Finally, the current focus is explicitly on production health rather than direct component wear. While this was a deliberate choice, the framework is fully compatible with integrating more advanced wear monitoring methods. For instance, methods for tracking pump performance degradation through case drain flow analysis [12] represent a prime candidate for a future “leaf” in the health tree, allowing for better prediction of the remaining useful life of key components.

7. CONCLUSION

This paper presented a novel health tree framework for the condition monitoring of brownfield industrial hydraulic systems. By combining a hierarchical structure, an aggressive multiplication-based aggregation logic, and an intuitive graphical interface for capturing expert knowledge, the system successfully bridges the gap between decades of hands-on experience and the need for digital oversight. The implementation in a live rolling mill demonstrated that a resource-efficient approach can yield a significant and rapid return on investment. The framework not only prevented unplanned downtime but also fostered a proactive maintenance culture. This work provides a practical and scalable methodology for extending the operational life and reliability of critical aging assets.

Biographies

Reiner Stammberger received his diploma in hydraulic engineering from TU Dresden in 1989 and joined SMS subsequently. Having engineered countless hydraulic systems for various steel mill applications all over the world, he switched to the fluid service department in 2007. As senior project manager and engineer he is responsible for modernisations and development projects with regard to fluid systems. In this position he can draw from centuries of experience in the steel and hydraulic industry.

Arne Platzbecker received the B.Sc. and M.Sc. degrees in mechanical engineering from RWTH Aachen University, Germany in 2020 and 2022 respectively. In 2022 he joined SMS group in Mönchengladbach for a two-year trainee program with focus towards fluid engineering. In his current position he supports customers to improve their fluid systems in the aftermarket and is responsible for the hydraulic test benches from SMS group around the world..

Joachim Nagelmann has been working at SMS in the IIoT and SmartSensor Solutions division since 2022 and has many years of experience in industrial automation as well as industrial data processing. In his current research project, he is investigating hydraulic systems using modern IIoT technologies to advance data-driven industrial optimizations.

Maximilian Schmidt received the Diplom-Ingenieur degree in mechanical engineering from TU Dresden, Germany, in 2017, and worked at thyssenkrupp Carbon Components GmbH until 2022, developing resin transfer moulding production systems and digitalization solutions for automotive manufacturing. Since 2022, he has been a Research Associate at the Chair of Fluid-Mechatronic Systems (Fluidtronics) at TU Dresden, where his research focuses on developing physics-based condition monitoring frameworks for industrial hydraulic systems, bridging domain expertise with modern information technology for predictive maintenance applications.

Ahmad Al-Issa received the B.Sc. and M.Sc. degrees in mechanical engineering from AL-Mustansiriya University, Baghdad, Iraq in 2009 and 2012, respectively. This was followed by approximately 2 years as a university lecturer and then a 6-year industrial phase as a hydraulic engineer at General Company for Grain Processing, Ministry of Trade, Baghdad, Iraq. Currently, he is a research assistant and pursuing his PhD degree at Chair of Fluid-Mechatronic Systems, TU Dresden, Germany. His research focuses on thermal analysis and energy condition monitoring of complex industrial hydraulic systems.

Tobias Schulze is working as a research associate and pursuing his Ph.D. at the Chair of Fluid-Mechatronic Systems (Fluidtronics) at TU Dresden, Germany. He serves as the team leader for the Fluid-Mechatronic Systems Group, with his research focusing on stationary hydraulic systems, specifically hydraulic deep drawing presses and electrohydraulic compact drives.

Jürgen Weber has been appointed in 1st March 2010 as a University Professor and the Chair of Fluid-Mechatronic Systems as well as the Director of the Institute of Fluid Power at TU Dresden, and took on the leadership of Institute of Mechatronic Engineering in 2018. He finished his doctorate in 1991 and was an active Senior Engineer at the former Chair of Hydraulics and Pneumatics until 1997. This was followed by a 13-year industrial phase. Besides his occupation as the Head of the Department Hydraulics and Design Manager for Mobile and Tracked Excavators, starting in 2002, he took on responsibility for the hydraulics in construction machinery at CNH Worldwide. From 2006 onwards, he was the Global Head of Architecture for hydraulic drive and control systems, system integration and advance development CNH construction machinery. Furthermore, Jürgen has been head of the Consulting Board for HYDAC, Sulzbach/Saar, for 10 years, still being a member, and was also appointed as a member of the Supervisory Board of Musashi Europe GmbH. He is a fellow and now chair of the Global Fluid Power Society. The membership of 5G Lab Germany at TU Dresden is a further indicator for more than 15 years of experience in management and coordination of research alliances as well as the activities as surveyor, PhD supervisor, over 300 publications, technical books and lecture notes.

Energy-efficient handling through passive vacuum generation and biomimetic functional principles

Abstract.

Automated handling is an established process within the context of industrial and automated production, usually carried out by robotic systems with gripper systems. Conventional suction grippers rely on compressed-air-based vacuum generation – with a significant associated energy consumption and required infrastructure. A possible alternative is the usage of passive vacuum-based handling technologies, which offer the opportunity to entirely avoid the previously necessary expensive infrastructure. However, within the current state of development, passive systems inherently lack pressure regulation capabilities, which introduces the risk of vacuum leakage and therefore a reduced gripping reliability. The present research therefore aims to develop a new type of energy-efficient, reliable and location-independent handling technology based on passive vacuum generation and the development of a framework for identifying and avoiding impending sealing failures. The approach is biologically inspired and designed to operate entirely without the active supply of external energy for vacuum generation. On the basis of these developments, opportunities for significant potential savings in terms of energy use, CO_2 emissions and operating costs could be enabled.

1. INTRODUCTION

Vacuum handling technologies are widely used in industrial automation due to gentle handling, high cycle rates and flexibility across object geometries [1]. As deployments scales and task diversity increases, the efficiency and infrastructural footprint of vacuum generation become critical constraints, especially in mobile and decentralised settings. The rapid growth of e-commerce and warehouse automation has significantly increased the demand for fast, flexible handling systems. Automated storage and retrieval systems and autonomous picking stations frequently rely on vacuum gripping to manage packaging materials, cartons and irregularly shaped goods [2, 3].

In conventional industrial automation, the pressure difference is commonly generated pneumatically via compressed air due to the inherent simplicity and low component costs. On mobile and decentralised platforms, however, compressed air becomes impractical: the energy density of compressed air is low, on-board air tanks are not viable for extended duty cycles, even with periodic recharging. The use of hoses to connect to the compressed air supply constrains the workspace and safety envelope. Electrical vacuum generators such as pumps or blowers require continuous electrical power and increase system complexity and noise [1, 4]. These constraints motivate the passive generation of pressure differences with the goal of creating and maintaining the pressure difference during the handling cycle without an external power supply. However, passive systems lack active pressure regulation. As a result, leakage events can erode the holding force and compromise process reliability [5, 6]. For market acceptance, passive vacuum handling must not only generate the pressure differences efficiently but also ensure high process safety. This requires minimising leakage through an innovative gripper design as well as in situ detection and avoidance of leakage events.

This paper addresses this challenge via three complementary strategies, which are developed in the following chapters. Section 2 surveys passive generation of the pressure difference and safety measures for vacuum maintenance. Biomimetic compensation concepts for enhancing the sealing and compliance are presented in section 3. Section 4 develops a process-safety framework for the detection of imminent leakage-induced failures. Section 5 concludes with an overview of the addressed challenges, future potentials and an outlook.

2. ACTIVE AND PASSIVE SUCTION GRIPPERS

2.1. General Operation Principles for Suction grasping

The operating principle of suction grippers is based on a pressure difference between the ambient pressure and the internal volume of the suction cup, which is positioned close to the surface of the handled object. When the gripper and the object are pressed against each other, the suction cup is sealed against the ambient pressure, enabling a frictional connection and the creation of a pressure difference [7]. Since handling is conventionally carried out under ambient conditions, a negative pressure must be generated inside the suction cup [8, 9].

The achievable holding force F for a given task can be defined by [8]

$$F=\Delta p \cdot A_{eff} \cdot z \cdot n \cdot \eta \cdot \frac{1}{S} \qquad (2.1)$$

where $\Delta p=p_{amb}-p_i$ describes the difference from the environmental and the internal pressure, A_{eff} the effective sealed area of the gripper and z the number of grippers. The deformation coefficient n, the system efficiency rate η and the safety factor S can be used to take gripper characteristic and process-induced uncertainties into consideration. In principle, this pressure difference can be generated using two different principles, which are described as active and passive principles in the following [10].

2.2. Active Generation of Pressure Differences

The industrially established principle as the usage of "active" grippers. Here, the pressure difference is created (active suction cup [11]) by either an electric or pneumatic vacuum generator [10, 12]. These vacuum generators reduce the gas mass within the suction cup's internal volume, thereby decreasing the pressure within the suction cup. The internal volume of the suction cup can be reduced during the process of evacuation, depending on the design of the suction cup. In the case of the suction cup being designed as a suction plate, the internal volume remains constant. This indicates that the internal volume of the suction cup can be described as $V_1 \geq V_2$ and the absolute pressure as $p_1>p_2$ [7].

2.3. Passive Generation of Pressure Differences

Another possibility is the generation of the pressure difference within a closed system, thereby ensuring a constant mass within the suction cup (passive suction cup [11], see Figure 2.1 (left)). In the "passive" applications, the pressure difference is established through the application of a force resulting in an increase in the internal volume. With this applied force and the deformation of the gripper, the internal volume of the suction cup V is enlarged and the condition $V_1<V_2$ applies. According to the ideal gas law, this results in a decrease in the absolute pressure p within a closed, isothermal system. This pressure difference generation process, which merely results from the deformation of the gripper, is conventionally described as passive and therefore cannot compensate for pressure increases in the suction cup caused by inadequate sealing. "Passive" specifically implies that the required force F is applied by the handling device, thereby eliminating the need for an independently powered vacuum system

.

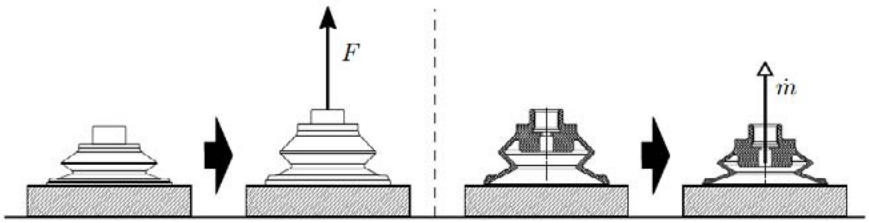

Figure 2.1. Passive vacuum suction cup – closed system (left)
and active suction cup – open system (right) [7]

In contrast to active generation of pressure difference, which relies on a continuous energy supply from pumps or compressors, passive generation of pressure difference relies exclusively on the volume change within a previously defined volume as a result of a discrete external force. For instance, the design of a passive suction gripper may take form of a clamping pivot and a slide damper (Figure 2.2). During operation, a discrete external load presses the cup onto the surface, reducing the chamber volume and expelling air. The elastic lip seals the interface, thereby creating a pressure differential that results in the cup adhering to the surface. The release process is actuated by opening the slide damper, thereby allowing the chamber to vent [8]. However, leakage cannot be actively compensated, so the holding force decays if the seal is disturbed. Consequently, the energy required to generate the vacuum is significantly lower than for an actively operated vacuum generator.

2.4. Use-Case: E-Commerce and Resulting Challenges

To utilise this high degree of energy efficiency, the systems have to be qualified for industrial usage. Especially the required reliability of the grasping forces is currently not achievable for all surfaces. In e-commerce fulfilment, heterogeneous items, uneven or film-covered surfaces, contamination and short cycle times increase the risk of leakage-induced detachment. Therefore, three practical challenges are focused:

(i) System-level adaptation of the pressure difference,

(ii) Suction-cup design for sealing robustness and

(iii) Leakage-aware handling strategies.

Currently, passive systems struggle with very short cycles and the majority of approaches are only capable of functioning in a leak-free manner when operating within an ideal environment. In practice, the likelihood of a small leakage in the seal of the passive suction cups during handling cannot be ruled out, raising the risk of a loss of the handled component. Existing systems have not yet been designed to compensate for this impending leakage and there is no established process setup for a proactive reduction of handling parameters such as speed or acceleration, nor a move to a safe position. Other promising approaches involve a flexible membrane that can easily adapt to the surface of a handled, which can generate sufficient pressure differences for a handling process through a small stroke to increase the volume beneath the membrane [13]. Another focus lays on concepts that minimise leakage. Soft sealing lips that adapt optimally to the respective workpieces are of key importance for this [6]. Initial concepts have been developed and implemented to combine extremely soft sealing lips with harder suction cups [1].

In the following chapters, the different possibilities (i) - (iii) are investigated.

3. POSSIBLE SAFETY SYSTEMS FOR ACHIEVING RELIABLE HANDLING WITH PASSIVE GRIPPERS

In order to achieve the highest possible process reliability when using passive vacuum gripping systems, there are generally two possible development goals: First, the development of suction grippers with optimal sealing properties should be considered. These grippers should be designed to achieve optimal sealing with the handled components, thereby allowing the lowest possible leakage airflow into the evacuated suction gripper. If a leakage airflow eliminates the created pressure difference, the gripping force is also removed, resulting in the handled object being dropped. Secondly, an additional safety system can be employed to prevent the component from falling off in the event of high leakage, thus ensuring the continuity of the current running process without damaging the component.

The following approaches are therefore being further considered as safety systems:

- Redundant vacuum generator
  - Active, e.g. using a small electric pump
  - Passive, e.g. using a second passive suction cup or a matrix of suction cups that can compensate for the failure of a suction cup
- Additional storage volume
  - Rigid, e.g. an additional pneumatic cylinder as storage
  - Flexible, e.g. a bellows
- Additional safety element
  - Mechanical, e.g. a clamp
  - Electric field
  - Magnetic (if the workpiece is ferromagnetic)
  - Adhesive

Within this approach, this could only be achieved via a redundant pump that intervenes in an emergency. However, this would then no longer be a purely passive solution. Two implemented approaches (Figure 3.1 and Figure 3.2) can therefore only represent the starting point for targeted further developments for a leakage-robust passive vacuum gripper design.

The redundant system in Figure 3.1 consists of a high flow suction cup and an adhesive tape. For a passive holding solution, the adhesive tape mounted on the gripper will grasp the workpiece. If the holding force is not high enough or if a failure occurs, the vacuum gripper can be activated to hold the workpiece like in a standard vacuum handling application.

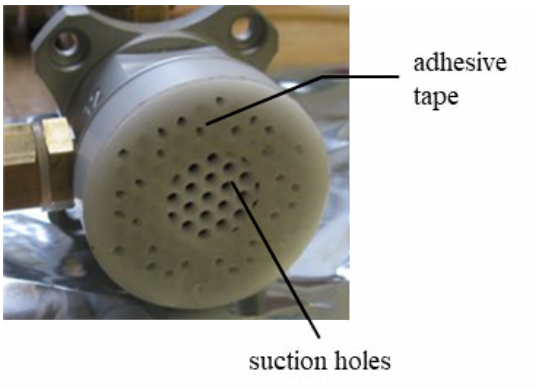

Figure 3.1. Redundant system with an additional adhesive tape that can hold the component in case of vacuum system failure

A first functional prototype shown in Figure 3.2 was equipped with a membrane, a pressure mechanism, a venting valve, a vacuum sensor, an additional pump (top of Figure 3.2) and a mechanical connection to common robot flanges. If leakage occurs during passive handling, this can be recognized by the vacuum sensor and the additional pump can be activated. Alternatively, there could be a solution with an additional vacuum realized by a pre-loaded air cylinder or a bellow.

Figure 3.2. Redundant system with an additional pump (top), a system with a compressed air cylinder as a pre-loaded accumulator (bottom left) or with a flexible bellows (bottom right)

4. LEAKAGE COMPENSATION BASED ON BIOMIMETIC PRINCIPLES

In biology, multiple reversible attachment mechanisms based on suction have evolved, providing engineering with a wealth of role models for vacuum-based, flow-free, energy-efficient suction devices. Most organisms utilising suction are aquatic, especially leeches are of particular interest for biomimetic approaches due to their semi-aquatic nature and ability to attach underwater as well as on land. The hematophagous Mediterranean medicinal leech (*Hirudo verbena*) evolved a remarkable mechanism to hold on the body surface of its hosts (mammals and fish), which could inspire the solution to a classical engineering problem: how to attach securely and reversibly to a wide range of substrates without the assistance of an external vacuum source. The leech accomplishes this through two muscular suction cups located at the anterior and posterior ends of its body [14], (Figure 4.1). These two suckers enable the leech to attach and move on surfaces underwater and on land that are smooth, rough, or even porous [15, 16].

Figure 4.1. Mediterranean medicinal leech *Hirudo verbana* with its anterior (A) and posterior (B) suckers. White arrow: Grasping-like deformation of the posterior sucker.

The leech alternately attaches and detaches both suckers for locomotion (inchworm-like gait or vermiform crawling), while the anterior sucker additionally provides a stable fixation point for the jaws during feeding, i.e. blood intake [14] as seen in Figure 4.1A. For attachment, both suckers employ the same physical principle – generation of negative pressure by musculoelastic sucker deformation – yet differ in their functional design and redundancy. The posterior suction disc is exclusively used for locomotion and attachment, while the anterior sucker fulfils multiple roles in locomotion and feeding. The procedure of surface contact formation and attachment from the inside out of the suction discs is equal in both types. This process dramatically reduces the dead volume and increases the contact area with the object's surface when compared to the classical suction cup designs commonly used in industrial applications. Even though the “normal” suction performance of both suckers is already impressive, the anterior sucker can additionally actively adjust the pressure difference between the sucker chamber and the surrounding medium (water or air) via the mouth orifice in the case of an approaching leakage. Thereby, the anterior sucker reaches slightly higher attachment force maxima than the larger posterior sucker in pull-off tests, while the posterior sucker sets the pressure difference and needs to adjust to such events solely through sucker deformation and cavity sealing. [15] The latter is demonstrated in Figure 4.1B in which the posterior sucker is attached to a flexible surface and pulled, leading to a particular pronounced, almost grasping-like deformation of the sucker to generate an increased pressure difference and counter an imminent leakage. The reliable performance of both suckers demonstrates that strong, flow-free suction can be achieved without an active pump, making the leech an ideal biomimetic role model for passive, vacuum-based suction grippers.

4.1. Functional Basis of the Leech Suction System

The anterior sucker of *H. verbana* is formed by its first four body segments and the posterior sucker by its seven terminal body segments. Both suckers contain strong musculature organised in circular, radial and other orientations, as well as connective and glandular tissue. When the leech attaches with the posterior sucker, the sucker flattens and spreads over the surface, thereby increasing its contact area. The rim forms an airtight seal, while the sucker musculature enlarges the cavity volume, reducing the internal pressure. No valves or ducts are involved: all pressure differentials arise from the mechanical interplay of elastic deformation and sealing. This mechanism is inherently reversible; releasing the sucker simply involves local muscular contraction at the rim to admit air or water flows into the cavity. [15]

A defining feature of both *H. verbena* suckers is their distributed actuation: most of the sucker contact surface is controlled by fine musculature and capable of fine deformation. This allows continuous adjustment of local contact pressure and shape, providing adaptive and consistent surface contact even on rough, uneven or porous substrates. Although capillary bridging is necessary for maximum attachment forces, the attachment remains suction-dominated across many substrate conditions (even those characterised by porosity) as the leech is capable of closing surfaces cavities and holes with its highly deformable suckers. [15] The ability to maintain suction on non-airtight substrates illustrates the robustness of the system and highlights the leech's highly adaptable attachment strategy. When confronted with objects that do not offer sufficient surface area for suction (e.g. hairy surfaces or mesh structures), the leech's ability to locally control and deform its suckers provides secondary attachment mechanisms, such as clamping, spacing and locking at object edges or into object spaces [15]. The muscles and connective tissue in the suckers that cause these unique deformation and attachment properties are anatomically derived from the tissue layers in the leech's basic body segments. The way in which the tissues within the suckers are anatomically and functionally organised has not yet been investigated in detail. However, a complete understanding of the morphology and anatomy is a prerequisite to encoding the functional principle and abstract them for engineering.

4.2. Design Implications for Passive Suction Grippers

Both suckers, but especially the posterior one demonstrates the possibility of a stable suction through shape change and sealing alone. From this follow three critical engineering requirements for passive suction cups: 1) negative pressure generation by structural deformation, 2) minimisation of leakage and 3) delay of peel or detachment events. These are realised biologically through geometry, compliance and muscular control.

The first important aspect is negative pressure generation by structural deformation. Instead of state-of-the-art suction cups, that get deformed and attached to a surface when their dead volume is evacuated by an applied vacuum (Figure 2.1), a biomimetic passive sucker should be capable of deforming itself to generate a negative pressure difference, preceded by an initial surface contact that is as large as possible, with minimal dead volume.

The second aspect is leakage control: The rim of the leech sucker is highly compliant and structured with radial furrows. These grooves act as fluid reservoirs and distribute mucus

uniformly across the contact area, forming a tortuous path for air leakage. Since an industrial requirement are residual-free handling devices, a biomimetic optimised suction gripper cannot rely on applied liquids for maximal sealing and attachment forces. Possible alternatives could be the use of materials with different stiffness and micro-patterned rims to increase the contact area and to provide a comparable sealing function without residues.

The third aspect is detachment control: In mechanical terms, failure of suction typically initiates as a peel at the sucker edge. The leech mitigates this for the posterior suction disc by a joint-like neck constriction connecting sucker and body, which allows pitch–roll flexibility and maintains uniform compression along the rim. Additionally, the secondary attachment mechanisms could inspire suckers with mechanisms that mechanically counteract the detachment of the sealing lip, prevent it altogether, or even lead to automatic re-gripping or jamming of the formerly attached object in the event of suction failure. This could be achieved through structural and material-immanent functions in the suction cup.

In sum, *H. verbana* provides a rigorous template for flow-free, purely passive suction and leakage control. The posterior sucker demonstrates that a pump-less vacuum can be generated and stabilised through geometry and sealing alone. In contrast, the anterior sucker highlights the importance of a pump as an additional fail-safe mechanism where feasible. With these elements, passive suction grippers can achieve the leech's hallmark combination of adaptability, robustness and passive attachment.

5. INCREASING PROCESS SAFETY

Passive vacuum handling eliminates the need for compressed-air infrastructure; however, it removes the ability to actively re-establish or regulate vacuum during operation. As a result, leakage caused by surface topography or off-axis loading can lead to a seal deformation and weakening and result in the detachment of the handled object. The object loss following the sealing detachment can occur within milliseconds. The early detection of the sealing deformation is therefore crucial for the purpose of either adapting the robot motion or ensuring the safe placement of the object. Therefore, the development of an integrated approach represents a potential solution for enabling passive vacuum handling technologies in industrial automation in order to establish a sufficient process safety.

Process safety in this context can be understood as the probability of completing a pick-and-place operation cycle without an occurring object loss. To prevent leakage-induced object loss, the critical moment of the imminent object detachment at the gripper-object interface has to be identified and analysed. Leakage-induces object loss can occur from a variety of sources. These can be grouped into following [3]:

(i) Influences from the gripper characteristics, e.g. seal degradation

(ii) Influences from the object properties such as surface roughness, load, mass eccentricity or surface contamination

(iii) Process-induced influences, e.g. shear load spikes during acceleration or jerk as well as off-axis loading during the pick process and transport phase.

In order to react to an imminent object loss, it is necessary for the detachment to be detected in advance. This results in the need of a sufficient holding force level to be able to ensure the object is being attached to the gripper for the required time between the detection and potential reaction strategy.

5.1. Empirical Characterisation and Derived Optimisation Potential

In the following, the behaviour of the sealing detachment and resulting leakage is investigated. Especially the sealing itself is focussed, therefore the influences from the gripper (i) and object characteristics (iii) are reduced as much as possible. For this purpose, systematic static pull-off experiments were performed with a 7-axis robot on a smooth, non-porous surface using a standard bellows suction cup (FG 62 NBR-55 N018 from Schmalz) functioning as a passive gripper to initially derive the main process-induced effects (iii). For these experiments, an in-cup pressure sensor was integrated into the suction cup setup to obtain the internal suction cup pressure $p_i(t)$. Furthermore, a 6-DoF force/torque transducer located at the robot flange captured the occurring load, while an ultrasonic distance sensor measured the end-effector extension along the surface normal (Figure 5.1).

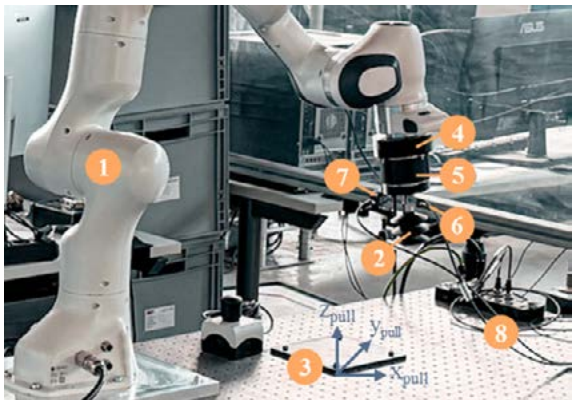

Figure 5.1. Experimental setup
(1) robot arm, (2) bellow suction cup functioning as a passive gripper,
(3) PLA plate, (4) flange adapter, (5) force transducer, (6) vacuum sensor,
(7) ultrasonic sensor, (8) IO-link master

Within the experimental investigation, the approach depth, approach angle, process speed and acceleration for linear motion were varied by the factorial experiments. The process depth is defined as the distance from the ultrasonic sensor to the pull-off surface with a maximum possible compression d_{max} with approx. -20 mm for the depth value compared to the initial undeformed state of the suction cup. The approach depth influences the deformation and sealing and the loads to the sealing lip as well as the handling object. The velocity and acceleration were varied as a percentage of the maximum robot speed and acceleration to investigate the influences on the sealing and release behaviour through occurring dynamic effects, e.g. viscoelastic effects. The variation of the rotational angle

between the gripper verticals and the surface normal was varied within the range of $w \in \{-20°, 0°, 20°\}$ to examine its impact on the sealing behaviour and force distribution.

The investigated response variables were the measured internal pressure difference, the pressing force applied to the sealing to the surface as well as the pull-off force. The experiments were performed with 20 process variable combinations, each with $n=50$ trials (see Table 5.1). For each parameter combination, the maximum level of pressure difference and the minimum and maximum vertical force values were measured and averaged across the repetitions. To unify the sampling rate, the lower-rate vacuum data was anti-alias filtered and resampled to 150 Hz to match the force sampling rate. Due to the data acquisition of the vacuum and ultrasonic sensor via IO-Link-master and TCP/IP, a delay in the data stream compared to the USB-based force/torque data may occur. To avoid this distortion in the temporal overlap of the various data sources, an initial pull-off movement was performed before each trial to align the data streams by an offset correction based on the first prominent peak during the start-up motion, compression and pressure establishment.

The initialisation phase is characterised by a contactless interaction between the suction cup and the pull-off surface. The robot approached the surface orthogonally without any load besides the end effector setup consisting of gripper as well as cables and without cup deformation or pressure change ($F_Z=p_i(t)=0$) (Figure 5.2 (a)). The behaviour of the vacuum gripper during the pull-off experiments could then be segmented into three phases (Figure 5.2 (b)-(d)):

- Sealing phase,
- Leakage onset,
- Contact rupture.

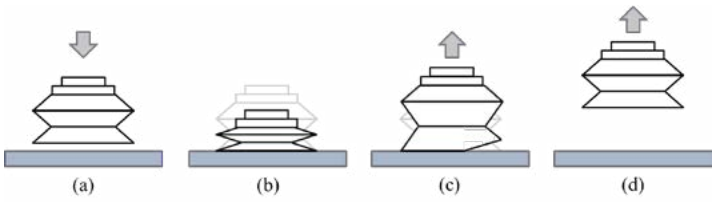

Figure 5.2. Phases of the pull-off experiments
(a) contactless phase, (b) sealing phase, (c) leakage onset due to local occurring sealing detachments, (d) contact rupture leading to complete sealing detachment

During the approach to the defined approach depth, the normal force -F_Z occurs, leading to a sealing lip deformation, thereby sealing the gripper to the pull-off surface. When a positive pull force is applied, a pressure difference in the gripper leads to an adhesion of the seal to the surface until the collapse of the holding force $+F_Z$ at contact break. After release, the gripper and kinematic structure exhibit a short elastic ring-down (Figure 5.3). These phase markers provide consistent anchors for feature computation.

Table 5.1. Section of the performed factorial pull-off experiments

No.	v_{robot}	a_{robot}	w [°]	Δp_{max_avg} [mbar]	$F_{Z_min_avg}$ [N]	$F_{Z_max_avg}$ [N]	$\sigma(p_{max_avg})$ [mbar]	$\sigma(F_{Z_max_avg})$ [N]
1	50%	50%	0	451.72	-39.65	57.64	16.91	4.52
2	100%	50%	0	475.21	-38.17	59.42	22.17	4.27
3	50%	100%	0	477.18	-39.37	56.13	24.8	7.64
4	100%	100%	0	495.65	-39.61	56.71	19.94	9.41
5	50%	100%	20	432.93	-37.58	66.92	9.41	4.1
6	100%	50%	20	454.20	-43.82	72.24	1.78	1.58
7	100%	100%	20	440.81	-44.31	69.58	3.12	1.14
8	50%	50%	-20	393.20	-57.69	63.51	14.15	2.57
9	100%	100%	-20	375.98	-58.35	58.46	24.82	5.07
10	50%	100%	-20	391.83	-58.79	64.06	11.01	1.93

Over the 50 repetitions for each parameter set, the standard deviation remained comparatively small in relation to their respective means, thereby signifying a high degree of repeatability. Varying the initial movement as well as the pull-off speed and acceleration showed negligible effects in the tested static conditions due to short distances and therefore short acceleration distances, though dynamic trajectories are expected to introduce viscoelastic and inertial effects.

The impact of a varied approach angle was demonstrated and indicated, that non-orthogonal approaches reduced maximum pressure difference by 15-25 % due to asymmetric sealing. An orthogonal approach has been demonstrated to achieve the highest average pressure difference values, while average pull-off forces F_{Z,max_avg} show a slightly higher level at w=20°. This discrepancy can be attributed to the fact that the achievable holding force is also dependent by an angle-induced pre-compression, which is described with the deformation coefficient n. A tilted approach has been shown to increase local lip compression and bending stiffness. It has been observed that the strongest average contact force occurs at a negative approach angle, indicating a higher pre-load which influences the initial sealing behaviour while achieving a lower pressure difference. Therefore, the selection of approach angle should be dependent on the specific characteristics of the surface and the task. Research in future will focus on the quantification of the trade-off between angle-induced precompression and maximum cavity pressure difference with the aim of deriving task-adaptive approach strategies.

6. CONCLUSION AND OUTLOOK

The overall goal of the presented publication was the investigation of energy efficient handling systems with a focus on passive suction grasping. However, even though the usage of a passive suction cup is a very energy efficient solution to decrease energy consumption, process safety topics such as system failure and the possible loss of the workpiece must be considered. As a result, the three different aspects of achieving reliable grasping with passive grippers were investigated, derived from a use-case of a usage in short-cycle e-commerce handling tasks. Next to systemic safety concepts, biomimetic-inspired suction designs were focussed. Additionally, redundant safety strategies and mechanisms were investigated to enable a wide range of possible applications in automated processes.

Overall, the findings highlighted the possibilities and possible further research avenues for passive suction grippers to achieve industrially acceptable reliability. As a next step, the highlighted research avenues should be analysed further and combined into prototypical functional demonstrators, to empirically investigate possible process limitations. Additionally, modelling and simulation approaches could significantly accelerate development processes for passive vacuum handling systems and should be researched alongside physical demonstrators. Overall, the passive handling technology can be described as an emerging technology with a high potential for various use-cases. If a high degree of reliability can be achieved, significantly enhanced efficiencies for automated handling systems are opened up for various industries. Additionally, elements of these approaches could also be transferred to conventional vacuum handling technologies, opening up further potential for increased energy efficiency.

Development and Experimental Validation of a Novel Origami-Inspired Pneumatic Actuator Concept with Progressive Force-Stroke Characteristics

Philipp Hüpper, Olivier Reinertz, Katharina Schmitz

RWTH Aachen University, Institute for Fluid Power Drives and Systems, Aachen, Germany, philipp.huepper@ifas.rwth-aachen.de

Abstract.

Pneumatic actuators currently face limitations in achieving a progressive correlation between force and stroke under isobaric conditions. This characteristic bears the potential to significantly improve applications such as vibration isolation, which benefits from minimal stiffness and low eigenfrequency, and automation, where reduced air consumption can be achieved, e.g., in clamping devices. Conventional actuator designs struggle to provide these features because they require the active area to increase with the stroke.

This paper deals with a novel origami-inspired actuator concept, which offers a promising solution by increasing the active area progressively over its stroke. The primary challenge lies in the structure's design. From a mathematical point of view, origami actuators with rigid facets represent shape-variable polyhedrons, which are isochoric despite a possible form change, making them unsuitable as pneumatic actuators. However, engineering approaches demonstrate that slight elongations of selected edges during form change can enable significant volume changes. The goal is to overcome technical challenges by developing an airtight origami structure that transmits force along its facets and edges while permitting minor facet deviations.

A working prototype is designed, manufactured and experimentally investigated on a force-stroke test rig. Measurement results validate the feasibility of the concept and the achievement of the targeted properties.

1. INTRODUCTION

Origami is the art of paper folding. Although origami was traditionally used for artistic purposes, it found technical applications in the 20th century [1]. Examples include space-efficient, folded structures for rocket transportation [2]; medical products, such as stents [3]; and foldable concrete structures designed to achieve high local stiffness [4]. Complex patterns are created by introducing mountain and valley folds into a sheet of paper [5]. This results in rigid facets connected by movable creases. Points where these creases meet are referred to as vertices [5].

In a new approach, Reinertz demonstrated that origami can be used for designing a pneumatic actuator chamber with a progressive force-stroke characteristic. By inverting the principle of a bellow actuator, this approach utilizes rigid facets to transmit force while allowing deformation along the creases. Currently, no commercially available pneumatic actuators offer a progressive stroke characteristic, though such actuators would be highly beneficial for suspension systems due to their low eigenfrequency and could contribute to energy savings in automation. [6]

This paper will turn this new approach, as shown in Figure 1.1.a), into a working prototype. Manufacturing difficulties will be solved by tailoring the mechanical properties of Reinertz's proposed geometry. An experimental investigation will demonstrate the desired progressive force-stroke characteristic of the actuator, which could result in a low eigenfrequency.

Sadeghi et al. already employed origami techniques to develop a quasi-zero stiffness pneumatic actuator [7]. The proof-of-concept prototype revealed both the desired progressive force-stroke characteristic and low eigenfrequency [8]. However, this design lacks practicality because the end facets of the used Miura-Ori origami change significantly in size during actuation, as shown in Figure 1.1.b). This is not beneficial for a pneumatic actuator because the required sliding seals between the facets and adjacent end faces induce significant amounts of leakage and friction. Additionally, the point of force application moves relative to the end faces.

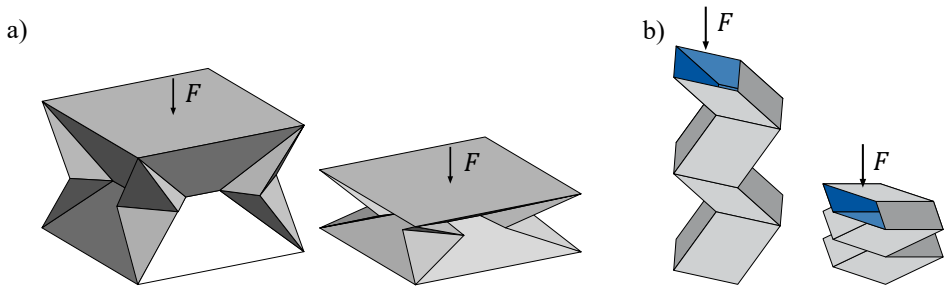

Figure 1.1. a) Reinertz's proposed geometry [6]; b) origami structure of Sadeghi et al. [7]

Building upon Reinertz's approach, the goal is to create a polyhedron whose facets do not change during deformation [6]. From a mathematical perspective, however, it is impossible to alter the volume of a deformable closed polyhedron without changing its facet shapes [9], making such structures infeasible as pneumatic actuators. Nevertheless, Reinertz's design

creates a change in volume through slight deviations from a mathematically exact polyhedron, achieved by the elasticity of a few creases [6].

The scope of this paper is to first optimize the proposed geometry for manufacturing a working prototype. After analyzing critical points, the origami pattern will be optimized numerically to minimize facet deformation. The manufactured prototype will finally be tested on a testbed to characterize the pneumatic properties of the actuator, focusing on the force stroke correlation under isobaric conditions.

2. ANALYSIS OF CRITICAL POINTS

To further improve feasibility, the proposed geometry, shown in Figure 2.1.a), is slightly modified. For the realization of technical origami structures, vertices are critical points since multiple creases converge there. The complexity of sealing and force transmission increases as the number of meeting creases increases. As shown in Figure 2.1.b), one way to reduce this complexity is by lowering the maximum number of creases that meet at each vertex. The size of these new facets can be tailored so that the pneumatic properties of the actuators remain comparable.

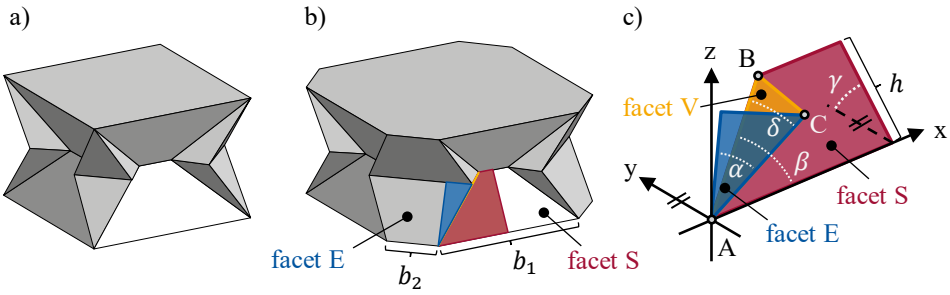

Figure 2.1. a) Reinertz's proposed geometry [6]; b) modified geometry; c) one vertex of the origami-pattern

For analytical purposes, the structure can be simplified to a single vertex, as illustrated in Figure 2.1.c). This reduction is possible because the entire actuator structure can be formed by reflecting this vertex multiple times. In this configuration, the facets are labeled E, S, and V with corresponding angles α, β, and δ. The actuator stroke is defined by angle γ. For clarity in further discussions, key points A, B, and C are also marked.

In a classic origami pattern, angles α, β, and δ are related by Equation 2.1 and do not change. This relation is not effective for a functional actuator. As Reinertz demonstrated, an actuator can be created by allowing a small elongation of the crease $\overline{BC}$ [6]. Therefore, the angle δ must change during actuation.

$$\alpha + \beta + \delta = 90° \tag{2.1}$$

The goal is to minimize stress on facet V and its connecting creases, as well as to simplify manufacturing, by keeping changes in δ as small as possible. The alteration in δ over a full actuator stroke is defined as $\Delta\delta$ by Equation 2.2:

$$\Delta\delta = \delta_{\max} - \delta_{\min} \tag{2.2}$$

Here, δ_{max} is the maximum value of δ during the actuator stroke, and δ_{min} is the corresponding minimum value. Minimizing $\Delta\delta$ requires numerical optimization of the angles α, β, and δ. This optimization process will be discussed in detail in the following section.

3. NUMERICAL OPTIMIZATION OF THE ORIGAMI PATTERN

To minimize $\Delta\delta$, a geometric analysis is required to describe the angle δ as a function of the other geometric parameters and the actuator stroke. The distances between points A, B, and C ($\overline{AB}$, $\overline{AC}$ and $\overline{BC}$) are defined as shown in Equations 3.1 to 3.3:

$$\overline{AB} = h \cdot \sqrt{\left(\frac{1}{\tan\beta}\right)^2 + \cos^2\gamma + \sin^2\gamma} \tag{3.1}$$

$$\overline{AC} = h \cdot \sqrt{\frac{1}{2}(\cos\gamma + \tan\alpha)^2 + \frac{1}{2}(\cos\gamma - \tan\alpha)^2 + \sin^2\gamma} \tag{3.2}$$

$$\overline{BC} = h \cdot \sqrt{\left(\frac{1}{\tan\beta} - \frac{\sqrt{2}}{2}(\cos\gamma + \tan\alpha)\right)^2 + \left(\cos\gamma - \frac{\sqrt{2}}{2}(\cos\gamma - \tan\alpha)\right)^2} \tag{3.3}$$

Using the law of cosines, the angle δ can be calculated by Equation 3.4:

$$\delta(\alpha,\beta,\gamma) = \arccos\left(\frac{\overline{AB}^2 + \overline{AC}^2 - \overline{BC}^2}{2\cdot\overline{AB}\cdot\overline{AC}}\right) \tag{3.4}$$

$\delta(\alpha,\beta,\gamma)$ is independent of the height h, as it is eliminated. By choosing values for α and β, δ can be determined depending on γ. It can be shown that δ follows a trajectory similar to Figure 3.1.c). As γ approaches zero, $\frac{\partial\delta}{\partial\gamma}$ also approaches zero. Depending on the values of α and β, δ reaches a minimum before always increasing as γ approaches 90°, which represents the maximal possible stroke.

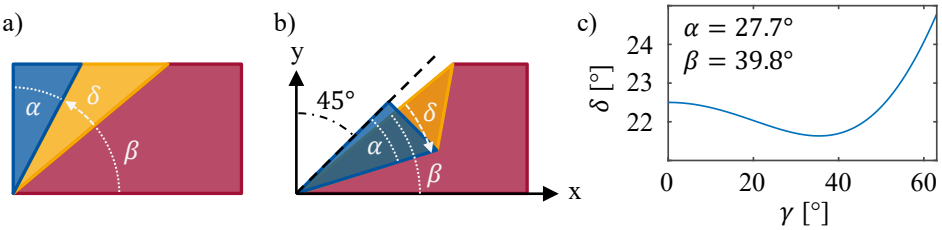

Figure 3.1. Exemplary course of $\boldsymbol{\delta}$ over the stroke $\boldsymbol{\gamma}$

To maximize the stroke while minimizing changes in δ, γ could theoretically be set near zero or around the minimum point of δ. However, setting γ close to zero is not technically feasible because it would cause actuator components to intersect. Therefore, γ is defined as $\gamma = [21°, 45.8°]$. This range includes the minimum point of δ and allows for a maximal stroke that is twice as large as the minimal stroke.

To ensure that the structure closely resembles origami, the relationship given by Equation 2.1 is taken into consideration. This relationship guarantees that the origami pattern can be folded from a flat sheet of paper, as illustrated in Figure 3.1.a). The pattern

can be folded according to Figure 2.1.c). When the pattern is folded flat ($\gamma = 0°$), Figure 2.1.c) becomes Figure 3.1.b) when viewed from above. Then, α, β, and δ have the relationship given by Equation 3.5:

$$\alpha + \beta - 45° = \delta \tag{3.5}$$

Equating Equation 2.1 and Equation 3.5 yields $\delta = 22.5°$. Inserting this into Equation 2.1 yields the condition between α and β given by Equation 3.6:

$$\alpha + \beta = 67.5° \tag{3.6}$$

The maximum and minimum values of δ during the stroke $\gamma = [21°, 45.8°]$ are determined using Equation 3.4 with values of α and β that satisfy the condition in Equation 3.6. Then, the change in δ, $\Delta\delta$, is calculated using Equation 2.2.

With $\alpha = 27.70°$ and $\beta = 39.80°$, the change in δ, $\Delta\delta$, is minimal and less than 0.5°. Finally, δ is redefined as $\delta_{\text{new}} = 21.81°$. This value is the mean between $\delta_{\max}$ and $\delta_{\min}$. Although this contradicts the relationship of Equation 3.5, δ_{new} ensures that compression and elongation of the crease $\overline{BC}$ are balanced.

Subsequent work will proceed using these optimized parameter values.

4. PROTOTYPE DESIGN AND MANUFACTURING

Building on the previously optimized geometry, this section describes the process of translating the design into a functional prototype and addresses the associated technical challenges.

One of the main challenges in transferring an origami-inspired structure to a technical application is accounting for material thickness. While paper's negligible thickness allows for ideal folding, technical structures require facets with significant thickness to enable force transmission. This consideration has already influenced the lower limit of γ. It also allows Tachi's approach to be applied, in which origami pattern creases serve as rotational axes and material is strategically removed from areas where intersections would otherwise occur [10].

This actuator uses hinges, as used by Shao et al. [11], in creases that transmit compressive forces for several reasons. They are durable and cannot be wedged between facets under compression. They also avoid brittleness over time, which could occur with flexible materials. However, since traditional hinges are not airtight, an air pouch must be inserted inside, as in Sadeghi et al.'s method [8]. The relative movement of the hinges must be considered, as it could damage the air pouch.

Since facets E and S are the largest facets of the actuator, they bear most of the force that needs to be transmitted to the end facets of the actuator. These compressive forces need to be transmitted via the creases, so these facets are connected via hinges. This results in numerous precisely aligned hinge axes across the entire actuator, necessitating tight production tolerances.

During small strokes, facet V becomes wedged between facets E and S. In order to accommodate the material thickness of facet V without any material intersection, the material from facets E and S must be moved out of their respective planes. This adjustment does not affect pneumatic performance. The force output remains unchanged, as long as the

hinge axes remain correctly positioned. However, this modification results in less favorable internal load path within facets E and S, so these parts require reinforcement with support structures. Support structures on the inside of the actuator should be avoided to protect the air pouch.

These requirements, including hinged connections with precise positioning and small tolerances, out-of-plane material displacement, and reinforcement, result in highly complex components for facets E and S. Consequently, additive manufacturing is chosen for prototyping these parts. To be cost-efficient, FDM (fused deposition modeling) printing with PLA (polylactic acid) is used. However, the anisotropic mechanical properties resulting from print orientation must be considered, as demonstrated by Abdul Sani [12]. In general, to prevent hinge failure, the hinge axes should be perpendicular to the print layers. In case of this actuator, this orientation would expose parts of the components to perpendicular force transmission through the print layers, which could result in component failure. As a compromise, the components are printed at an angle (see Figure 4.1.). The wall thickness is set at $t = 4\,\text{mm}$, and steel rods with a diameter of $d = 2\,\text{mm}$ are used as hinge axes. Given these choices in materials and manufacturing methods, maximum internal pressure is limited to $p_A = 1\,\text{bar}_{rel}$. Support structures were iteratively improved under these conditions using an FEM (finite element method) simulation for facets E and S. The resulting parts for facet E and S are shown in Figure 4.1.. Figure 4.3. shows the parts assembled The dimensions corresponding to Figure 2.1. of the parts are $b_1 = 170\,\text{mm}$ and $b_2 = h = 50\,\text{mm}$.

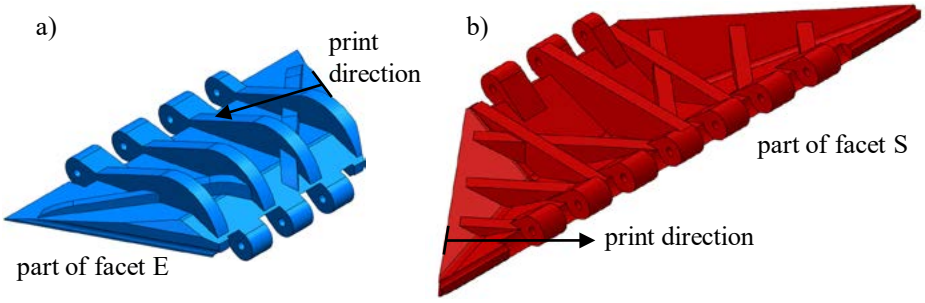

Figure 4.1. Parts of facet E and S, the shown print direction is perpendicular to print layers

A combination of steel and textile is used for both the hinges of facet V and the facet itself for several reasons. The fabric serves as a hinge, requiring significantly less space than a conventional mechanical hinge. These flexible fabric hinges are also well-suited for transmitting tensile forces, which are present along the outward-facing creases of facet V. A 1.5 mm sheet metal panel forms the main body of facet V, ensuring that it remains rigid and does not bulge under pressure. However, as it cannot accommodate for changes in δ, it is sandwiched between two layers of fabric. As the actuator operates, these fabric layers not only create the hinges but also compensate for variations in δ by stretching alongside the metal.

The sheet metal is held in place solely by stitching together the two surrounding fabric layers. In principle, combining the textile with an elastomer to form a composite material could make both facet V and its hinges airtight. Deleo et al. [13] and Zhakypov et al. [14] used similar approaches. However, since an air pouch is already used to achieve airtightness

due to the non-sealing hinges on facets E and S, this additional step is unnecessary. Linen is selected as the textile because it allows controlled stretching, can efficiently transmit tensile forces, and remains thin enough for compact integration. The resulting structure of facet V is illustrated in Figure 4.2..

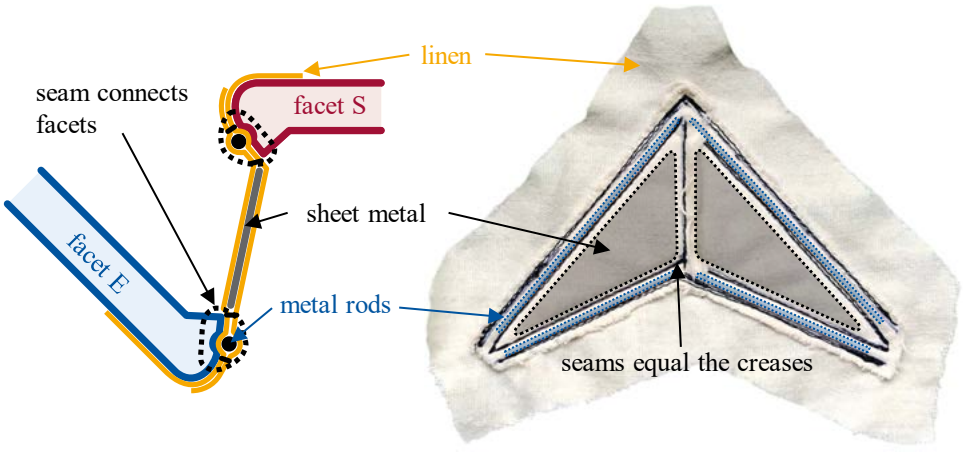

Figure 4.2. Design of facet V; Cross-section through facet E, V and S (left) and assembled facet V (right)

This design provides sufficient space for the air pouch while allowing facet V to fit between facets E and S throughout actuator movement. Metal rods, also enclosed within the two fabric layers of facet V, are stitched to facets E and S to connect facet V securely at both ends, as shown in Figure 4.2..

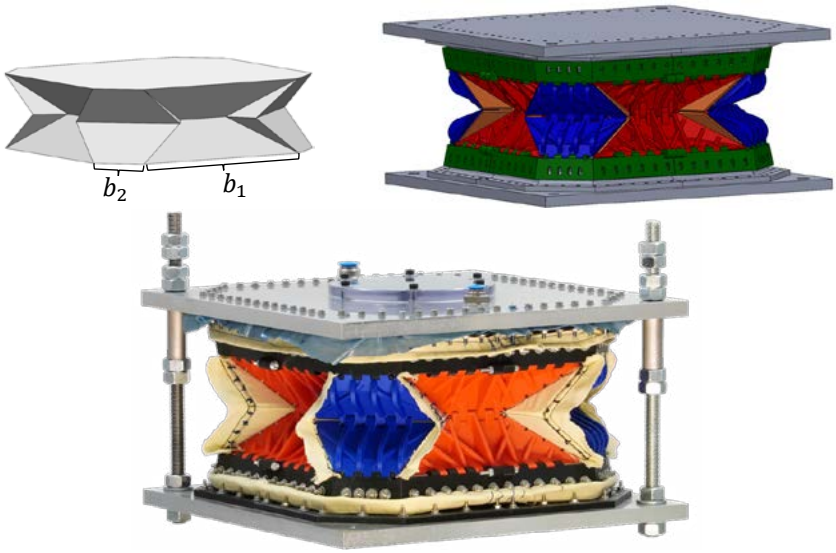

Figure 4.3. top: Origami-pattern and CAD-model of the prototype (screws are not shown); bottom: prototype of the actuator

Based on Sadeghi's approach, the actuator is sealed using a custom-made, tube-shaped air pouch made of 0.1 mm thick, low-density polyethylene film [8]. To protect the air pouch, all interior surfaces are kept flat with rounded corners and small gaps between parts. Additionally, a textile sleeve separates the moving origami elements from direct contact with the air pouch to prevent frictional wear or pinching, even when gaps open around moving joints. The air pouch's circumference exceeds what is needed. This ensures that the air pouch does not stretch but rather forms harmless folds of excess material.

Finally, the top and bottom of the actuator are closed off with 13 mm aluminum plates. These plates provide mounting points for mechanical and pneumatic connections. The air pouch is sandwiched between the printed origami parts and the aluminum plates. Silicone sealant ensures airtightness. Figure 4.3. illustrates the final prototype.

Like Tachi's approach, the rotational axes of the actuator correspond to the origami creases [10].

5. FORCE APPROXIMATION

Before conducting experimental investigations, the force-stroke characteristic of the developed actuator is first approximated mathematically. This preliminary analysis supports both the design of the testbed and the validation of subsequent measurement results.

To simplify the calculations, the origami structure is reduced to a two-dimensional bar model, as shown in Figure 5.1.. In this approximation, only facets E and S are considered. The contribution from facet V is neglected because its effect on the total output force is relatively small. The resulting pressure force of each facet F_{res} is concentrated at its centroid. Hereby z_s is the distance between the centroid and the hinge.

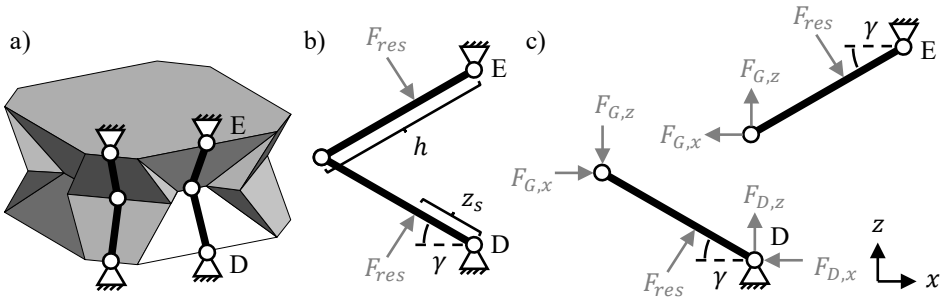

Figure 5.1. simplified mechanism for force approximation

The force $F_{G,z}$ can be determined for the lower and upper beams in Figure 5.1.c) if moment equilibrium is assumed at points D and E. Equating the two moment equilibria, it follows that $F_{G,z} = 0$. The force $F_{D,z}$ can be calculated using force equilibrium for the lower beam, as shown by Equation 5.1:

$$\Sigma F_z = 0 \Rightarrow F_{D,z} = -F_{res} \cdot \cos\gamma + F_{G,z} = F_{res} \cdot \left(\frac{z_s}{\cos\gamma \cdot h} - \cos\gamma\right) \tag{5.1}$$

The overall force generated by the actuator can then be expressed as shown in Equation 5.2:

$$F_{actuator} = 4 \cdot F_{D,z-facet\,S} + 4 \cdot F_{D,z-facet\,E} + F_{end\,face} \tag{5.2}$$

The force, $F_{end\ face}$, is the internal pressure multiplied by the area of the end face. The approximation of the actuator's output force will be used to validate the experimental results.

6. EXPERIMENTAL INVESTIGATION

To validate the proposed concept of an origami-inspired pneumatic actuator with a progressive force-stroke characteristic, this section describes the experimental procedures used to evaluate the previously designed prototype.

The primary focus of the experiments is to determine the force-stroke relationship of the actuator at constant internal pressures. To achieve this, a testbed is set up that can maintain a constant internal pressure, allow for variable stroke adjustments, and accurately measure the resulting force. Due to limitations of the available testing equipment, measurements can only be taken up to a maximum load of $5{,}000\ \mathrm{N}$. This restricts the maximum internal pressure p_A during testing.

During each test series, the internal pressure of the actuator is set to an initial value of $0.05\ \mathrm{bar}_{rel}$, which remains constant while the stroke is varied. The stroke is repeatedly decreased and increased three times before the internal pressure is raised by another increment of $0.05\ \mathrm{bar}$. This process continues until the actuator's output force reaches $5{,}000\ \mathrm{N}$. All measurements were recorded at a sampling rate of $1{,}000\ \mathrm{Hz}$ for high temporal resolution.

7. ACTUATOR CHARACTERIZATION

This section presents and analyzes the results obtained from experimental testing of the novel origami-inspired pneumatic actuator.

The previously described measurements were performed using the presented prototype. The maximum pressure is limited to $0.7\ \mathrm{bar}_{rel}$ as the output force would otherwise exceed $5{,}000\ \mathrm{N}$. For this reason, the maximum pressure for which the actuator is designed cannot be tested. To visualize the results, force is plotted against actuator stroke. The stroke x can be calculated from the angle γ. The angle $\gamma = [21°, 45.8°]$ corresponds to a stroke $x = [35.8\ \mathrm{mm},\ 71.6\ \mathrm{mm}]$ with the proposed dimensions of the prototype. To eliminate the influence of the end stops, x is set within the range of $x = [36.5\ \mathrm{mm},\ 72.3\ \mathrm{mm}]$. The lower end stop is defined by the actuator parts. The upper end stop can be set freely. Since the lower limit of x increased to eliminate the influence of the lower end stop, the upper limit is also raised to achieve the intended total stroke. In Figure 7.1. the force-stroke characteristic is exemplified for an internal pressure of $p_A = 0.3\ \mathrm{bar}_{rel}$. To reduce measurement noise each data point is averaged over the previous 100 samples. This is acceptable because the stroke changes relatively slowly.

The resulting plot shows a hysteresis between increasing and decreasing stroke. The hinge friction could be the main cause of this effect. When retracting, frictional forces act in the same direction as the measured force. When extending, they oppose it. Consequently, measured force values are lower during extension than during retraction at any given stroke position.

Figure 7.1. also displays the approximated force curve for $p_A = 0.3\,\mathrm{bar}_{rel}$ based on the previous calculations from section 5. Both the magnitude and trend of measured values closely match these theoretical predictions.

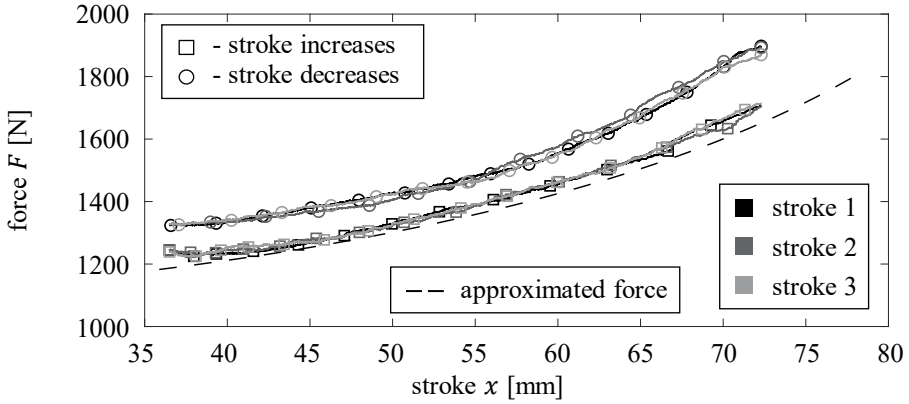

Figure 7.1. Actuator output force F plotted against actuator stroke x, with internal pressure $p_A = 0.3\,\mathrm{bar}_{rel}$ and approximated force according to section 5

To further analyze performance and minimize the effect of pressure fluctuations during testing, each measured force value was divided by its corresponding pressure reading. The resulting "active area" metric A_{active} is proportional to the output force, yet independent of the pressure. These active area results for an internal pressure of $p_A = 0.3\,\mathrm{bar}_{rel}$ are shown in Figure 7.2..

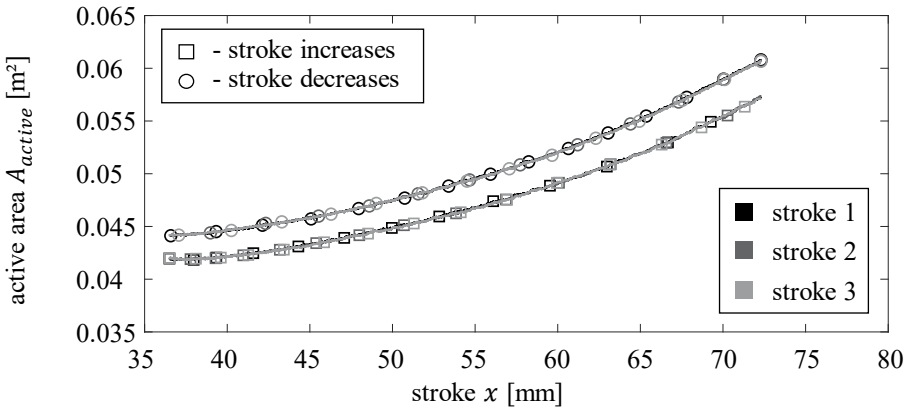

Figure 7.2. Active area A_{active} plotted against actuator stroke x, with internal pressure $p_A = 0.3\,\mathrm{bar}_{rel}$

The three stroke cycles now align more closely with each other. This indicates that the previously observed fluctuations were largely due to minor variations in internal pressure rather than inconsistent actuator behavior.

The active area serves as a robust measure for comparing different pressure levels independently of the internal pressure. Figure 7.3. presents the active area of the actuator at different internal pressures. The internal pressure, p_A, ranges from $0.05\ \mathrm{bar}_{rel}$ to $0.7\ \mathrm{bar}_{rel}$ and describes the internal pressure of the actuator.

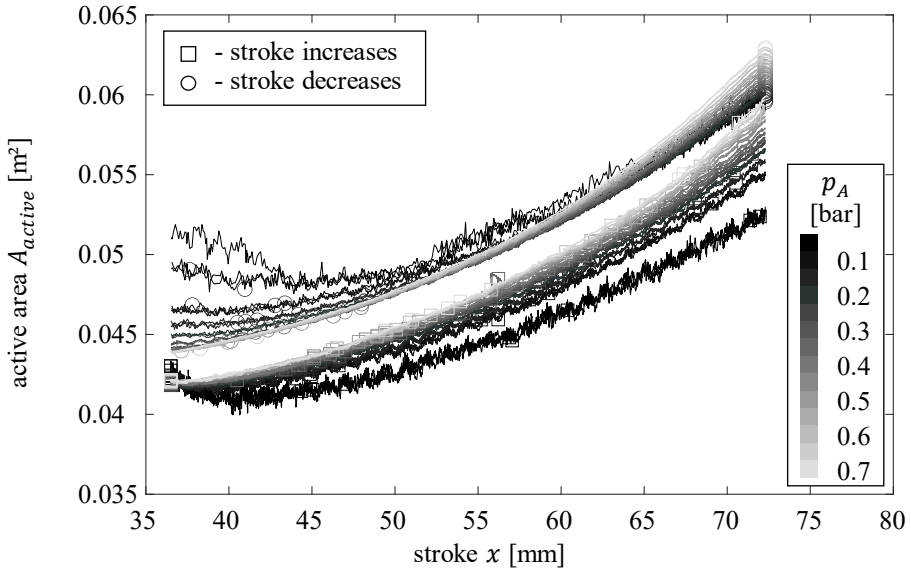

Figure 7.3. Active area A_{active} plotted against actuator stroke x, with different internal pressures p_A

At lower pressures, greater deviations are observed. These are likely because friction has a proportionally larger effect at low pressure. Friction could increase at low strokes, as the support structures of Facet E move closer together and rub against each other. At higher pressures the curves converge consistently. For strokes above approximately $x = 60\ \mathrm{mm}$, some divergence appears at higher pressures. This is likely due to stretching or deformation of parts under load, which results in minor changes in γ. These changes result in greater variations in output force at extended positions.

Overall, these results demonstrate that the actuator exhibits repeatable behavior and delivers a progressive force-stroke characteristic consistent with prior calculations.

8. CONCLUSION AND DISCUSSION

In this work, a novel origami-inspired pneumatic actuator concept featuring a progressive force-stroke characteristic was developed. An initial analysis of the geometric relationships served as a basis for the design and prototype implementation with minimized stretching of the facets.

The design uses 3D-printing. A textile-metal composite is used to achieve the necessary deformations in the actuator's facets. This approach allows the complex origami-geometry to be realized in a technical structure.

Experimental validation shows that the prototype works as intended. The measured force-stroke curves match the mathematically predicted progressive behavior. Results are consistent across multiple tests, showing that the actuator's performance is reproducible.

These findings confirm that it is possible to build an origami-based pneumatic actuator with a progressive force-stroke characteristic, by integrating flexible materials at key points.

Despite these achievements, high manufacturing effort remains a limitation due to complex components that require significant assembly effort. Future work can further develop this concept. Various origami-patterns could be explored to tailor pneumatic properties further based on usage requirements. Material selection and production methods can also be improved. Reducing manufacturing complexity and employing alternative materials for enhanced mechanical performance could facilitate the industrial use of such actuators. Potential applications include suspension systems or automation technology. In these fields, actuators with tailored force-stroke characteristics offer significant advantages. A simpler design could miniaturize the actuator, qualifying it for broader applications.

Overall, this study demonstrates both the feasibility and potential of origami-inspired pneumatic actuators for advanced engineering applications.

Abstract.

This paper demonstrates how the Asset Administration Shell (AAS) can be used as an integration and orchestration layer for automated, product-specific processing of real machine data. Using a ballpoint pen assembly machine, standardized AAS mechanisms enable cloud-based visualization, energy analysis, and CO_2 accounting. The approach highlights product-related sustainability assessment in fluid power systems and illustrates the AAS as a key enabler for interoperable and scalable digital engineering workflows.

Keywords. Fluid 4.0, Asset Administration Shell (AAS), AAS-orchestrated data processing, Digital Twin, Fluid Power Systems, Energy and CO_2 analysis, Sustainability assessment, Industry 4.0

1. INTRODUCTION

The increasing demands for transparency, energy efficiency, and sustainability in industrial production require new, integrated digital concepts for information and data processing. In fluid-based production systems in particular, there has been a lack of standardized approaches for consistently utilizing real machine data for analysis, visualization, and product-related sustainability assessments.
This article presents an end-to-end solution orchestrated entirely by the Asset Administration Shell (AAS) [1], which is demonstrated using a ballpoint pen assembly machine as an example. The aim is to present the end-to-end flow of information from the real machine via cloud-based services to product-related CO_2 accounting and visualization in a comprehensible manner.
To provide context for the application example, the following chapter first introduces the machine used.

2. MACHINE AND SYSTEM OVERVIEW

The left-hand side of **Figure 2.1** shows the machine used to demonstrate the AAS-orchestrated data flow. The machine is an *Industry 4.0* [2] demonstrator from the *Fluid 4.0*

[3] research project. The machine, built by project partner *Emerson Aventics* [4], produces ready-to-use ballpoint pens from four basic components: the housing, refill, spring, and cap. The actual assembly process is carried out by valve-controlled pneumatic grippers and rotary actuators, while electromechanical linear axes transfer the components from the transfer points of the storage magazines to the respective assembly positions. After successful assembly, the machine assigns a unique serial number to each manufactured ballpoint pen, which is printed on a Fluid 4.0 product sticker and attached to the pen.
This serial number then allows the owner to access the product-related production data for their ballpoint pen using any AAS-enabled application.

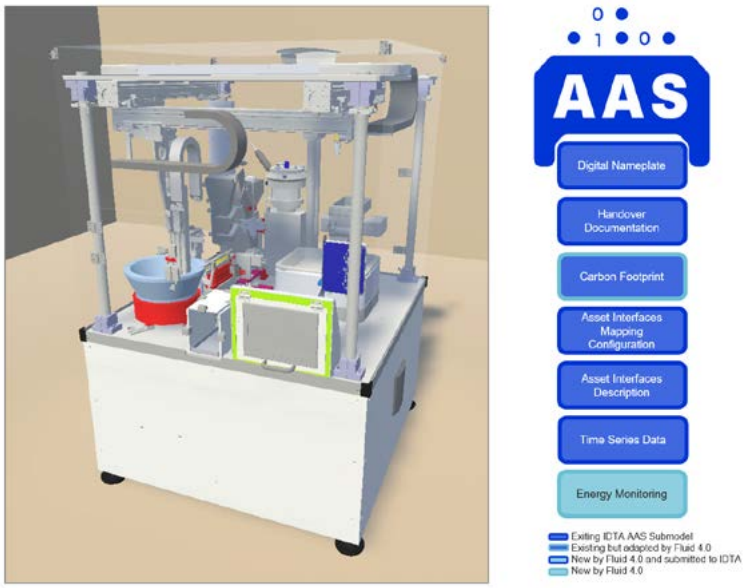

Figure 2.1 : Ballpoint pen assembly machine and AAS submodels used

During the assembly process, the machine collects the data listed below and continuously transmits it to the *MQTT broker* [5] of the project partner *Fluidon* [6]:

- pneumatic air consumption,
- electrical energy consumption,
- valve signals
- Positions of the linear axes
- serial number of the ballpoint pen being produced.

This production data forms the basis for AAS-orchestrated data processing.
The right-hand side of Figure 2.1 shows an overview of the AAS submodels used in the application example. The legend distinguishes between submodels that have already been standardized by the *IDTA* [7] and those that have been newly developed or expanded as part of the Fluid 4.0 research project.

3. AAS-ORCHESTRATED DATA PROCESSING WORKFLOW

Data processing is carried out via a data processing workflow created in the SaaS development environment *Fluidon Cube* [8]. For the sample application, the processing of production data is deliberately implemented in small steps in order to present the individual interactions with the AAS submodels involved in a didactically comprehensible manner. **Figure 3.1** shows the sequence of process steps with which the project partners implemented AAS-orchestrated data processing.

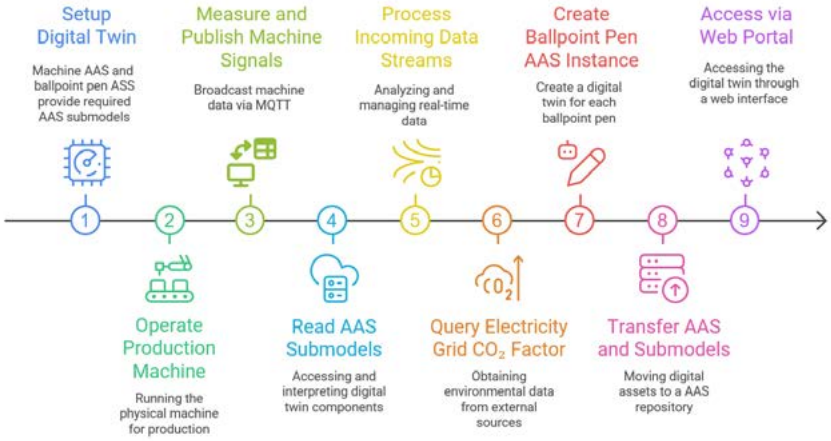

Figure 3.1 : Overview of the process steps

3.1. Preparatory work

In the first process step, an instance AAS of the machine and a type AAS of the ballpoint pen were first created (see Figure 3.1-1, *"Setup Digital Twin"*). The following process step (see Figure 3.1-2, *"Operate Production Machine"*) is representative of the preparatory work on the machine. Pneumatic pressure and flow sensors, a system for recording the electrical power consumption of the linear axes, and a label printer were retrofitted. The third process step (see Figure 3.1-3, *"Measure and Publish Machine Signals"*) represents the integration of all necessary signals into the control system's data acquisition, their processing, and their transmission to the MQTT broker.

3.2. The data processing workflow

The fourth process step (see Figure 3.1-4, *"Read AAS Submodels"*) symbolizes the start of the actual AAS-orchestrated data processing. After the workflow has retrieved the machine's AAS submodels and connected to the MQTT broker, signal processing takes place (see Figure 3.1-5, *"Process Incoming Data Streams"*). Following the query of the current CO_2 emission factor (see Figure 3.1-6, *"Query Electricity Grid CO_2Factor"*) and calculating the CO_2 parameters, an instance AAS of the ballpoint pen just produced is created in the seventh process step (see Figure 3.1-7, *"Create Ballpoint Pen AAS Instance"*).

3.3. Provision and use of data

In the eighth process step, the generated instance AAS and the associated submodels are transferred to any AAS repository server (see Figure 3.1-8, *"Transfer AAS and Submodels"*).

The information contained therein or linked to it is then available for interoperable access, for example via a web portal or other AAS-enabled applications (see Figure 3.1-9, *"Access via Web Portal"*).

4. PARTICIPATING ASSET ADMINISTRATION SHELLS

At the heart of AAS-orchestrated data processing are the instance AAS of the machine and the type AAS of the ballpoint pen. As already presented in the right-hand section of the image at Figure 2.1, both standardized AAS submodels and those developed jointly with other Fluid 4.0 project partners were used to create them.

4.1. Instance AAS of the ballpoint pen assembly machine

With the aim of graphically illustrating the structural design of an AAS, **Figure 4.1** shows a screenshot of the instance AAS of the machine. In the context of the application example, the instance AAS can be accessed via the AAS repository server of the project partner *IQstruct Engineering* [9]. Access to the machine's AAS instance is controlled by IQstruct Engineering via an access rights management system based on preliminary work from *Eclipse BaSyx* [10] and prototypically implemented as part of the Fluid 4.0 research project.

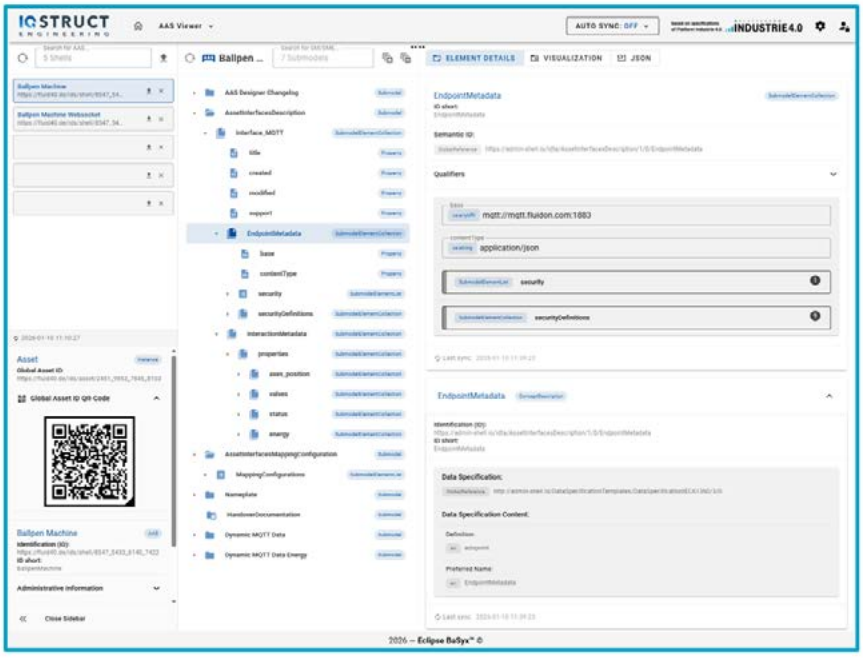

Figure 4.1 : Instance AAS of the ballpoint pen assembly machine

The middle section of the image at Figure 4.1 shows all the submodels contained in the AAS. The two AAS submodels *Asset Interface Description* (AID) [11] and *Asset Interface Mapping Configuration* (AIMC) [12] are used for the application example.
The right-hand side of the image shows elements from the *Submodel Element Collection* (see[1, p. 56]) *"EndPointMetadata"* of the AID submodel (see[11, p. 16]). All information

required for the automatic connection of the data evaluation workflow can be read from the elements in this collection. In the application example, the MQTT broker of the project partner Fluidon is entered here.
The AIMC submodel is used for the formal description of the mapping of technical machine interfaces to semantically defined AAS properties. It enables a clear decoupling between the physical or IT data source (e.g., fieldbus, MQTT, OPC UA) and the semantic structure of the administration shell. This allows production data to be automatically collected, interpreted, and further processed by the data processing workflow without project-specific adjustments. The submodel thus forms the central basis for AAS-orchestrated, scalable data processing.

4.2. Type AAS of the ballpoint pen

Figure 4.2 shows a screenshot of the type AAS of the ballpoint pen. The submodels required for the application example are listed in the left-hand part of the image at Figure 4.2. In addition to the *Nameplate* submodel [13], these are the *Handover Documentation* [14] and *Time Series Data*[15] submodels, as well as the *Carbon Footprint* [16] submodel, which was expanded as part of Fluid 4.0.

Figure 4.2 : Type AAS of the ballpoint pen

To demonstrate interoperability, the Type AAS in the application example is provided via Fluidon's AAS repository server and not via IQstruct Engineering's AAS repository server. A direct comparison of the screenshots from Figure 4.1 and Figure 4.2 shows that the two AAS are also managed on two different AAS repository server implementations. IQstruct Engineering uses the Eclipse *BaSyx Java V2* [17], while Fluidon uses the *Eclipse AASX Server* [18]. This is to illustrate that it is irrelevant for AAS-orchestrated data processing where and with which server implementation the participating AAS are hosted. Interoperable access to information is possible at any time via the standardized AAS mechanisms.
The following chapter describes how the two administration shells and their submodels are used in AAS-orchestrated data processing.

5. AAS-ORCHESTRATED DATA PROCESSING

The AAS-orchestrated data processing workflow is explained using the sequence diagram shown in **Figure 5.1**. Four actors are involved in the workflow:

- *Operator*, who interacts with the data processing workflow
- *Fluidon Cube*, which hosts the workflow
- *Web APIs*, representing the web services involved
- *Real Machine*, as the process data source

It is clear that the actors *Operator* and *Real Machine* are only actively involved in the process at the beginning and end. The actual data processing, on the other hand, is fully automated, as the distributed systems involved can be accessed via the standardized, interoperable access mechanisms of Asset Administration Shell.

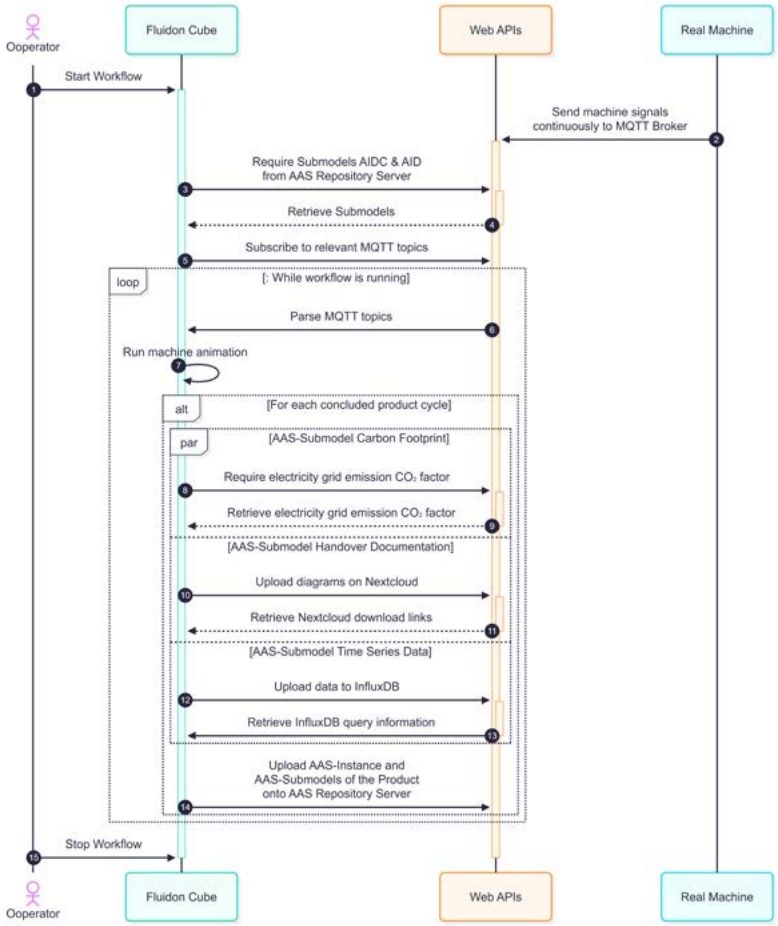

Figure 5.1 : Sequence diagram of AAS-orchestrated data processing

5.1. Start of AAS-orchestrated data processing

In the first step (see Figure 5.1-1), the operator starts the data processing workflow. It is irrelevant whether the machine is already in production at this point or – as shown in the figure (see Figure 5.1-2) – only starts the production process after the workflow has been started.

5.2. Data transfer and data preprocessing

The data processing workflow consists of several tasks, the respective functional scope of which is tailored to the process steps described in Figure 5.1. Each task performs a maximum of one AAS-supported interaction with external services in order to keep the data processing sequence comprehensible for the user of the application example. In the example, the workflow has 8 processor cores at its disposal, so that data processing takes place in parallel tasks. **Figure 5.2** shows the view of the data processing workflow in the *Fluidon Cube* development environment [8].

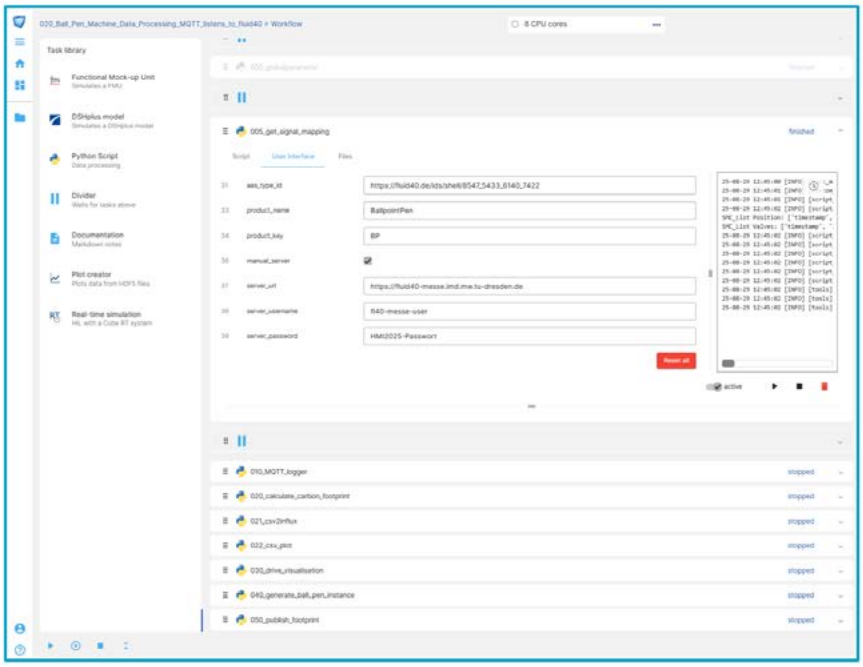

Figure 5.2 : Fluidon Cube data processing workflow [8]

The individual data processing steps were implemented using Python scripts, specifically using freely accessible libraries from the BaSyx environment [10], such as *AAS Python SDK* [19] or *aas-core-python* [20], as well as AAS-specific libraries [21], which were developed as part of Fluid 4.0 and will be handed over to the BaSyx community after the project is completed. The data-processing Python scripts can be viewed by the user on request and can serve as a template for using the BaSyx libraries in their own applications.
The user specifies under *31 aas_type_id* which machine the workflow is connected to and defines the name of the product under *33 product_name*. In addition, they specify on which AAS repository server the generated product instances are to be stored. In the application example, a repository server of the project partner *TU Dresden* [22] is used for this purpose. At the beginning of the process flow (see Figure 5.1-3), the workflow first authenticates itself with the AAS repository server and receives the AAS submodels AID and AIMC from it (see Figure 5.1-4). After successfully connecting to the MQTT broker (see Figure 5.1- 5), the workflow subscribes to the corresponding topics and starts continuous data recording.

The workflow receives the current production data (see Figure 5.1-6) and stores it temporarily.

5.3. Visualization of production data

Some of the data is processed numerically and forwarded to a 3D visualization of the assembly machine in the workflow dashboard (see Figure 5.1-7). **Figure 5.3** shows this dashboard, which integrates online graphics to display the temporal progression of selected process signals in addition to the 3D visualization.

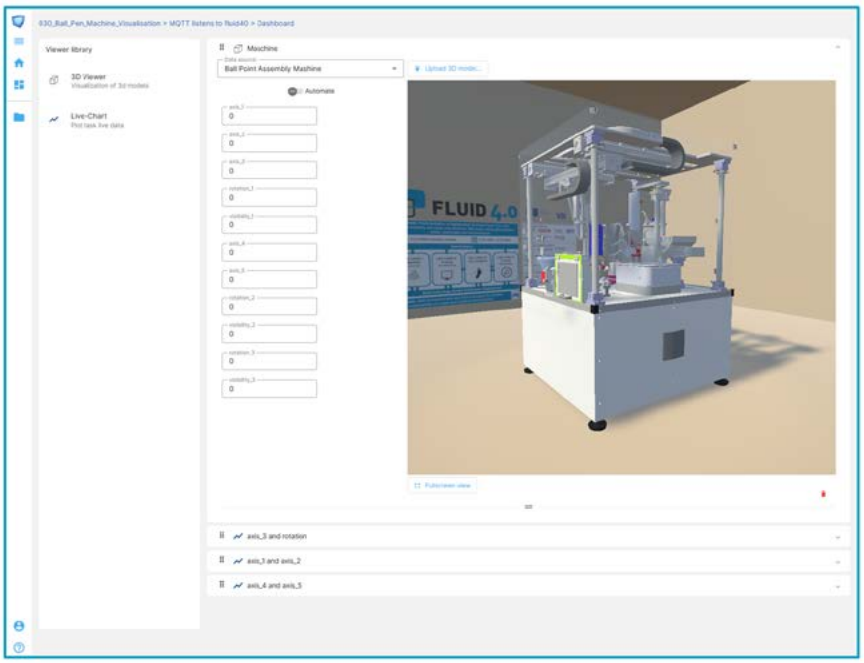

Figure 5.3 : Visualization of the ballpoint pen assembly machine

The visualization can be displayed:

- **live,** parallel to the ongoing production process, or
- **retrospectively** based on the stored time series data.

This creates a digital twin of the machine that visualizes the current or historical machine status regardless of location.

5.4. Energy analysis, CO_2 accounting, and documentation

As soon as the machine reports that the production of a ballpoint pen has been completed, energy analysis, CO_2 accounting, and product-related documentation are initiated in parallel tasks. Based on the recorded production data, the energy consumption per production cycle is determined, distinguishing between

- pneumatic energy (amount of compressed air used) and
- electrical energy (movements of the axes).

This differentiation is particularly important for fluid technical systems, as pneumatic energy is often insufficiently taken into account in classic CO_2 balancing. In the application example, this circumstance is taken into account by using a *conversion factor* that converts the consumed pneumatic energy into an electrical power equivalent for its generation. **Figure 5.4** shows the corresponding input field for this conversion factor in the workflow task. The conversion factor is multiplied by the balanced pneumatic energy; the resulting electrical equivalent is then added to the balanced electrical energy.

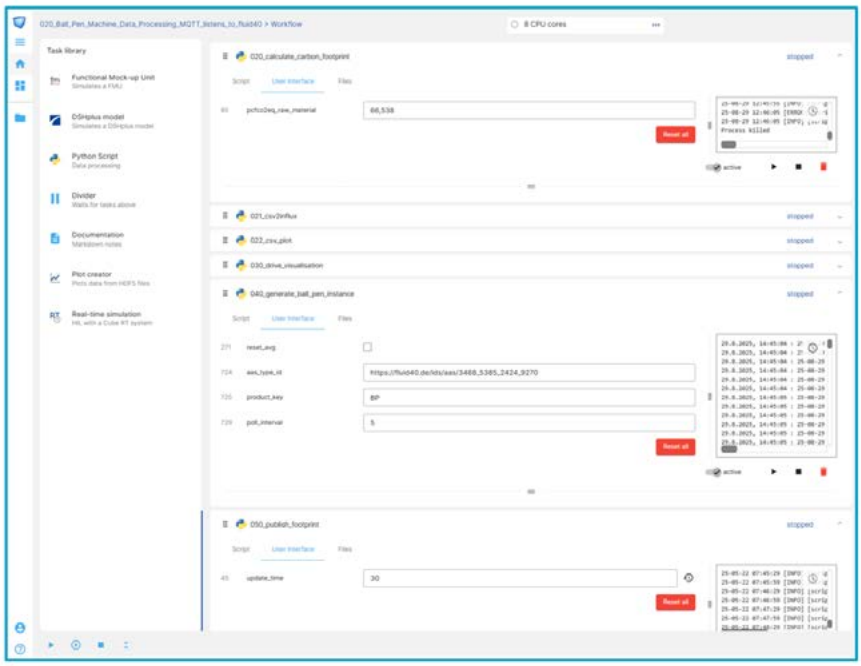

Figure 5.4 : Workflow detail for CO2 accounting

To determine the CO_2 footprint, the CO_2 emission factor of the power grid valid at the respective time of production is automatically queried via external servers (see Figure 5.1-8 and -9). Multiplying this emission factor by the determined electrical energy results in an individual, product-related CO_2 value for each ballpoint pen. This is stored in the *Carbon Footprint* submodel of a newly created product instance AAS for the ballpoint pen.
At the same time, another task generates diagrams (see Figure 5.1-9) that show, for example, the axis positions of the handling system or the development of pneumatic and electrical energy consumption over time. The diagrams are stored on a Nextcloud drive belonging to the project partner Fluidon; the download links generated (see Figure 5.1-11) are stored in the *Handover Documentation* submodel of the product instance AAS.

In addition, the production data is stored long-term in a time series database (InfluxDB) (see Figure 5.1-12). The associated database queries (see Figure 5.1-13) are stored in the *Time Series Data* submodel of the product instance AAS. An AAS-based interface thus enables targeted access to historical production data – for example, based on the serial number or a time period – which supports further analysis even long after production has been completed.

5.5. Uploading the instance AAS of the ballpoint pen

Once the data analysis and submodel creation are complete, a product-related instance AAS for the ballpoint pen is generated in the final process step (see Figure 5.1-14). To do this, the type AAS presented in Figure 4.2 is loaded and instantiated with the results determined in the workflow, creating a concrete product instance AAS. Finally, this is transferred to the previously specified AAS repository server.

6. USER ACCESS TO THE BALLPOINT PEN AAS

The owner of a ballpoint pen can use a web application to retrieve the corresponding product instance AAS by entering the serial number printed on the product. This access provides both product-related sustainability indicators such as the carbon footprint and process-related visualizations and documents. **Figure 6.1** shows an example of user access via the Fluid 4.0 research project website. The image shows an entry from the *Carbon Footprint* submodel.

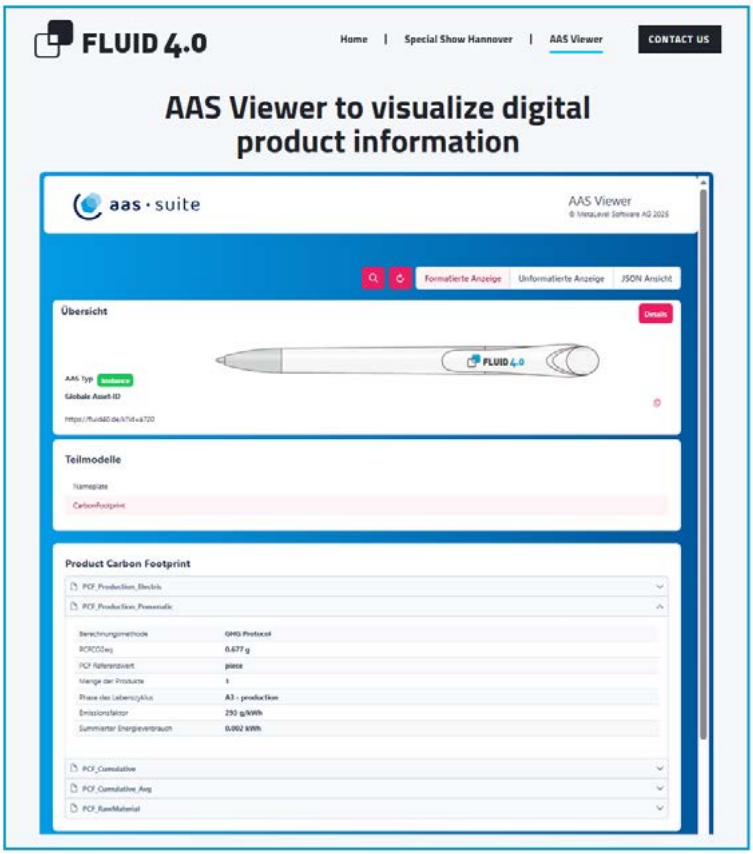

Figure 6.1 : User access to the ballpoint pen AAS

The functionality was implemented using a browser plugin provided by the associated project partner *Metalevel* [23]. This plugin can be integrated into any website with minimal

effort and is connected to any AAS repository server on the backend side by Metalevel. **Figure 6.2** illustrates user access using a sequence diagram. The *client application* represents the browser plugin in the user's web application and the backend at Metalevel.

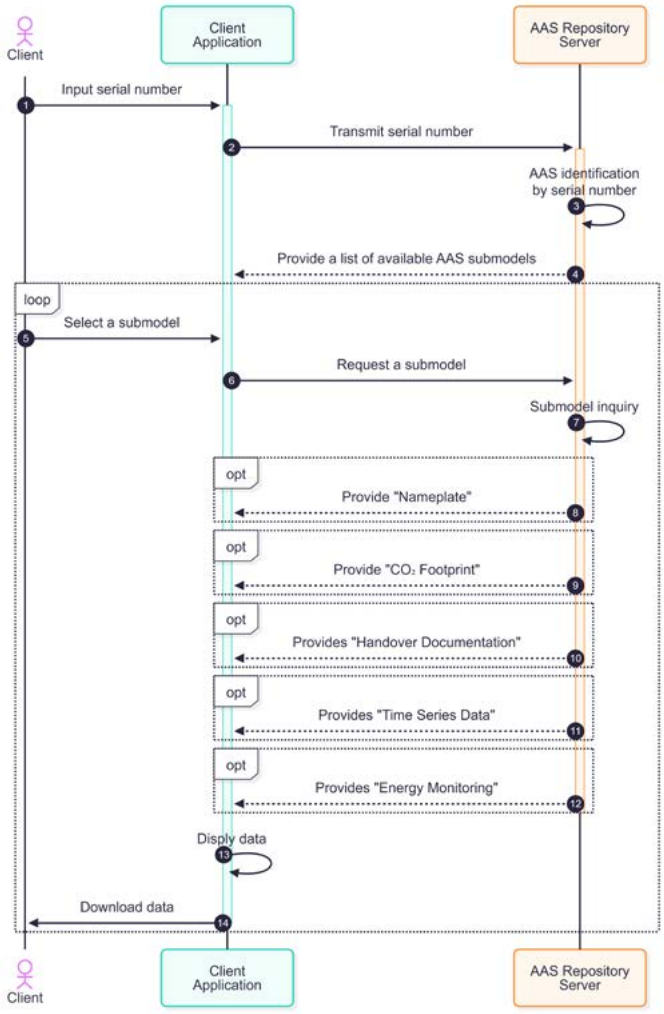

Figure 6.2 : Sequence diagram of user access

The serial number entered by the user (see Figure 6.2-1) is transmitted to the *client application*, which then queries the AAS repository server for the AAS associated with the serial number (see Figure 6.2-2). The AAS repository server determines the appropriate product instance AAS (see Figure 6.2-3) and transmits the metadata required to access the contained submodels to the *client application* (see Figure 6.2-4).
The user selects the relevant submodel in the browser plugin (see Figure 6.2-5), which is then requested by the *client application* from the AAS repository server (see Figure 6.2-6). The AAS repository server determines the requested submodel and transfers its contents to

the browser plugin (see Figure 6.2-7 to 11), where they are visualized (see Figure 6.2-12). The user can then access and download the displayed data. **Figure 6.3** shows an example of a results graph depicting the axis positions of the handling system during the production of a ballpoint pen.

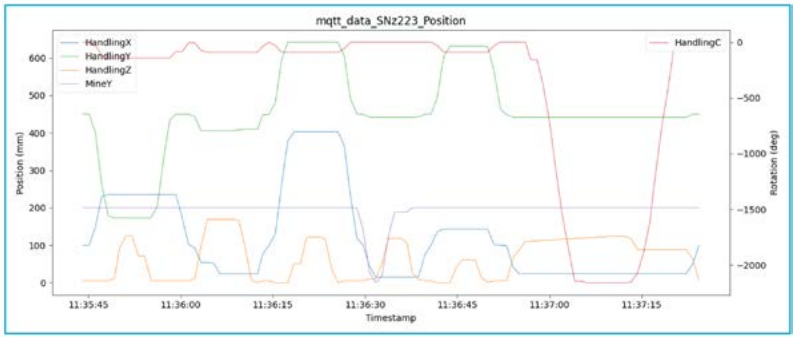

Figure 6.3 : Result diagram from the handover documentation

Furthermore, access to the product AAS is not limited to a single application. Thanks to the standardized interfaces and semantic descriptions of the Asset Administration Shell, the stored information can also be used by any AAS-enabled application. These include, for example, mobile applications for product information, analysis tools for quality or sustainability assessments, and engineering or simulation tools that access historical production data.

Another such use case is access to the time series data referenced in the *Time Series Data* submodel. Authorized users can use the database queries stored there to access specific historical production data, for example, to analyze process deviations, track individual batches, or perform further statistical evaluations.

The separation between data storage, semantic description, and access via standardized AAS mechanisms thus enables flexible and future-proof use of product data throughout the entire lifecycle. New applications or services can be connected to the product AAS without adapting the existing data processing, allowing the AAS to function as a central integration interface for product-related information.

7. SUMMARY

This article uses an industrial demonstrator to show how the Asset Administration Shell can be used as a consistent integration and orchestration layer to automatically collect, process, and provide real machine data for specific products. Using the example of a ballpoint pen assembly machine, it was demonstrated how production data can be linked to cloud-based services via standardized AAS mechanisms and used for visualization, energy analysis, and CO_2 accounting.

The solution presented illustrates in particular the interaction between machine instance AAS and product type or product instance AAS, as well as the role of standardized and project-specific extended AAS submodels for modular data processing. Through AAS-orchestrated workflow execution, central processing steps – from data acquisition and analysis to documentation – are fully automated and decoupled from specific IT or server implementations.

A particular focus was placed on the product-related sustainability assessment of fluid technology systems. The separate accounting of pneumatic and electrical energy and its consolidation into a product-specific carbon footprint shows how AAS-based data structures can be used for transparent and reproducible sustainability assessment.
Finally, it was presented how the generated product instance AAS can be used by different AAS-enabled applications via standardized interfaces. User access via a web application is only one example of a use case. Overall, the example underscores the potential of the Asset Administration Shell as a central basis for interoperable, scalable, and sustainable digital engineering and production processes, especially in the context of fluid power production systems.

8. ACKNOWLEDGEMENT

This work has been funded by the European Union (EU) and supported by the German Federal Ministry for Economic Affairs and Energy (BMWE) in the Fluid4.0 project – Revolutionizing Fluid Engineering: Implementation of digitalization for fluid power 4.0 in the cross-industry and cross-manufacturer data space using asset administration shells, submodels, and demonstrators (project numbers 13IK039E, 13IK039D, and 13IK039H). Micha Koebele received his M.Sc. degree from RWTH Aachen University in 2021. Since 2024, he has been working at FLUIDON GmbH as a development engineer, focusing on dynamic system simulation, model-based engineering, and automated simulation workflows for hydraulic and pneumatic systems. His work particularly addresses the integration of simulation models with digital twin concepts and Asset Administration Shell–based data structures in the context of Industry 4.0.

Heiko Baum studied mechanical engineering at RWTH Aachen University and completed his doctorate in 2001. Since 2001, he has been the managing director of FLUIDON GmbH, where he focuses on model-based engineering, digital twins, and automated simulation workflows for hydraulic and pneumatic systems. His long-standing experience in the simulation and development of fluid power systems bridges industrial applications and research projects in the context of Industry 4.0 and the Asset Administration Shell.

Jan Edler studied mechatronics at the University of Magdeburg and graduated with a Dipl.-Ing. After serving as the construction leader for all customer-specific pneumatic cylinders for Aventics GmbH, he began introducing the Emerson Intelligent Automation Software stack into global factories. His vast knowledge of pneumatic construction, data generation, and analytics converges with his close collaboration with universities and the digital twin initiatives driving the AAS.

Philipp Niemann-Stryczek has studied Computer Science at Trier University of Applied Science after graduating as a State-certified Technician, specialized in Automation Technologies at Aachen Technical College. Before founding and becoming Managing Director of IQstruct Engineering GmbH in 2018 he has been commissioning automobile production lines and developed distributed server backend systems. His passion creating digital twins is widely used within AAS related software and virtual commissioning solutions.

CFD-Based Optimization of a Supersonic Vacuum Ejector Using Combined 2D–3D Simulations and Latin Hypercube Sampling

Abstract.

This study proposes a combined two-dimensional (2D) and three-dimensional (3D) CFD-based optimization workflow with Latin Hypercube Sampling (LHS) for vacuum ejector nozzles operating in the supersonic flow regime. The reliability of the numerical framework is first established through detailed validation against experimental measurements under both open- and closed-suction operating conditions. The results demonstrate that the adopted CFD setup, boundary conditions, and the RNG k-ε turbulence model can accurately reproduce the measured ejector performance. The numerical simulations further provide detailed insights into the internal supersonic flow structures, including oblique shocks, shock reflections, and downstream shock trains.

Building on this validated CFD framework, the combined 2D–3D optimization workflow is applied, in which a 2D axisymmetric model is coupled with LHS to perform large-scale parametric screening of ejector geometries with enhanced suction performance. The most promising configurations identified from the 2D–LHS optimization are subsequently reconstructed and verified using full 3D simulations. The close agreement in predicted performance improvement between the 2D optimization results and the corresponding 3D validation confirms the reliability of the proposed workflow. Owing to its reduced computational cost and validated predictive accuracy, the methodology provides a practical and efficient design tool for the development of energy-efficient vacuum ejectors and is well suited for industrial applications.

1. INTRODUCTION

Vacuum ejectors are widely used for generating negative pressure in industrial automation and material handling, particularly in systems for gripping, holding, and transporting components.

To better understand and quantify the influence of ejector geometry on overall performance, Computational Fluid Dynamics (CFD) has been extensively applied. Several studies have reported that 3D CFD simulations can accurately reproduce the flow phenomena observed in Schlieren visualization experiments, confirming the capability of numerical models to capture shock-wave and pseudo-shock structures within ejector nozzles. Zhu and Jiang [1] demonstrated that experimentally observed shock trains can be accurately predicted by 3D simulations, while Chen et al. [2] confirmed close agreement between numerical reconstruction of the first shock wave and experimental data. Similar investigations on Laval nozzles showed that Large-Eddy Simulation (LES) achieves excellent consistency with Schlieren results, capturing multi-shock pseudo-shock systems and shock–boundary layer interactions [3].

Although 3D CFD simulations can provide highly accurate representations of ejector flow fields, their considerable computational expense makes them impractical for large-scale optimization studies and industrial applications. Consequently, an increasing number of publications have focused on two-dimensional (2D) CFD analyses as a more efficient alternative. Gagan et al. [4] and Schieder [5] demonstrated that 2D axisymmetric simulations can approximate 3D results with reasonable accuracy for most ejector configurations. More recently, Little et al. [6] compared 2D CFD predictions with Schlieren and shadowgraph visualization results for a large-scale air ejector and reported strong agreement between simulation and experimental observations under on-design operating conditions, confirming that 2D CFD can reliably capture key flow features and performance trends. These findings indicate that, while 3D modeling remains indispensable for resolving complex flow interactions, 2D CFD provides a validated and computationally efficient approach for ejector design and performance evaluation.

CFD-based optimization studies have identified several geometric parameters that strongly influence ejector performance. Wang et al. [7] found that the divergent angle and throat length of the primary nozzle are critical to the entrainment ratio, while Ruangtrakoon et al. [8] showed that the throat diameter and area ratio affect both entrainment capability and back pressure. Dong et al. [9] highlighted an optimal range of mixing chamber length for peak performance, and Wang et al. [10] demonstrated that 2D CFD can effectively guide design optimization before 3D validation. Building on this, Yann et al. [11] optimized three key geometries—the constant-pressure mixing chamber length, throat diameter, and constant-area mixing chamber length—under varying nozzle configurations, showing that the coupling between these dimensions and nozzle geometry plays a decisive role in shock structure and energy efficiency.

Building upon these previous efforts, the present study proposes an integrated methodology that combines 2D and 3D CFD simulations with Latin Hypercube Sampling (LHS) for efficient and accurate ejector optimization. The LHS method ensures uniform coverage of the parameter space with far fewer samples compared to conventional random sampling [12]. In this framework, the ejector geometry is parameterized so that each key geometric

parameter can be systematically varied within a predefined range. Using the LHS method, multiple combinations of these structural parameters are generated, resulting in a large set of sample ejector configurations that comprehensively cover the multidimensional design space. The 2D model, established through appropriate geometric simplification, is applied to simulate each sample configuration under identical boundary conditions, allowing rapid evaluation of suction performance. The most promising configurations obtained from the 2D simulations are subsequently reconstructed as full 3D models under identical computational and boundary conditions, to quantify the performance improvement achieved through optimization. This combined CFD–LHS framework enables systematic and accelerated optimization of ejector geometry, providing both high computational efficiency and reliable performance enhancement.

2. MEASUREMENT

The vacuum ejector investigated in this study is the nozzle module of a compact industrial ejector supplied by a leading manufacturer of vacuum-handling technology. A custom-designed adapter was used to mount the ejector on the experimental test bench while preserving the original inlet, suction, and outlet flow paths and ensuring airtight connections.

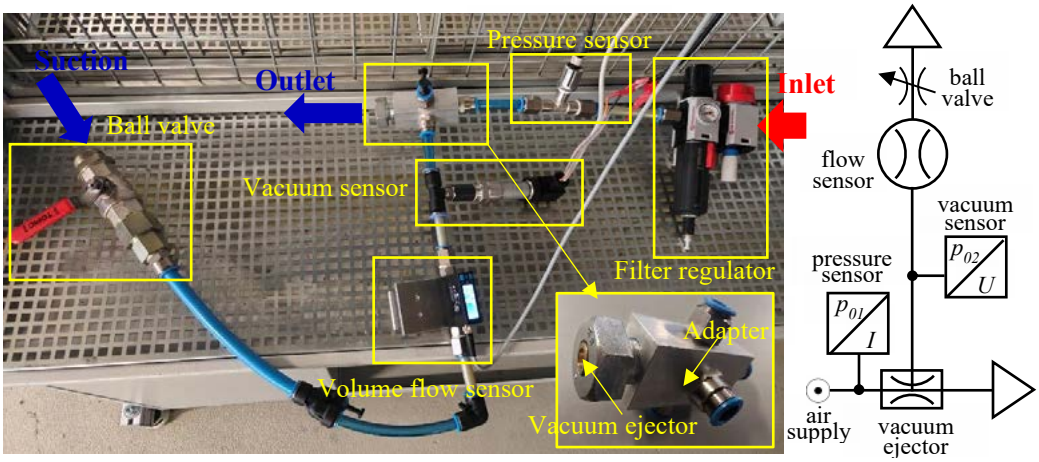

Figure 2.1 Experimental setup for vacuum ejector performance measurement with corresponding schematic diagram.

As shown in Figure 2.1, compressed air from the supply line passes through a filter–regulator unit and a pressure sensor before entering the motive nozzle as the primary flow. The inlet pressure p_{01} is measured upstream of the ejector, while the suction pressure p_{02} is recorded at the suction port using a vacuum sensor. The entrained air flow rate is monitored by a volume-flow sensor installed in the suction line.

A ball valve positioned between the flow sensor and the atmosphere allows adjustment of the suction-port boundary condition. With the valve open, ambient air is entrained into the ejector and the suction pressure can be continuously varied to represent different loading

conditions (**open case**). When the valve is fully closed, the suction port is sealed and no air is entrained, corresponding to zero suction flow (**closed case**). This setup enables systematic characterization of ejector performance over a wide range of suction pressures and operating conditions. The experimental results are presented in Section 4 and compared with numerical simulations to evaluate the predictive accuracy of the CFD model.

3. CFD MODELING

Following the experimental measurements presented in the previous chapter, this section focuses on the numerical modeling of the ejector system. The modeling procedure begins with the governing conservation equations and the applied turbulence modeling approach, which together form the theoretical basis of the simulation framework. Subsequently, the 3D computational model is introduced, followed by a grid-independence study to ensure solution accuracy. To enhance computational efficiency, a 2D axisymmetric model is then developed as a simplified representation of the ejector geometry.

3.1. Fundamentals

3.1.1. Governing equations

The governing equations of the steady compressible flow inside the ejector are expressed in conservative form as follows. The mass conservation equation is given by

$$\frac{\partial(\rho u_i)}{\partial x_i} = 0 \ , \tag{3.1}$$

where ρ denotes the local fluid density, u_i the velocity component in the x_i direction.

The momentum conservation equation is written as

$$\frac{\partial(\rho u_i u_j)}{\partial x_j} = \rho f_i - \frac{\partial p}{\partial x_i} + \frac{\partial}{\partial x_j}\underbrace{\left[\mu\left(\frac{\partial u_j}{\partial x_i} + \frac{\partial u_i}{\partial x_j}\right) - \frac{2}{3}\mu\delta_{ij}\frac{\partial u_k}{\partial x_k}\right]}_{\tau_{ij}} \ , \tag{3.2}$$

where p represents the static pressure, f_i the body-force component per unit mass, and μ the dynamic viscosity of the working fluid; subscripts i, j and l denote Cartesian coordinates following the Einstein summation convention; δ_{ij} is the Kronecker delta and τ_{ij} the viscous stress tensor.

The energy conservation equation is expressed as

$$\frac{\partial}{\partial x_j}[u_i(\rho E + p)] = -\frac{\partial}{\partial x_i}\left(\sum_j h_j J_j\right) + S_h \ , \tag{3.3}$$

where E denotes the total energy per unit mass, h_j the specific enthalpy of the j^{th} species, $J_{j,i}$ the diffusive mass flux of species j in the x_i direction, and the S_h the volumetric energy source term accounting for additional heat transfer or dissipation effects.

3.1.2. Turbulence model

Accurate turbulence modeling is fundamental to the numerical prediction of high–Mach-number flows, making the selection of an appropriate turbulence model a critical component of the computational setup. Several studies have examined the applicability of different turbulence models for ejector flow simulations. Bartosiewicz et al. [11] conducted a comparative assessment of six turbulence closures for supersonic ejectors and reported that the RNG k-ε and SST k-ω models yielded the best agreement with experimental pressure distributions. Zhu et al. [13] performed a geometry-optimization study involving three turbulence models and found that the RNG k - ε formulation provided the closest correlation with the measured entrainment ratios. In a subsequent investigation, Zhu and Jiang [1] combined Schlieren visualization with three-dimensional CFD analysis and confirmed that the RNG k-ε model reproduced the shock-wave wavelength and mixing characteristics more accurately than other models. Collectively, these studies demonstrate that the RNG k-ε model delivers reliable and consistent performance in predicting the flow features of single-phase supersonic ejectors. Therefore, this turbulence model is adopted in the present work to describe the turbulent flow field within the vacuum ejector.

For compressible turbulent flows, the instantaneous velocity field is decomposed into mean and fluctuating components using Favre (density-weighted) averaging. Accordingly, the velocity components are expressed as [14]

$$u_i = \tilde{u}_i + u_i'', \quad \tilde{u}_i = \frac{\overline{\rho u_i}}{\bar{\rho}}, \quad \overline{\rho u_i''} = 0 \ , \tag{3.4}$$

where $\tilde{u}_i$ denotes the Favre-averaged velocity and u_i'' represents the corresponding density-weighted fluctuation.

Applying the Favre-averaging procedure to the compressible Navier–Stokes equations yields the Favre-averaged momentum equations, in which additional terms arise due to the turbulent velocity fluctuations. The resulting Favre-averaged momentum equation can be written as:

$$\frac{\partial(\bar{\rho}\tilde{u}_i\tilde{u}_j)}{\partial x_j} = \bar{\rho}\tilde{f}_i - \frac{\partial \bar{p}}{\partial x_i} + \frac{\partial \bar{\tau}_{ij}}{\partial x_j} + \frac{\partial}{\partial x_j}\underbrace{\left(-\bar{\rho}\widetilde{u_i''u_j''}\right)}_{R_{ij}} \tag{3.5}$$

In Eq. (3.5), the term $-\bar{\rho}\widetilde{u_i''u_j''}$ represents the Reynolds stress tensor, which accounts for the momentum transport induced by turbulent fluctuations. Since this term introduces additional unknowns, the system of equations requires closure through an appropriate turbulence model.

In the present study, the Boussinesq eddy-viscosity hypothesis is adopted to relate the Reynolds stresses to the mean strain-rate tensor. Under this assumption, the Reynolds stress tensor is defined as

$$R_{ij} = -\bar{\rho}\widetilde{u_i''u_j''} = \mu_t\left(\frac{\partial \tilde{u}_i}{\partial x_j} + \frac{\partial \tilde{u}_j}{\partial x_i}\right) - \frac{2}{3}\bar{\rho}k\delta_{ij} \ , \tag{3.6}$$

where μ_t is the turbulent viscosity and k the turbulent kinetic energy.

Based on the Reynolds-stress closure in Eq. (3.6), the production of turbulent kinetic energy due to mean velocity gradients, G_k, is defined as the contraction of the Reynolds stresses with the mean velocity gradients and is written as

$$G_k = R_{ij}\frac{\partial \tilde{u}_i}{\partial x_j} \ . \tag{3.6b}$$

To complete the turbulence closure, transport equations for the turbulent kinetic energy k and its dissipation rate ε are introduced. In this work, the Renormalization Group (RNG) k-ε model is employed, as it has been shown to provide reliable predictions for high-speed compressible flows with strong shock–turbulence interactions.

The steady Favre-averaged transport equation for the turbulent kinetic energy k, including compressibility effects, is given by

$$\frac{\partial(\bar{\rho}\tilde{u}_i k)}{\partial x_i} = \frac{\partial}{\partial x_j}\left(\bar{\mu}\frac{\partial k}{\partial x_j} + \frac{\mu_t}{\sigma_k}\frac{\partial k}{\partial x_j}\right) + G_k + G_b - \bar{\rho}\varepsilon - Y_M + S_k \ , \tag{3.7}$$

where G_k denotes represents the production of turbulent kinetic energy due to mean velocity gradients, G_b denotes the production due to buoyancy effects, and S_k is an optional user-defined source term. The term $Y_M = 2\bar{\rho}\epsilon M_t^2$ accounts for the additional dilatational dissipation arising from compressibility, following the model proposed by Sarkar (1991). The turbulent Mach number is defined as $M_t = \sqrt{2k}/a$, where a is the local speed of sound.

The corresponding transport equation for the dissipation rate ε is written as

$$\frac{\partial(\bar{\rho}\tilde{u}_i \varepsilon)}{\partial x_i} = \frac{\partial}{\partial x_j}\left(\bar{\mu}\frac{\partial \varepsilon}{\partial x_j} + \frac{\mu_t}{\sigma_\varepsilon}\frac{\partial \varepsilon}{\partial x_j}\right) + C_{1\varepsilon}\frac{\varepsilon}{k}(G_k + C_{3\varepsilon}G_b) - C_{2\varepsilon}\bar{\rho}\frac{\varepsilon^2}{k} - R_\varepsilon + S_\varepsilon \tag{3.8}$$

In this equation, $C_{1\varepsilon}$ and $C_{2\varepsilon}$ are model constants, G_k and G_b retain their definitions from the k-equation, and S_ε denotes a user-defined source term. The additional term R_ε is specific to the RNG formulation and represents a correction accounting for the interaction between turbulence dissipation and mean strain rate, which enhances the model's performance in rapidly strained and high-shear flows. All empirical constants adopt their default values as implemented in ANSYS Fluent 2024R2.

$$\sigma_k = 1.0,\ \sigma_\varepsilon = 1.3,\ C_{1\varepsilon} = 1.42,\ C_{2\varepsilon} = 1.68,\ C_\mu = 0.0845$$

3.1.3. Advanced numerical settings for supersonic simulation

Supersonic CFD simulations are prone to numerical instabilities caused by strong shock interactions and steep flow gradients. To ensure stable and convergent solutions, the High-Speed Numerics (**HSN**) scheme and the built-in Solution Steering strategy of the density-based implicit solver in ANSYS Fluent were employed. These approaches enhance numerical robustness in shock-dominated flows and improve convergence behavior [15].

3.2. 3D modeling

To ensure the accuracy of the numerical results, the 3D simulation model was developed based on the internal configuration of the vacuum ejector assembled with the adapter, as illustrated in Figure 3.1. The annular gap volume, originally present in the compact ejector design, was also reproduced in the model to accurately represent the real operating condition, in which suction occurs from a single direction toward the ejector.

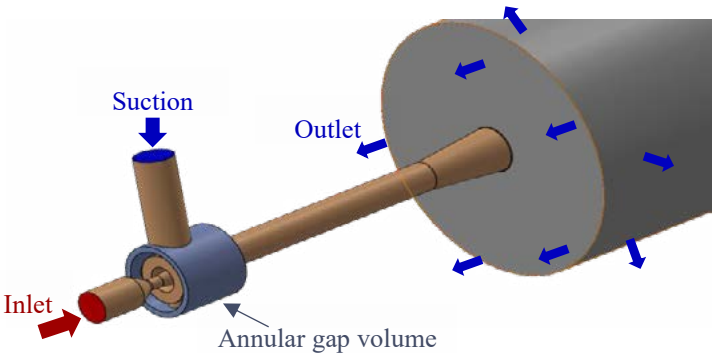

Figure 3.1 3D vacuum ejector model with annular gap volume

The computational domain was discretized using a poly-hexcore mesh generated in Fluent Meshing, as illustrated in Figure 3.2. This hybrid configuration combines structured hex-core regions with polyhedral transition zones, providing a good balance between mesh quality, numerical accuracy, and computational efficiency [16].

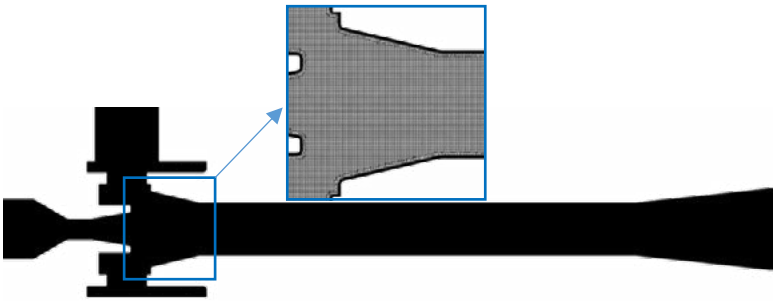

Figure 3.2 3D computational mesh of the vacuum ejector and detailed view

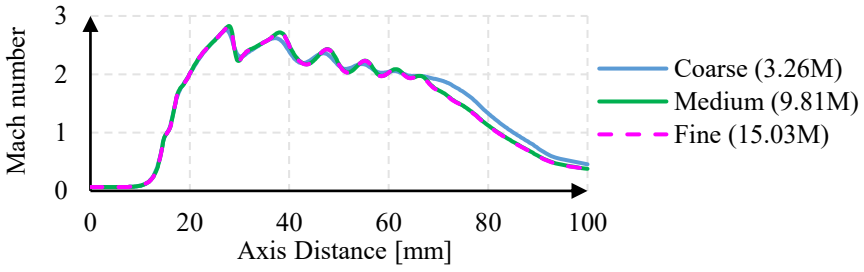

Figure 3.3 Comparison of Mach number distributions along the ejector centerline for different mesh resolutions

A grid independence study with three mesh resolutions was conducted to assess the influence of mesh density on simulation accuracy (Figure 3.3). The coarse, medium, and fine meshes contained approximately 3.26, 9.81, and 15.03 million cells, respectively. While the coarse mesh fails to adequately resolve the shock structures along the ejector centerline, the medium and fine meshes yield nearly identical Mach number distributions. Therefore, the medium mesh was selected for all subsequent simulations as an optimal compromise between numerical accuracy and computational cost.

3.3. Model reduction from 3D to 2D axisymmetric

Although three-dimensional CFD simulations yield highly accurate predictions of the ejector flow field, each case requires approximately five hours to complete on the TU Dresden high-performance computing (HPC) cluster (256 cores, Intel® Xeon® Platinum 8470). Consequently, such simulations are impractical for extensive parametric studies involving multiple geometric variations.

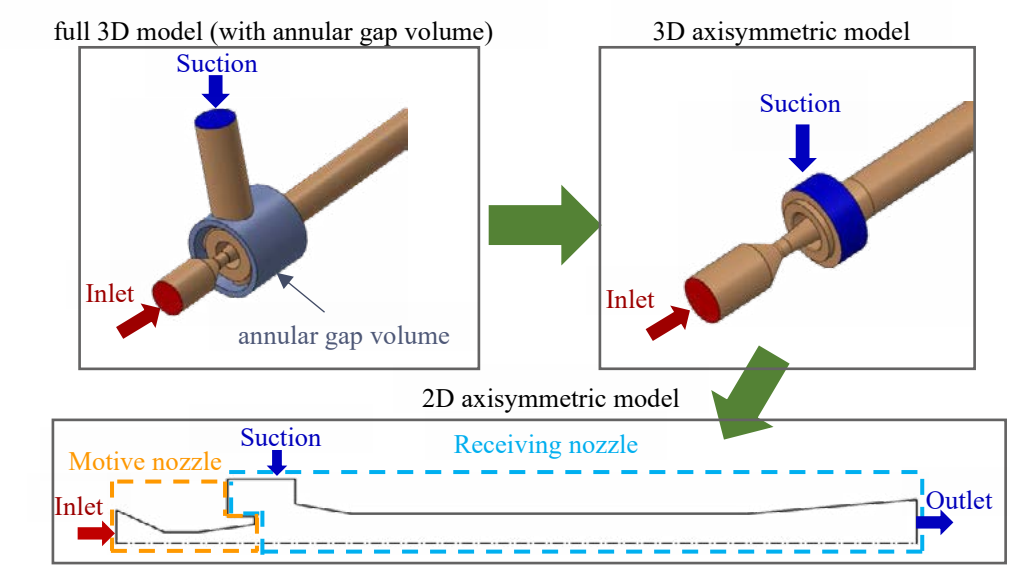

Figure 3.4 Transition from the 3D model to the simplified 2D axisymmetric model

To enhance computational efficiency, the model was progressively simplified, as illustrated in Figure 3.4. In the first step, the 3D ejector with the annular gap volume was reduced to a rotationally symmetric configuration, which preserves the main internal flow structures while omitting external domains. In the second step, this geometry was further simplified to a 2D axisymmetric model for parametric analysis.

In this process, it is important to note that the 2D axisymmetric simulations in ANSYS Fluent are solved in cylindrical coordinates, where all flow variables are expressed as functions of the radial and axial directions. Although the azimuthal (swirl) velocity component is neglected, previous validation work [5] has demonstrated that 2D axisymmetric formulations can still accurately capture the essential supersonic jet

characteristics, including shock-wave structures and entrainment behavior. Therefore, 2D simulations provide a reliable and computationally efficient approach for modeling supersonic ejector flows, particularly during the preliminary optimization phase.

3.4. Boundary condition and numerical setup

To ensure that the numerical model accurately represents the experimental operating conditions, the boundary conditions and numerical settings of the three-dimensional (3D) CFD simulations are summarized in Table 1. Two operating modes were investigated: the open case, in which the inlet pressure was kept constant while the suction pressure was varied to represent different loading conditions, and the closed case, in which the suction port was sealed and defined as a wall boundary while the inlet pressure was varied.

Table 1 Overview of boundary conditions and simulation parameters

		Open case		Closed case	
		Type	Value	Type	Value
Boundary conditions	Inlet	Pressure inlet	4.8 bar	Pressure inlet	2.3…6 bar
	Suction	Pressure inlet	-210…-810 mbar	Wall	–
	Outlet	Pressure outlet	Atmosphere	Pressure outlet	Atmosphere
Numerical setup	Solver	Density-based			
	Formulation	Implicit			
	Turbulence model	RNG k-ε			
	Wall treatment	Standard wall function			
	Material	Air			

4. RESULTS AND DISCUSSION

The boundary conditions and numerical settings summarized in Table 1 were implemented to analyse the flow characteristics and performance of the vacuum ejector under both open- and closed-suction operating conditions. In this section, the predicted internal flow structures obtained from different CFD models are first compared, followed by a quantitative validation against experimental measurements. Based on these results, the applicability of simplified axisymmetric models is discussed.

4.1. Flow-field comparison of different CFD models

Figure 4.1 compares the Mach-number contours obtained from the full 3D model, the 3D axisymmetric model, and the 2D axisymmetric model under identical boundary conditions. All three simulations predict the formation of the first oblique shock at nearly the same axial location, with comparable inclination and strength. This close agreement indicates that the generation of the initial shock is predominantly governed by the motive-nozzle geometry and can be robustly captured by both three-dimensional and axisymmetric formulations.

Downstream of the first shock, noticeable differences emerge between the full 3D model and the two axisymmetric configurations. In the full 3D simulation, the suction flow enters the ejector through a geometrically asymmetric inlet connected to the annular gap volume, resulting in localized three-dimensional flow interactions that influence the subsequent development of the supersonic jet. In contrast, the axisymmetric models employ an idealized annular suction boundary, which leads to a more circumferentially uniform inflow and, consequently, a more symmetric Mach-number distribution within the ejector.

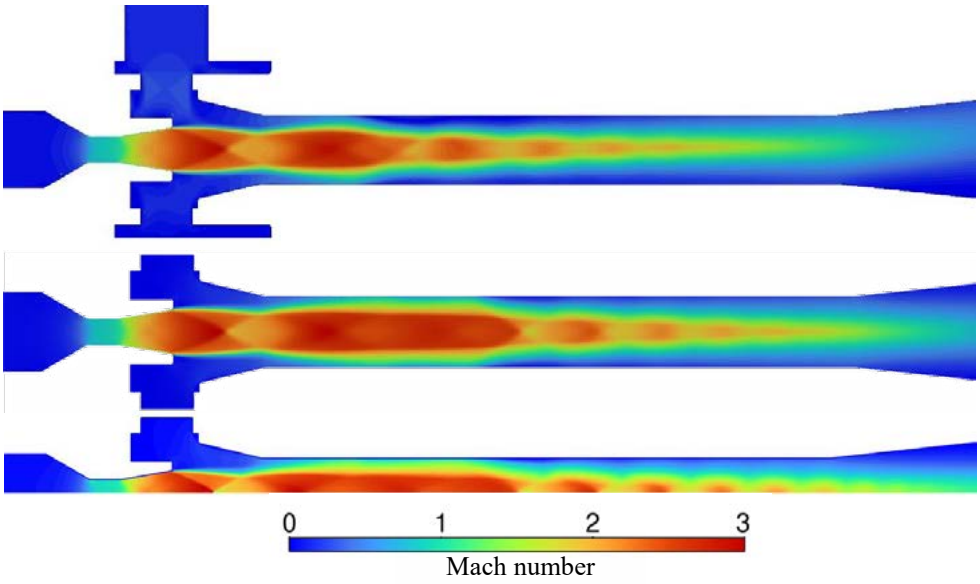

Figure 4.1 Mach-number contours of the full 3D (top), 3D axisymmetric (middle), and 2D axisymmetric (bottom) CFD simulations

When comparing the two axisymmetric simulations, the Mach-number distributions predicted by the 2D and 3D axisymmetric models are found to be qualitatively similar over most of the flow domain. Minor differences are mainly reflected in a smoother and less sharply defined shock train in the 2D solution, which can be attributed to the inherent limitations of the two-dimensional formulation, such as the inability to resolve three-dimensional effects including azimuthal velocity components, asymmetric mixing, and localized shock–turbulence interactions. Nevertheless, the overall expansion–compression pattern, shock spacing, and decay of the supersonic core remain consistent between the two axisymmetric models.

4.2. Quantitative validation against experimental data

The simulation results for both the open- (left) and closed-suction (right) cases within the operating range are presented in Figure 4.2. In this context, the vacuum level is defined as the pressure difference between the ambient atmospheric pressure and the absolute pressure measured near the suction port, i.e., Vacuum $= p_{atm} - p_{abs}$.

For the full 3D model, the predicted suction volumetric flow rates under open-suction conditions show excellent agreement with the experimental measurements. A similarly close correspondence is observed for the vacuum level under closed-suction conditions. This consistency across both operating modes demonstrates the validity of the applied boundary conditions, numerical setup, and turbulence modeling strategy, confirming that the adopted CFD framework can accurately reproduce the ejector performance.

The simplified 3D axisymmetric and 2D axisymmetric models successfully capture the overall performance trends of the ejector but predict slightly higher suction volumetric flow rates under open-suction conditions. As discussed in Section 3.3 and illustrated in Figure 3.4, this deviation arises from the geometric simplification of the suction region. In the axisymmetric configurations, the suction boundary is represented as an idealized annular surface, which effectively enlarges the area available for entrained air compared with the asymmetric suction inlet of the full 3D model. This enlarged entrainment area facilitates a greater inflow of secondary air and consequently leads to an overprediction of the suction flow rate in the open-suction case.

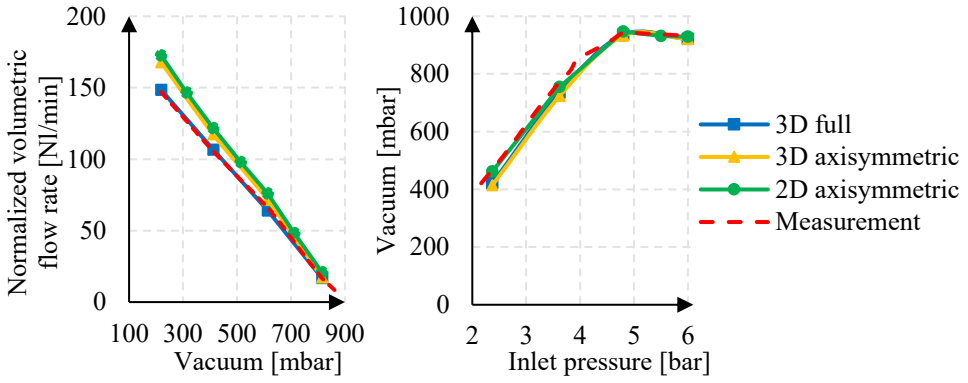

Figure 4.2 Comparison of experimental and simulation results for the open (left) and closed (right) suction cases using different CFD models

Under closed-suction conditions, however, the differences between the three models become negligible. Since the suction port is defined as a wall boundary and no external air is entrained, the internal flow field is no longer influenced by the suction boundary geometry. Instead, the ejector performance is primarily governed by the expansion, shock formation, and recompression processes of the motive jet. As a result, all three modeling approaches yield nearly identical predictions of the vacuum level.

4.3. Discussion and implications for model reduction

Taken together, the qualitative flow-field comparison and the quantitative validation against experimental data demonstrate that the dominant supersonic flow features and overall ejector performance are consistently captured by the axisymmetric formulations. While the full 3D model provides the most detailed representation of the internal flow field, the close agreement between the 2D and 3D axisymmetric results indicates that, once axisymmetry is assumed, the additional dimensional reduction introduces only limited deviations in the predicted flow field.

This finding supports the use of the 2D axisymmetric model for large-scale parametric simulations and preliminary geometry screening, where computational efficiency is essential and the primary interest lies in comparative performance trends rather than in detailed three-dimensional flow structures.

5. EJECTOR OPTIMIZATION WITH LATIN HYPER CUBE SAMPLING

In the present study, the optimization is conducted primarily under open-suction operating conditions, as this case directly reflects the ejector performance relevant to energy efficiency during practical operation. As stated in [17], the geometric parameters of a vacuum ejector strongly interact with one another, and it is therefore more meaningful to vary the key parameters simultaneously rather than individually. The vacuum ejector is parameterized as illustrated in Figure 5.1, and its geometry is defined by several characteristic dimensions that determine the internal flow passages.

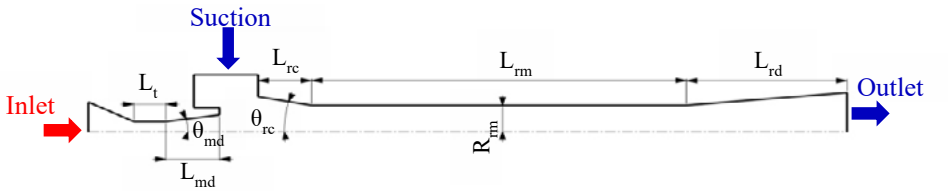

Figure 5.1 Parameterized geometry of the vacuum ejector

Based on previous studies, the throat section of the motive nozzle plays a crucial role in compressing and accelerating the primary flow to Mach number M=1 [18][19]. Variations of the throat radius R_t significantly affect the mass flow rate of the induced secondary stream and, consequently, alter the overall operating range of the ejector. Furthermore, changing R_t would require substantial modifications to both the motive and receiving nozzle geometries, thus reducing the comparability between the optimized and reference geometries. For this reason, R_t was not considered as a design variable in the present optimization. This approach also reflects the practice in commercial compact ejector product lines, where different models are primarily distinguished by their inlet mass-flow capacities rather than by variations in the throat size.

The definitions of the geometric parameters and their respective variation ranges are summarized in Table 2.

Using the LHS method, a total of **1500** sample geometries were generated based on the parameter ranges listed in Table 2. The sample size was selected to ensure sufficient coverage of the high-dimensional parameter space while maintaining a feasible computational cost [20].

Since the primary objective of the present study is the enhancement of energy efficiency, the optimization process was conducted with a clear emphasis on the open-suction operating condition, which accounts for approximately 80% of the overall performance weighting. The closed-suction case was incorporated as a secondary criterion (20%) to ensure that the optimized geometries still maintain an acceptable vacuum level.

In the first selection stage, all geometries exhibiting a higher suction volumetric flow rate than the reference ejector under open-suction conditions were retained as candidate geometries. Because the throat radius R_t was kept constant, the primary mass flow rate at a given operating point remained nearly identical across all simulations, allowing direct comparison of the normalized suction volumetric flow rate without additional correction.

Table 2 Definition and variation ranges of the geometric parameters

Parameter	Description	Variation range
R_t	Throat radius of the motive nozzle	-
L_t	Length of the motive nozzle throat section	-45% ... 750%
L_{md}	Length of diverge section of motive nozzle	-75% ... 150%
θ_{md}	Angle of diverge section of motive nozzle	-85% ... 235%
θ_{rc}	Angle of converged section of receiving nozzle	-85% ... 165%
L_{rc}	Length of converged section of receiving nozzle	-15% ... 470%
R_{rm}	Radius of mixing chamber	-5% ... 25%
L_{rm}	Length of mixing chamber	-35% ... 160%
L_{rd}	Length of diverge section of receiving nozzle	-20% ... 380%

In the second stage, the retained candidate geometries were further evaluated under closed-suction conditions. A weighted performance metric combining the improvements in open- and closed-suction cases was then applied to rank the candidate geometries. Based on this weighted evaluation, two optimized ejector geometries, denoted as **Opti1** and **Opti2**, were selected for detailed comparison.

The simulated performance of the optimized ejector geometries under both open- and closed-suction conditions is presented in Figure 5.2. The relative improvements are evaluated with respect to their corresponding reference configurations: the 2D results are normalized by the baseline 2D axisymmetric model shown in Figure 4.2, while the 3D results are referenced to the baseline full 3D model simulations. This consistent benchmarking strategy ensures that the optimization outcomes are assessed within the same modeling framework and avoids cross-dimensional bias.

In the open-suction case, the 2D axisymmetric and full 3D models exhibit highly consistent improvement trends across the investigated operating range. Both optimized geometries show similar relative gains in suction volumetric flow rate, and the agreement between the 2D-based predictions and their 3D validation results is particularly pronounced. This strong correspondence confirms that the adopted optimization strategy—screening candidate geometries using computationally efficient 2D simulations and subsequently validating the most promising designs with full 3D models—is both reliable and effective. Moreover, it demonstrates that two-dimensional simulations are capable of capturing the dominant performance trends relevant to energy-efficiency enhancement.

Under closed-suction conditions, although the quantitative improvements predicted by the 2D and 3D models differ slightly, the overall trends remain consistent. An important observation from the right-hand plot of Figure 5.2 is that enhanced suction performance under open-suction conditions is accompanied by a reduction in the achievable vacuum level under closed-suction operation. This behavior indicates an inherent trade-off between maximizing energy-efficient suction capacity and attaining high vacuum levels, suggesting that these two objectives cannot be simultaneously optimized within a single ejector geometry.

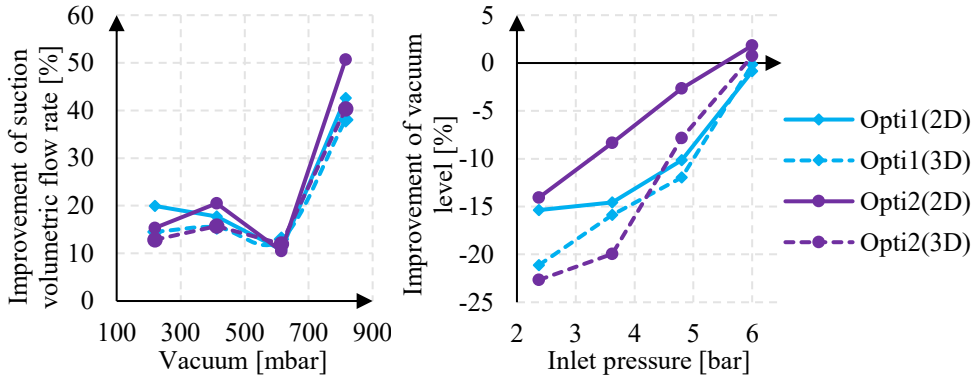

Figure 5.2 Improvement of the optimized ejector geometries under open- (left) and closed-suction (right) conditions

6. CONCLUSION

This study has demonstrated the accuracy and practical feasibility of an integrated CFD-based optimization methodology for vacuum ejector nozzles operating in the supersonic flow regime. By systematically combining experimental measurements with three-dimensional and two-dimensional numerical simulations, the reliability of the adopted CFD setup was established across both open- and closed-suction operating conditions. In particular, the RNG k-ε turbulence model was shown to accurately predict the suction volumetric flow rate in the open-suction case as well as the achievable vacuum level under closed-suction conditions, confirming its suitability for modeling supersonic ejector flows.

A key outcome of this work is the validation of a computationally efficient optimization framework that integrates 2D axisymmetric simulations with Latin Hypercube Sampling

(LHS) for large-scale parameter screening, followed by targeted full 3D model validation. The strong agreement observed between the optimization trends obtained from the 2D simulations and their corresponding 3D validation results demonstrates that the proposed workflow provides a reliable basis for identifying energy-efficient ejector geometries while significantly reducing computational cost. This confirms that simplified axisymmetric models, when properly validated, can be effectively employed in early-stage design and optimization of supersonic flow components.

The optimization results further reveal an inherent trade-off between maximizing suction capacity and achieving high vacuum levels, indicating that these performance objectives cannot be simultaneously optimized within a single ejector configuration. Consequently, the design of high-performance vacuum ejectors requires a balanced consideration of energy efficiency and attainable vacuum level, depending on the intended application.

Future work will extend the present methodology beyond numerical optimization by manufacturing and experimentally testing the optimized geometries to assess their real-world performance. Moreover, the proposed CFD–LHS framework is inherently applicable to a broad class of fluid-dynamic optimization problems in which the geometry can be parameterized and globally optimal configurations are sought. This includes, but is not limited to, ejector designs and other complex flow devices, where robust global exploration of the design space is required under strongly nonlinear flow conditions.

Abstract.

The development of hydraulic systems is becoming increasingly complex, especially in mobile machines with a wide range of fluid technology components. The joint research project Fluid 4.0, funded as part of kopa35c and embedded in the objectives of Manufacturing-X, is developing an end-to-end digital approach for the collaborative engineering of fluid power systems. The focus is on the Asset Administration Shell (AAS) as an interoperable digital twin. The article presents solutions for industry-relevant User Stories like “Machine AAS with linkage and physical composition of component AAS”, “Semantic Search within the dataspace to find suitable products” and “Automatic control software parametrization”. Therefore, occurring pain points inside the industry will be highlighted and helpful technologies based on the AAS introduced. This paper provides input to the application of existing and new approaches of the AAS to reduce manual effort and enhance collaborative engineering mainly inside the design process of fluid-mechatronic systems.

Keywords. Fluid 4.0, Digitalisation, Asset Administration Shell, Collaborative Engineering, Dataspace, Submodels, industry-relevant Use Cases

1. INTRODUCTION

The requirements for the development of stationary and mobile machines with hydraulic or pneumatic drive technology are increasing due to targets set by customers and legislation as well as technological developments and product diversity on the market. Particularly in the context of collaborative engineering (across departments and companies), standardised data helps to make efficient development decisions. The Asset Administration Shell (AAS) as a data container with a machine-readable interface and industry-standardised semantics

All Open Access articles are peer-reviewed, distributed under the Creative Commons Attribution-Non Commercial 4.0 International

represents a technological option for implementing this data-based decision-making basis. The publication of [1] provides interesting insights about the characteristics and technologies about the AAS with a high number of references to various tools and information about the usage inside the industry and applied technologies. The fluid power industry can already supply many components with digital representation in the form of an AAS. However, the added value only arises when the data is utilised in the development of the machine.

The Fluid 4.0 joint research project is developing solutions for the digitalisation of the following four key areas at the interface of fluid technology components and their use in stationary and mobile machines:

1. Control development of machines
2. Energy monitoring
3. Cross-industry CO2-balancing
4. Circular economy

The content of this publication will take part on the first key area “Control development of machines”, which also includes system layout design. At first in chapter 2, the state of the art and technology will be presented by describing the development of mechatronic systems and interoperable data models. The next chapter follows with the introduction of the main User Stories to support engineering processes based on the AAS. The relevant technologies, that have been used and developed to achieve the desired improvements inside those User Stories will be presented in chapter 4. Chapter 5 shows the usage of those technologies by presenting client applications, applied for the User Stories respectively. Therefore, a simplified example system will be used in addition to a demonstrator, resembling a mobile machine, for further validation. The conference paper will be finished with a conclusion and an outlook in chapter 6.

2. STATE OF THE ART AND TECHNOLOGY

2.1. Development of Mechatronic Systems

As described in VDI Guideline 2206, the development of modern mechatronic systems is subject to a staggered process. Basically, this can be described as a V-model. On the left branch, a system design with rough boundary conditions is repeatedly refined with increasingly fine-grained components until the lowest point of the “V” – the point of greatest detail – is reached. In the development phase – the right branch of the “V” – each hierarchical level is then checked from the lowest level upwards to ensure it fulfils the required function. This involves first testing individual components, subsystems, systems, and finally the entire machine/plant [2]. This so-called macrocycle of the V-Modell is shown as the inner cycle in Figure 2.1.

What also can be seen in the figure is that the inner cycle is layered with more outer cycles, which can be interpreted as different stages of a product, from a (digital) functional mock-up to a (digital) demonstrator, a prototype, a pilot series, and the “final” series product itself. There could be more outer cycles, like for each step of a “model facelift” or development of a new product version release. During the development process, multiple different domains must work together to create a suitable product. Typically, each domain works with its own tools; see [3], which is a major flaw during the design process, because of the limited

possibilities for the exchange of data between the different domains. This problem is often more complex when you look at the whole chain from the different companies that are involved for one product, starting at a “low” level from a TIER-X supplier, which may offer “simple” components like screws or cable connectors, along the path to the TIER II and TIER I suppliers, which offer complex elements and subsystems that the OEM has to integrate into their product.

One common way for exchanging data is PDF files, which often include unstandardized content and are not machine-readable by default. One point at which this circumstance becomes apparent in the development process is the parameterization of a lookup table to describe the often non-linear behaviour of a component during the application software development of a machine. Product data sheets often contain two-dimensional curves describing the control-relevant behaviour of components such as valves and pumps, which provide a good basis for parameterization. However, these curves are in a lot of cases only available as graphical representations of the data. The values for such a lookup table must be recreated manually. This is highly inaccurate and prone to errors. Another problem system developers face is the connection flanges of hydraulic components, which are also represented as a PDF graphic. Those flanges are essential when creating manifolds for complex systems. A remarkable fact is that Automation Studio has a function that has a large database for creating manifolds automatically [4]. Such a high integration of connection interfaces is lacking in many other tools.

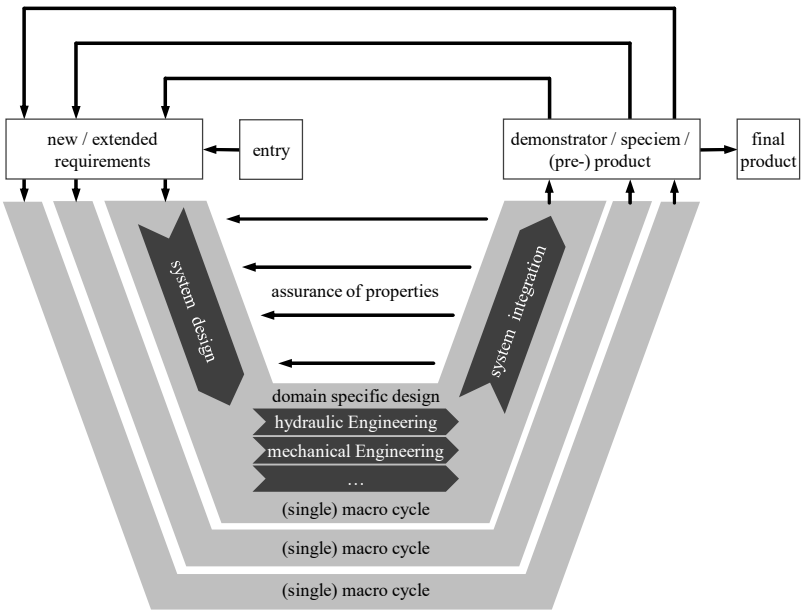

Figure 2.1. Multiple macro-cycles in the V-Model for the product development of a complex mechatronic product according to [2]

When looking at the V-Model again, it is hard to find a program architecture for an application, which is suitable to cover the whole development process and fits all requirements of each system level and domain. To describe a machine with its drive system

and the process, a system simulation tool with lumped parameters can be a good option. The product itself is often represented in a 3D CAD program, which is a geometrical description. Both describe the same product in different ways. But when changing major parameters of the product based on one of those systems, there is just manual feedback and no automatic functions that trigger a redesign. As an example, the systems engineer simulated the lumped model and identified that the system's dynamics are too slow; he decided to use a larger hydraulic cylinder, which offers higher forces. The larger force of the actuator is thus a changed requirement of the frame, which holds the actuator. This may lead to several changes in the mechanical / geometrical design to support the force into the frame of the machine.

It is therefore clear that the development of complex systems such as the hydraulic drive system of machines requires a large amount of data and information that must be exchanged across companies and departments. How can this be done efficiently while avoiding errors?

2.2. Interoperable Data Models

Interoperability can be defined as the ability of two or more systems to exchange and use information seamlessly. [5] In the context of engineering, product and machine data, i.e. layout, interfaces, and connectors, represent a crucial form of information that must be interpreted and applied by a wide range of stakeholders. These include designers and producers, who generate and maintain product data, as well as customers and OEMs, who need to consume the same data in their respective tool environments.

To support this exchange, several standardized formats for engineering data have been developed. Common examples include STEP, AutomationML (AML), and OPC UA, which are reviewed in detail by Ritz [3]. Each of these formats is formally specified and standardized, yet their adoption in practice remains heterogeneous. Not all manufacturers rely on the same data format, and the distribution of data is likewise inconsistent: some producers send engineering files by email after purchase, others make them available for download on websites, and in many cases, product specifications are still provided only as PDFs, which has been discussed above. Furthermore, different formats tend to dominate in different engineering domains, limiting seamless cross-domain data usage [6]. Technologies such as RDF offer higher semantic expressiveness and support reasoning mechanisms, but their adoption in industrial practice has been limited so far [7]. The resulting multitude of formats hinders comparability across components and complicates the composition of systems, a task that OEMs in particular must regularly perform. In contrast, interoperable and vendor-independent data formats have the potential to streamline engineering workflows, enabling consistent data exchange and integration across tools and domains.

Against this background, the AAS has emerged as a particularly promising approach. Developed in context of Plattform Industrie 4.0 and the Industrial Digital Twin Association (IDTA), the AAS provides a standardized digital representation of assets that is semantically enriched and interoperable across domains [8]. Its standardized metamodel, defined in IEC 63278, ensures syntactic interoperability. The AAS organizes asset-specific information into Submodels (SMs), which can be further standardized as Submodel Templates (SMTs) to guarantee the well-defined location of particular data elements. Finally, a standardized application programming interface (API) provides a uniform access

mechanism for reading and utilizing this information across various tools and platforms. Refer to chapter 4.1 for further details on the technical realization of the AAS.

3. USER STORIES

As described in chapter 2, the development process of mobile machines is highly collaborative and data intensive which leads to communication effort and is error prone. During an intensive user story development phase within the Fluid 4.0 project under the support of associated partners the most relevant processes with high potential for data usage and automation were identified. Thereby, three main problems were identified:

1. data on components and the machine are distributed
2. technical properties are rarely semantically standardised and usually not available in machine-readable form
3. there is a diverse tool landscape

Based on this, five user stories have been developed to accommodate this.

User Story I: Machine AAS

Based on the AAS of hydraulic components, the whole drive system of a machine should be described within a machine AAS as well. This would provide a single source of truth for machine-readable information about the system for all developers. The machine AAS should represent the physical and data linkage between the used components and their digital representation. Designers of hydraulic systems should be able to create a layout as the basis for further development steps.

User Story II: Semantic Search

Based on the layout and calculation of the size of the components, the engineers must search for suited products, which is a very manual and time-consuming task today. Hydraulic engineers shall be able to search for fitting products within the dataspace based on standardized technical properties of public information, such as data sheets. This approach has been applied in [9] for the parameterization of simulation models regarding Model Based System Engineering.

User Story III: Tool interfaces and automation

The automated information transfer between different tools shall be possible. Various applications in the engineering process can benefit from standardized data provision and take advantage of automating workflows, which required manual input before. By using freeware and other work-specific software tools, the applied usage of the AAS will be demonstrated and will contribute as an example and motivation for future AAS application integrations.

User Story IV: Simulation

Even though simulation models can be unique and complex, data are required to define the values of the components. Likewise, data from the AAS can be inserted automatically to save time and effort. On top of that, since simulation models often resemble the shape of a hydraulic schematic, a first approach to generate the first instance of a simulation model

automatically can be carried out, which will be presented in additional papers. The applicability of the AAS for the Simulation has been shown in [9], [10].

User Story V: Control development

As basis for virtual commissioning, control relevant parameters of the used components shall be imported automatically into the IDE (integrated development environment). Software developers benefit from fast and safe parametrization of the control units` I/O`s.

Figure 3.1. shows the implementation of these User Stories through five client applications and their interaction via a central AAS – the machine AAS as the single source of truth during the product development. In the focus of this contribution, the clients I, II III and V will be described in detail.

To implement these User Stories with the corresponding Clients a few building blocks and technologies are needed. In [3] a mock-up for a single application was shown in the outlook. This publication focuses on the identified clients, which are described in the following chapter. Basically, there are always three main building blocks:

1. Data modelling
2. Infrastructure and Interfaces
3. Clients and Tools

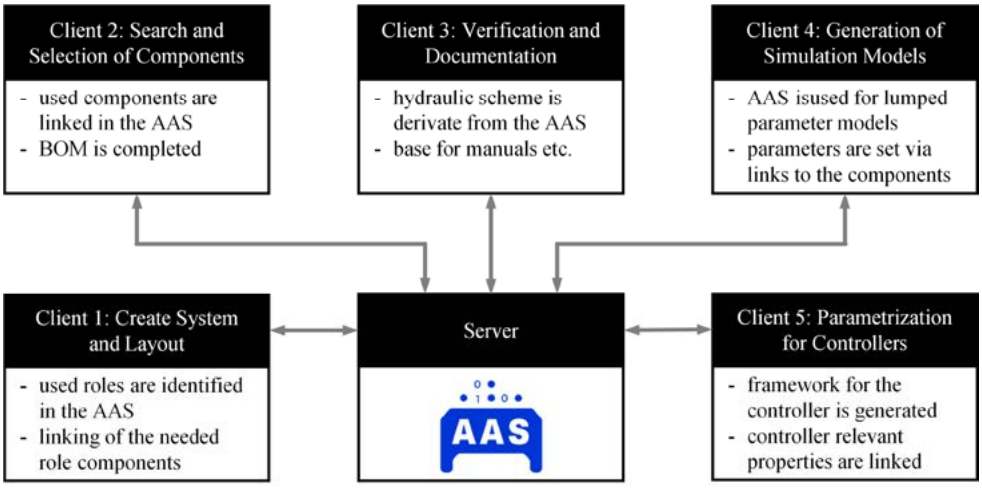

Figure 3.1. Client Applications for the implementation of the defined User Stories

4. INDUSTRY 4.0 TECHNOLOGY

4.1. AAS Infrastructure

The construction of an AAS follows the rules defined in its standardized metamodel [11]. An AAS is composed of SM, each of which contains hierarchically structured SubmodelElements (SMEs). These SMEs can take on various types, such as Properties, Ranges, References, or Collections. The structure and nesting depth of SMEs is highly variable and depends on the specific information that needs to be represented. Different SMEs can be grouped in a SubmodelElementCollection (SMC), which also can include

other SMCs. To provide consistency across use cases, SMTs define a pre-specified structure for SMs and their elements. Such templates are tailored to specific domains or application scenarios, for example the *Digital Nameplate for Industrial Equipment* or the *Generic Frame for Technical Data for Industrial Equipment in Manufacturing* [12]. Refer to chapter 4.3.3 for an in-depth elaboration on the information that these provide. Templates are not developed in isolation but are discussed and refined in dedicated working groups, ensuring cross-industry applicability and acceptance (standardization process).

Two types of AAS infrastructure are distinguished. A Type-1-AAS is exchanged in the form of a serialized file, typically encoded as XML, JSON, or RDF, and often wrapped in an AASX package for convenient bundling [13]. In contrast, a Type-2-AAS is hosted on a server, which provides an application programming interface (API) via HTTP for reading and modifying AAS contents [14]. This includes operations such as changing the value of SMEs, adding or rearranging SMEs, or adding and removing complete AASs and SMs. Beyond basic access, a Type-2-AAS also supports a query language that allows clients to request AASs or SMs from a server that match certain criteria [14]. There exists a vast landscape of open-source AAS applications that implement the AAS metamodel and API specification to varying degrees. Among them, some have just recently included support for the AAS query language.

From a security perspective, the AAS infrastructure already integrates attribute-based access control (ABAC) mechanisms [15]. These mechanisms allow fine-grained regulation of who can access or modify specific AAS contents. However, information signing for ensuring the integrity and authenticity of exchanged data is not yet part of the standard. At the time of writing, there is no publicly available off-the-shelf AAS server application that reliably and completely implements this specification.

For implementing business logic and user stories working with the AAS, the community has created several Software Development Kits (SDKs). The SDKs provide the necessary functions to insert, edit, delete, as well as serialize and deserialize the information inside an AAS. For example, SME can be added to SMs, their values edited, and the result serialized to an exchangeable format like JSON.

4.2. Dataspaces

A dataspace is a decentralized technology for sharing information. Its central focus lies in ensuring data ownership and sovereignty, meaning that data providers retain full control over the conditions under which their data is made available and used [16].

To support interaction among participants, dataspaces typically include centralized services such as a catalogue, which enables the discovery of connector endpoints of other parties, and a wallet, which stores participant certificates. Each participant in a dataspace can act as a data provider, a data consumer, or both, depending on their role in each exchange.

On the provider side, internal rules are defined that govern the conditions under which a consumer can access information. Consumers can issue requests to provider endpoints but must present authentication information; the provider then decides whether the consumer is eligible to receive the requested data. These access rules can go beyond simple eligibility checks and include detailed usage policies, such as restrictions on how often the data may be accessed, how it may be processed, or whether it can be forwarded to third parties. In this

way, policy enforcement mechanisms ensure that data sovereignty is preserved even after access has been granted [17].

The technical realization of these interactions is achieved through dataspace connectors. These connectors must be configured either as providers or consumers, although some implementations support a dual configuration in which a connector can serve both roles. A provider-side connector must be connected to backend resources, such as databases or repositories, to expose the relevant information. At the architectural level, contracting takes place on the control plane, while the actual data exchange occurs on the data plane [18].

Within the Fluid 4.0 key areas and User Stories, each vendor maintains an AAS repository and a SM repository containing AAS (and their linked SMs) for all offered products. At a minimum, each AAS is required to include the SM *Generic Frame for Technical Data for Industrial Equipment in Manufacturing* [12]. One dataspace connector is deployed per vendor, linked to the AAS/SM repositories, and another connector is operated by the customer. The customer issues a query, routed through its connector, to all vendor connectors to retrieve *Technical Data* SM that meet certain criteria – for example, a specific ECLASS number identifying pumps or valves (User Story II). Based on the retrieved SMs, the customer then issues a second query to the AAS repositories (or rather, the dataspace connectors acting on their behalf) to collect all AASs that reference these SMs. The result is a consolidated list of AAS associated with the targeted product category. The whole process and involved components are visualized in Figure 4.1.

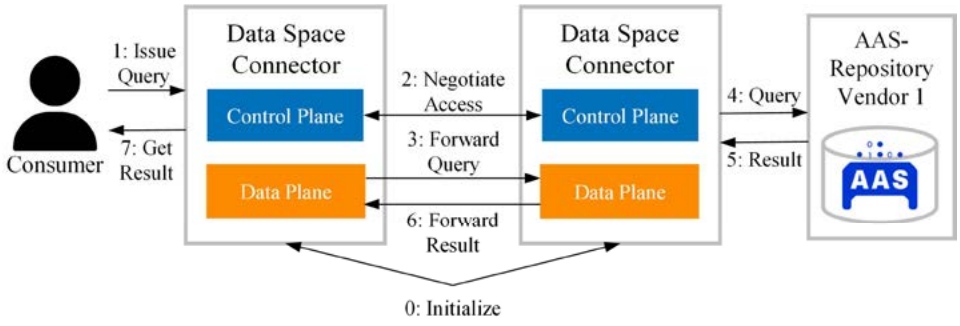

Figure 4.1. Workflow for querying through the Dataspace

4.3. Relevant Submodels for collaborative engineering

SMs are the key elements of an AAS containing domain-specific information in a structured way. Given the well-known location of data according to the SMT, the extraction of information can be carried out automatically, regardless of the manufacturer who populated the information. The diversity in the presentation of product-specific details inside the uniquely designed datasheets of the companies will be bypassed completely.

Up until now, many SMs have been published, e.g., the *Digital Nameplate for Industrial Equipment* [19] or *Handover Documentation* [20]. As the name implies, SMs are mainly designed for specific purposes, like [20], which offers information about the asset's manufacturer and its identification. Beyond that, machine manufacturers can create their own client applications to interact with the machine-readable information of the assets for their individual purposes. In the end, one of the main purposes of the SMTs lies in the

standardized provision of asset-specific information in a machine-readable format. As a result, the engineering process can be designed more efficiently through the new possibilities in automation.

In the process of applying the User Stories by developing the client applications, that has been illustrated in Figure 3.1., required data were missing that couldn't get included in the defined structures of existing SMTs. This includes the information in diagrams, which are only graphically, but not machine-readable provided inside the datasheets of the manufacturers. Those data play a major role inside the control development of User Story V, since software developers need to extract the information manually to handle the control behaviour of hydraulic components accordingly for their unique application. This contributes to the necessity of a SMT to retrieve machine readable information from a graphic in a standardized generic syntax.

Furthermore, to realize the User Stories I, III and IV, a new approach for a SMT has been created to automatically generate a hydraulic schematic. To develop a fluid technological drive system, the hydraulic schematic contains the information about which components are included and how there are connected respectively. The provision of the information in a generic machine-readable syntax of the AAS generates many opportunities for the realization of the User Stories. By applying graphic editors to draw hydraulic schematics, the AAS of the developed system, regarding to Use Case I, can be generated in combination with the graphic information stored inside a SM. This would help to create hydraulic schematics in various data formats for communication and documentation (Use Case III), as well as serving the graphic information as basis for the simulation models of fluid-technological systems (Use Case IV), while interacting with one medium as single source of truth. [9] has been mentioned, that the automatic generation of the structure and topology of a simulation model should be achieved in the future. The content of those new SM approaches will be further discussed in the following chapters 4.3.1 and 4.3.2.

To realise User Story II, existing SMTs need to be applied, like *Generic Frame for Technical Data for Industrial Equipment in Manufacturing* [Data]. This SM contains all necessary information to classify a component and verify its system compatibility by its technical properties. As a result, search algorithms for fitting components can be implemented. A more specific insight of this SMT will be presented in the chapter 4.3.3.

4.3.1. Characteristic Curves

As explained above, the characteristics of hydraulic components and systems are usually characterized by nonlinearities. For this reason, an application was submitted to the IDTA as part of the Fluid 4.0 joint research project to create a new SMT *Characteristic Curves*. The aim is to develop a uniform and universal description of characteristic curves that can be used for the technical properties of a wide variety of products and various applications.

On the one hand, (multidimensional) characteristic curves are often a widely used approach for modelling component behaviour in system simulation. On the other hand, the inverse behaviour of the components is essential for achieving good control behaviour of the respective drive axes. Since the corresponding SM is still under development, no definitive representation can be provided at this point. However, Figure 4.2. Figure 4.2.shows an example of both a characteristic curve mapping $\mathbb{R}^1 \rightarrow \mathbb{R}^1$ and a higher-dimensional

characteristic field representing a mapping of the order $\mathbb{R}^2 \rightarrow \mathbb{R}^1$. This can be extended to any number of dimensions.

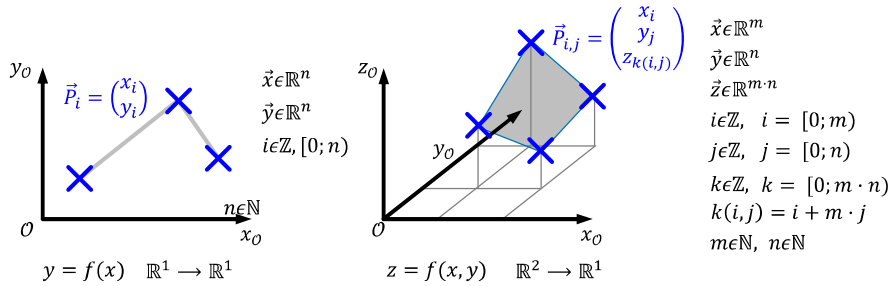

Figure 4.2. Examples for a representation of characteristic curves, according to the planned IDTA SM Characteristic Curves

Generally, it makes sense to create a link to a semantic lexicon, such as ECLASS [21], to build a unique assignment of the contained values to the corresponding variables of the respective components. At the same time, it is planned to store the boundary conditions under which the respective behaviour is mapped, such as the kinematic viscosity υ that was present during a valve measurement.

4.3.2. Model Reconstruction

In the fluid technology industry, the hydraulic schematic is a document of high significance. It contains the integrated components in a visual representation and their connections to one another. It provides the blueprint to achieve the planned movement sequences of the machine via hydraulic components. For engineering tasks, the schematic serves as a fundament for communication, planning and decision making. On top of that, they are also used for maintenance and monitoring of hydraulic systems afterward.

To improve the efficiency of the engineering process, the task occurred to develop a SM, which enables the possibility to reconstruct a hydraulic schematic generically according to User Story I. Schematics are most often available in graphic or software-specific files, especially between employees with different working backgrounds. A standardized template, which includes all necessary parameters of a hydraulic schematic, would offer the opportunity for interaction in a specific work-related environment. This will play a major role in the AAS of hydraulic systems, which will be further discussed in chapter 4.4. Since simulation models and hydraulic schematics are highly related, the information inside the SM can be used for the automated generation of simulation models as well, see User Story IV. This could also be used for the electrical engineering as well with same benefits, ideally using the same BOM as shared data for the systems engineering.

Up until now, the SM consists of two SMCs with the following names: *Model Components* and *Connections*. A *Model Component* is a graphic element inside the schematic, e.g. a pump, valve, or cylinder. It includes specific properties for a unique identification and visual placement inside the schematic. The identification includes the component name, a display designation for tags inside the model, a description for further details, and an element identification to categorize it based on ECLASS [21] standardization. Additionally, a model

component possesses attributes to describe its virtual appearance inside the model. This includes position, size, and orientation, as well as information about the unique positions and IDs of component-specific ports. This approach is visualized in Figure 4.3.

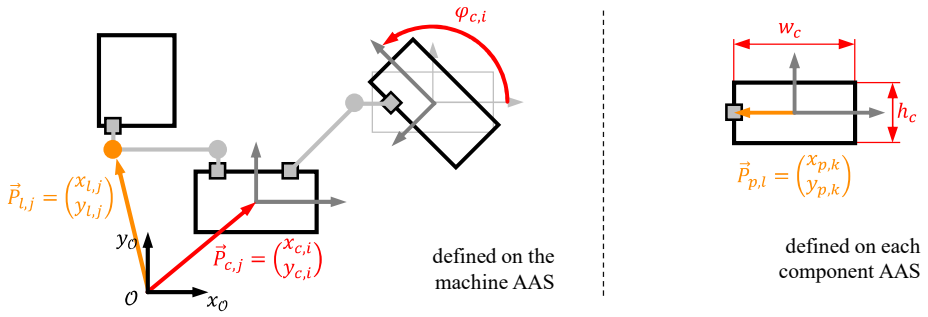

Figure 4.3. Basic approach for Semantic Position Description

Connections is the second SMC inside the SM *Model Reconstruction* and contains the information to describe the linkages between the model components respectively. Inside the SMC is a *Source* and *Destination*, which includes the name of the model component in combination with the specific ID of the port. By determining a source and destination, the direction of flow can additionally be described. To picture the hydraulic schematic more accurately, the SMC *Connections* also include *Points* and *Line*. *Points* determine the coordinates of the key points to describe the path of the line respectively. The coordinates to describe the location of those points share the same reference as the position coordinates of the model components. Additionally, *Line* includes information about the width and shape of the line in first instance.

4.3.3. Generic Frame for Technical Data for Industrial Equipment in Manufacturing

To establish User Story II the SM *Generic Frame for Technical Data for Industrial Equipment in Manufacturing* [12] is used and extended. Besides *Product Classification,* an important property to identify the specific type of hydraulic components, the SM contains most technical data, which used to be found inside the datasheets. From a different point of view, this SM is the provider of machine-readable data, ideally combined with a sematic id based on ECLASS or other dictionaries. From a general view, this SM is the source to retrieve most of the necessary information that is required for automatic product search (User Story II).

This SM includes SMC like *Product Classifications* and *Technical Properties. Product Classifications* associates the asset with product classes in common classifications systems like ECLASS, e.g. an axial piston pump or a hydraulic cylinder. *Technical Properties* includes technical parameters to describe the characteristics of the components respectively. These parameters relate to International Registration Data Identifiers (IRDI) [22], to enable a unique identification of the property. This SM is the basis to implement Use Case II, since the conditions are met to automate the search process for required components, because a model components suitability to be integrated inside the machine can be verified by its product group and technical parameters.

4.4. The AAS for hydraulically-driven machines

Machines with a hydraulic drive system are a composition of hydraulic components according to a defined layout. Even though you could treat the components like pumps or valve as systems themselves, in context of Fluid 4.0, the focus lies on stationary machines, like a hydraulic press, and mobile machines such as wheel loaders or excavators.

According to User Story I, the digital representation of the machine drive system is one fundamental basis for collaborative engineering. From a machine manufacturers perspective data consistency is required from the machine AAS to the component AAS without duplicating data. The physical and logical linkage of component AAS within the machine layout is already part of the SM *Model Reconstruction* in chapter 4.3.2. Besides the idea of a structural reconstruction of hydraulic plans, the SM offers the opportunity for an interaction with the selected system components and their unique AAS by using API. The linkage between specific component AAS and their model-based representation inside the *Model Reconstruction* has yet to be finalized. First approaches are the synergetic application of the SM *Hierarchical Structures enabling Bills of Material* [23], which contains the used components inside the systems and, if available, the reference to their specific AAS.

The combination of both SMs *BOM* and *Model Reconstruction* would enable the possibility to simultaneously provide all required data interactively, since the information have been linked through the *BOM* and an interface for interaction has been provided through the *Model Reconstruction*. A machine AAS, consisting of both SMs, would tremendously support the provision of information, to enable an automated data exchange, the creation and parametrization of simulation models, the efficient exchange of components, and to retrieve component-specific information like the characteristic curves.

5. CLIENTS AND VALIDATION

The User Stories described in chapter 3 will be addressed by the client applications shown in Figure 3.1. This chapter presents an overview of the applications in combination with an assessment of how precisely the requirements have been fulfilled. All client / user applications use the aas-core-works SDKs as basic communication stack with the AAS [24].

5.1. Systems Engineering and Model Reconstruction

The first User Story aims for a digital twin of a hydraulic system that can later be shared and detailed further. Typically, after the objective of the system has been defined and all necessary translational and rotational movement patterns have been detected, the design of a hydraulic system begins with the hydraulic schematic. It includes all necessary actuators for power transmission, e.g., cylinders or hydraulic motors, as well as the required valves and hydraulic lines to control the flow of power, and finally, the providers for hydraulic power, like pumps.

There are various software tools to generate a hydraulic schematic by dragging and dropping the hydraulic components. Usually, there are libraries of commonly used components that can easily be embedded into the own design. Connections between the components via their unique ports are established in the same graphical manner. From that schematic, the initial version of an AAS for the hydraulic system is created. To achieve it, a graph editor program is required to create the library, which contains all the necessary components to draw

hydraulic schematics. In this project, *yEd* [25] has been used, since it is a free tool that can generate various diagrams. Besides the visualization aspect, it is important to embed component parameters inside the library, which can later be retrieved through an XML or GraphML-file. To create the AAS out of the file, a Python program has been developed, which executes the deserialization process by using the aas-core-works SDK [24]. First, the SM *Model Reconstruction* from chapter 4.3.2 will be applied. It contains all the information to recreate the hydraulic schematic as detailed as it was created in *yEd* before. This provides the opportunity for later interactions, like the establishment of references to individual component AAS. In Figure 5.1., a cylinder drive system has been designed inside *yEd* by using the prepared library of elements and later transferred into an AAS by using the implemented Python application.

Figure 5.2. shows an example application of the SM *Model Reconstruction* by recreating the hydraulic schematic inside a vector graphic. To simulate the generation of a hydraulic system, a second Python application has been programmed to identify the parameters inside the SM *Model Reconstruction* and generate a vector graphic (*.svg) out of it. The result is shown on the right side of Figure 5.2. The hydraulic schematic has been created by retrieving information from the AAS. This shows the advantage of an AAS as single source of truth which can be used as harmonization inside multiple tools using different file formats.

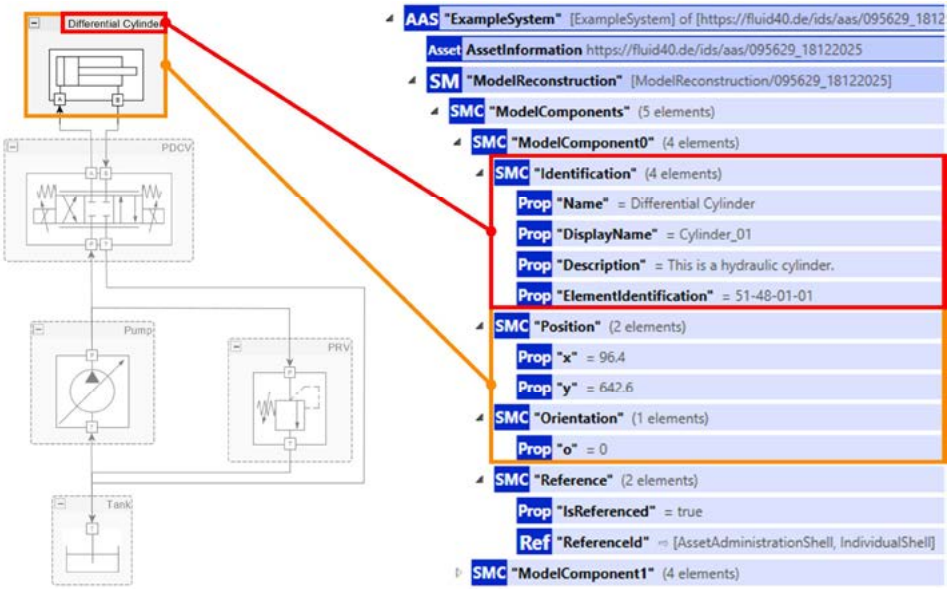

Figure 5.1. Example System of a hydraulic cylinder drive by using yEd (left) and its representation as AAS (right), which was generated automatically by the python script

In chapter 2, the ineffectiveness of the process in finding fitting components for a hydraulic system by manually analysing various datasheets has been highlighted. It contributed to User Story II for a standardized data format, which can be applied for an automized search process. By defining the relevant parameters, the values of various AAS can be analysed and automatically identified as a fitting component. The basic requirement includes the

knowledge of the exact location, where the information will be stored, a fitting identifier, and compliance with the syntactic representation.

To achieve it, the SM *Generic Frame for Technical Data for Industrial Equipment in Manufacturing* will be used to store the individual parameters of the components. By using the IRDI, the technical properties will receive a unique reference for a specific assignment. On one hand, the SM stores the information about the product class of the component by using ECLASS identification. On the other hand, the individual technical parameters for the specific product group will be listed. By using AAS API calls to retrieve the information, the suitability of the component can be assessed through the comparison of the available and required parameters. This process enables automatic search by scanning accessible servers of the component vendors, including AAS of the traded components. Even though the process works as anticipated, difficulties occurred by scanning the server for suitable components. By repetitively requesting the AAS (including *Technical Data*) from the server and checking whether the component matches the desired parameters, the time for computing increased noticeably with a higher number of components. To reduce the client-side computing effort and increase the efficiency of this process, the AAS Query Language [14] has been applied. It assists the search process tremendously, since the server pre-filters the results instead of the client application.

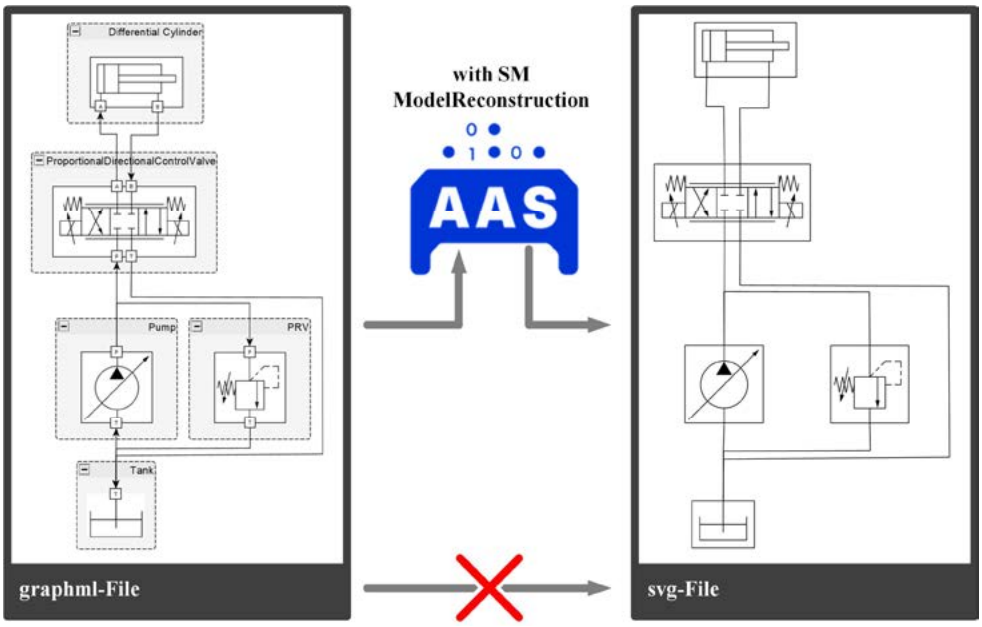

Figure 5.2. Vector graphic of a hydraulic system (right) created by the data of the Submodel Model Reconstruction inside the AAS of the system

A query request requires a payload specifying the constraints of the query. Various definitions can be integrated to specify the necessary properties that the AAS of the components need to provide in combination with the sought values. For example: *"Filter for all component AAS which represents a hydraulic pump with a displacement of 100 cm³ or higher on this server."* By intuitively using logical and comparison operators in the syntax

of the Query Language, this technology can be used to extract the relevant AAS from a large pool of assets. After the relevant components have been identified, more information can be retrieved for downstream purposes. [9] has been also using the query language to filter the available assets to select the fitting components, including their parameters, for the simulation model.

User stories III, IV and V have some strong similarities. In all of them, the machine AAS is used to collect the demand data for specific customers and the connections between all components. A specific advantage of user story V is described in more detail below.

5.2. Control Development for a miniature hydraulic Wheel Loader

The implementation of User Story V is explained using a demonstrator developed in Fluid 4.0. For this purpose, a reduced and simplified version of a hydraulic wheel loader has been designed to represent the advantages of the machine AAS, which links to their component AASs. The demonstrator is shown in Figure 5.3. The main purpose of this demonstrator is to visualize the control development and highlight the advantages of using the AASs in combination with the new SM *Characteristic Curves* (refer to chapter 4.3.1).

To demonstrate this effect interactively, a user interface has been designed as visualized in Figure 5.3. A task was set to insert missing parameters to map a curve of a proportional flow control valve, which has been depicted in red colour inside the hydraulic scheme. This curve describes the amount of flow that passes through the valve, depending on the electrical current applied to the magnet from the control unit. The valve is responsible for the translational speed of the hydraulic cylinder.

As described in chapter 3 before, the values of the lookup table representing the curve need to be retrieved manually from a graphic inside the data sheet today. By applying the new SM *Characteristic Curves*, which provides the data machine-readable in a clearly defined syntax, the required information can be inserted automatically by the application with the click of a button. This leads to the desired movement of the wheel loader kinematics.

To demonstrate the occurrence of errors, a graphic for a different-sized valve has been prepared. Even though there are slight differences between the curves, the movement of the wheel loader changes tremendously. In the end, the demonstrator envisions the advantages of reducing the effort of implementing parameters from graphics and reducing the risk of mistakes. Both ways of parametrization of the control software, the manual way today and the automatically one based on component AAS with SM characteristic curve of the valve, can be compared interactively. The benefits are directly noticeable. The first concepts of this demonstration were shown at the special show during Hannover Messe 2025. The feedback from the visitors were fed back into the development steps of the workflow presented within this contribution.

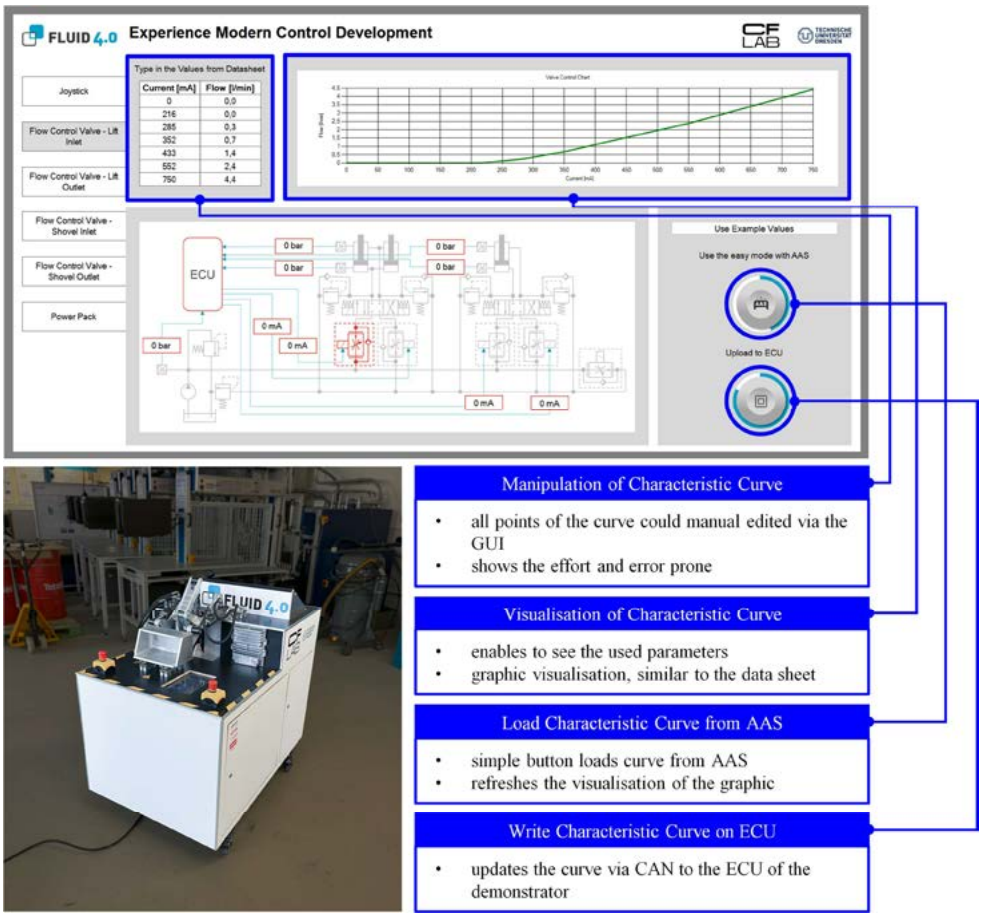

Figure 5.3. Miniature hydraulic wheel loader as demonstrator (bottom left) and interactive User Interface (top) to adjust control software manually or with the SM Characteristic Curve automatically

6. CONCLUSION AND OUTLOOK

This article highlighted the current problems in collaborative engineering of complex mechatronic systems such as hydraulic drive technology in mobile machines. Based on industry-relevant User Stories, an overall concept was developed using the AAS, and a total of five client applications. The essential building blocks for implementing collaborative engineering in fluid technology systems are information modelling, infrastructure, interfaces, and tools for automated signal flow. The administration shell technology, combined with the interaction possibilities offered by established web technologies and interfaces, forms a crucial basis for implementing these building blocks in the context of cross-company communication via dataspaces. The semantic description of an asset's properties using the existing SMs allows the implementation of basic User Stories. However, there has been a lack of specific implementations for User Stories in collaborative

engineering like “Machine AAS with physical based linkage of component AAS”, “Semantic search within the dataspace” or “Automatic control software parametrisation”. With the help of the SMs “*Model Reconstruction*,” “*Generic Frame for Technical Data for Industrial Equipment in Manufacturing*,” and “*Characteristic Curves*” the most important User Stories in fluid engineering system design can be implemented. The first prototypes have already been built to carry this out.

The results of these investigations have already been incorporated into the IDTA standardization processes for partial model development. In the following work, User Stories III and IV will be implemented and the overall process will then be evaluated. The software modules will be made available as open source repositories on GitHub until the end of the project: https://github.com/fluid40

7. ACKNOWLEDGEMENT

This work has been funded by the European Union (EU) and supported by the German Federal Ministry for Economic Affairs and Energy (BMWE) in the project Fluid4.0 – Revolutionizing Fluid Engineering: Implementation of digitalization for fluid power 4.0 in the cross-industry and cross-manufacturer data space using Asset Administration Shells, Submodels and demonstrators (project numbers 13IK039L and 13IK039C). The views and opinions expressed are solely those of the authors and do not necessarily reflect the views of the European Union or the European Commission. Neither the European Union nor the European Commission can be held responsible for them.

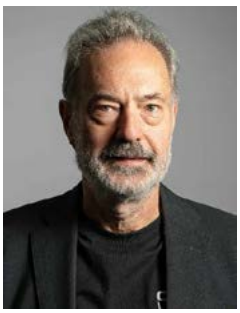
Biographies



Paul Lukas Remde received the diploma degree in mechanical engineering from TU Dresden in 2024. He is working as scientific research assistant at Construction Future Lab gGmbH since 2024 and is currently a developer inside the Fluid 4.0 project. His main task is the application of I4.0 technologies by developing client applications and demonstrators.

Benjamin Beck received the diploma degree in mechanical engineering from TU Dresden in 2013. He worked as research assistant and group leader for mobile hydraulic systems at the chair of Fluid-Mechatronic Systems at TU Dresden from 2013 to 2023. His research areas include functional safety, energy efficiency and function development of hydraulic drive systems with independent metering for mobile machines. Now he works in addition as strategy and sales lead at Construction Future Lab gGmbH and coordinates the joint research project Fluid 4.0.

Denis Ritz completed his mechanical engineering studies at TU Dresden in 2018 and is currently a research assistant at the Chair of Fluid Mechatronic Systems at TU Dresden. His research centers on control strategies and the development of mobile hydraulic drive systems, with a strong emphasis on systems engineering. Prior to his academic studies, he completed a vocational training as a farmer, providing him with practical insights into mobile machinery.

Jürgen Weber has studied mechanical engineering at the TU Dresden and successfully finished his doctorate in 1991. Until 1997, he was the active senior engineer at the former chair of Hydraulics and Pneumatics. This was followed by an approximately 13-year

industrial phase. He was active in various positions in the R&D department of the agricultural and construction machinery manufacturer CNH. Effective March 1st, 2010, Dr.-Ing. Jürgen Weber has been appointed university professor and chair of Fluid-Mechatronic System (Fluidtronics) at the TU Dresden. Since July 2018 he is the leader of the Institute of Mechatronic Engineering. He is also one of the founders and managing director of the Construction Future Lab gGmbH.

Tom Gneuß received the degree *Master of Science* from the TU Dresden in 2024. Since then, he is working as a research associate at the Chair for Industrial Communications. His main focus lies on the integration of brownfield devices into interoperable Industry 4.0 ecosystems.

Nico Braunisch received his diploma from the TU Dresden in 2019. Since then, he is part of the research group at the Chair for Industrial Communications. During his research, he has gained extensive knowledge in the field of IIoT, Industry 4.0, and automation.

Martin Wollschlaeger studied Electrical Engineering at Otto-von-Guericke University Magdeburg, earning his doctorate in 1991 and Habilitation in 2001. After working at ifak

Magdeburg, he became professor and chair of Industrial Communications at TU Dresden in 2003, where he also directs the Institute of Applied Computer Science. His research focuses on industrial communication and automation networks, including Ethernet-based systems, information modeling, and semantic integration. He contributes to standardization (DKE, IEC) and leads national and European research projects in areas such as Industrie 4.0 and 5G.

Vertical Integration of Energy Data – an Architectural Evaluation of Asset Administration Shell (AAS)

M.Sc. Fabian Geibel[1], Dr-Ing. Karin Tischler[2]

[1]*Bosch Rexroth AG, Ulm, fabian.geibel@boschrexroth.de*

[2]*Bosch Rexroth AG, Lohr am Main, karin.tischler@boschrexroth.de*

Abstract.

Understanding the energy consumption of a process is key to optimize the economic and ecological performance. Today's data integration process still comes with manual effort especially during the initial set-up. The Asset Administration Shell (AAS) is a framework of open standards for normalized, referenced and machine-readable information that enables the exchange and collaboration among different players within a broad ecosystem. This research investigates the technological aspects of the AAS and provides a detailed concept on how to implement an AAS architecture in a practical energy monitoring use case. The test results show that AAS has the potential to reduce the manual effort during the vertical integration of energy data. Nevertheless, AAS needs to be adopted by a broad range of hardware and software suppliers to scale this approach. A reflection regarding the impact of Artificial Intelligence (AI) reveals further potential.

Keywords. Asset Administration Shell (AAS), Energy Data Integration

1. MOTIVATION

The vertical integration of energy data from machines into IT applications is crucial for energy monitoring and reporting. Furthermore, it is the basis for use cases with higher economic and ecological impact like optimizing energy consumption, managing systems, quantifying the efficiency of applied measures and various other applications within industrial settings to achieve an optimized operation.

The integration of energy data is a typical task of machine operators. While the general procedure is well-known it comes with high manual effort. Each machine has different interfaces and individually specified data. There is an continuously increasing number of machine types that can be rather complex and specific. However, the energy consumption should be provided as a meaningful dataset. Currently, each machine builder or sensor

All Open Access articles are peer-reviewed, distributed under the Creative Commons Attribution-Non Commercial 4.0 International

supplier provides his own solution(s) that must be integrated. The initial set-up of the communication services includes the search for the right interface description and the extraction of the configuration information. Due to supplier- and device-specific variations of common standards the configuration and mapping has to be repeated for each interface and in many applications for each datapoint again. This work is evaluating how the concept of the Asset Administration Shell (AAS) can address these challenges and supports the vertical integration of energy data.

Once the integration is established, the understanding of the data is key to generate benefit. Therefore, the data itself has to be provided with meta-data e.g., regarding origin, type and quality. Even more value comes with context information, like measurement location and process details or product information. This work also shows how AAS can support the combination of such information.

2. CONTEXT

This research focuses on the evaluation of AAS technology applied to the vertical integration of energy data in the context of established standards. A hydraulics demonstrator of an injection molding machine from Bosch Rexroth [1] serves as an example and the basis for the implementation (Figure 1). The hydraulics demonstrator includes a physical energy meter as well as a database service. The concrete components and the implementation are described in chapter 5.

Figure 1: Hydraulics demonstrator of an injection molding machine – Bosch Rexroth AG [1].

3. AS-IS PROCESS AND CHALLENGES

Performing energy management strongly relies on historic time-series data. A first major step to establish the functionality is the configuration of the communication between the participants. In the context of this research, the data is related to a physical system, a machine or device, referred to as an *Asset*. Assets can contain further Assets e.g., an energy meter for monitoring. Services that allow an interaction with the data are classified as an *Asset service* if located on a physical part of the Asset (e.g., an OPC UA [2] server running on the PLC of the machine), or as *Asset related service* running on another machine or IT system (e.g., an influxDB [3] database running on a separate device).

This research investigates the processes and challenges based on two tasks (Figure 2):

- Task 1: Store real-time data (RT) in a database (DB).
- Task 2: Read time-series data (TS) from a database (DB).

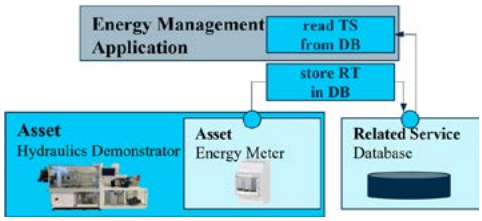


Figure 2: Overview task 1 and task 2. Task 1: Store real-time data (RT) in a database (DB). Task 2: Read time-series data (TS) from a database (DB).

After defining the term "Communication interfaces of participants" in chapter 3.1, the two main tasks and their processes are described in chapter 3.2 and chapter 3.3. Based on today's processes the main challenges are stated in chapter 3.4. A simplified example in chapter 3.5 shows how the configuration effort for the vertical integration of energy data can be assessed.

3.1. Communication interfaces of participants

Each participant (data sources and data sinks) provides a communication interface. The interface follows specific protocols and offers data in a structured way. Descriptions of the interfaces are needed for the configuration of the communication between two participants.

Elements of the interface description are e.g., for an OPC UA [2] communication: the endpoint URL, the node ID or browse path, credentials and data types. For databases e.g., influxDB providing a SQL interface [3], additional information about tables, tags and fields are required. Additionally, further meta-data like units, valid ranges, applicable actions are required for a correct processing of the data.

3.2. Task 1: Store real-time data in a database

The task "Store real-time data in a database" is realized by a service with three computing steps (Figure 3). An initial manual configuration of the service to communicate with the interfaces is necessary. The service then runs in a loop to read from the source, process the data and write the result to the sink.

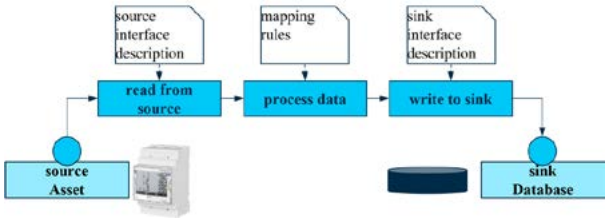

Figure 3: Task 1: Store real-time data (RT) in a database (DB) (dashed line: Initial configuration, continuous line: Running data process).

The overall process is shown in Figure 4. The user searches for the interface descriptions of the data source and the data sink from the providers or integrators of the source system (Asset) and the sink system (database). The user interprets the description and configures the runtime service for each source-sink element pair that needs to be mapped. This includes the set-up of a runtime service to communicate to the interfaces of the source and the sink (chapter 3.1).

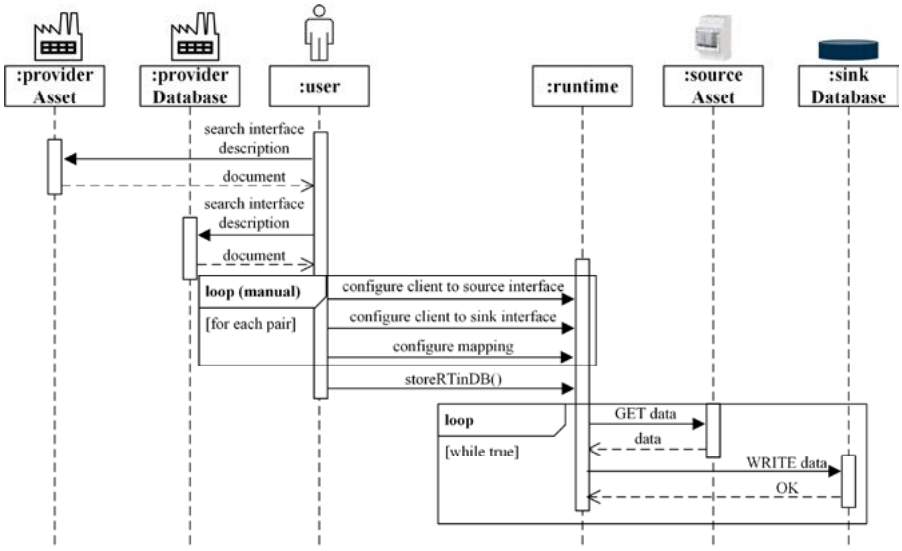

Figure 4: Process to initiate and perform task 1: Store real-time data (RT) in a database (DB).

3.3. Task 2: Read time-series data from a database

The task "Read time-series data from a database" is realized by one computing step, part of a runtime e.g., an energy management application (Figure 5). An initial configuration of the service is necessary to communicate to the interface of the source (chapter 3.1). The application defines how often the service performs the task.

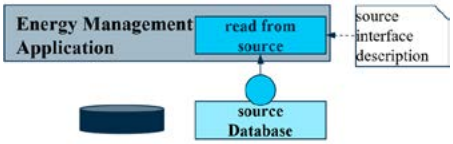

Figure 5: Task 2: Read time-series data (TS) from a database (DB) (dashed line: Initial configuration, continuous line: Running data process).

The overall process is shown in Figure 6. The user searches for the right interface description of the data source at the provider or integrator of the source system. The user interprets the

description and configures the runtime service. This includes the set-up of a client to communicate to the interface of the source (chapter 3.1).

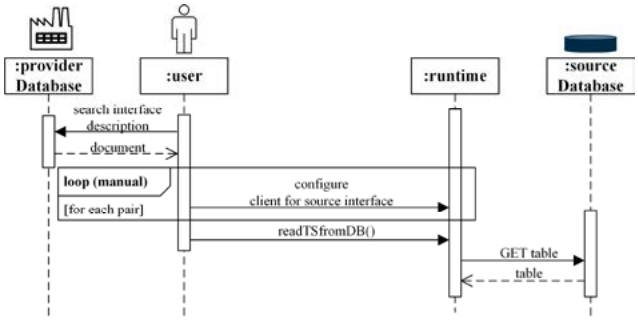

Figure 6: Process to initiate and perform task 2: Read time-series data (TS) from a database (DB).

3.4. Challenges

The manual steps during the integration process of energy data are identified facing the following four challenges:

Challenge 1: Find the right interface description for the Asset.

The interface description usually is not directly linked to the Asset. Typically, the interface description is provided as part of the product documentation. The documentation is provided via different and supplier-specific channels like printed manuals or on the manufacturer's website. In some cases, a detailed interface description can be retrieved from a webserver on the Asset itself. The identification of the information source with the correctly associated file and version might be difficult.

Challenge 2: Use the interface description to configure the service.

The interface description is often provided in a non-machine-readable way, such as tables in different formats or with a vendor specific variation of a standard. The configuration information is manually transferred into the services which is time-consuming and error-prone.

Challenge 3: Decouple and reuse code and configuration.

The configuration of the services that communicate to the interfaces and the mapping of the data between the interfaces is done directly inside the code or with a service specific configuration file. Code and vendor specific configuration information can't be reused easily. Additionally, different protocols need different connector services.

Challenge 4: Understand the data.

Meta-data and context information to understand the data coming from the interfaces, like semantic descriptions, measurement location, parameters and detailed data of the production process or the Asset itself are needed for the right interpretation of the energy data. For example, an increase of energy consumption might be related to a higher demand of the process, different production material, changes in environmental conditions, inappropriate machine configuration or machine wear. Depending on the correct understanding, it is possible to derive suitable measures or classify a change "as expected".

3.5. Evaluation example of the implementation effort

The following example shows how an assessment of the implementation effort for the vertical integration of energy data is possible (Figure 7). The effort must be quantified individually for each use case and set-up. The example consists of several Assets (A) (e.g., machines on a shopfloor), that offer the same amount of data points (D) (e.g., actual power consumption) via the same communication interface standard (e.g., OPC UA). Every data point from every Asset needs to be integrated into several user applications (U) (e.g., for energy management). The description of the communication interface is stated in each Asset's documentation.

The overall configuration effort (c) is based on the number of Assets (a), the number of user applications (u) and the number of data points per Asset (d). The effort is exemplarily defined as $c=a*d*u$. This example visualizes that with a rising number of Assets, data points and user applications, the configuration effort rises. In case of different communication interface standards, additional effort would be necessary.

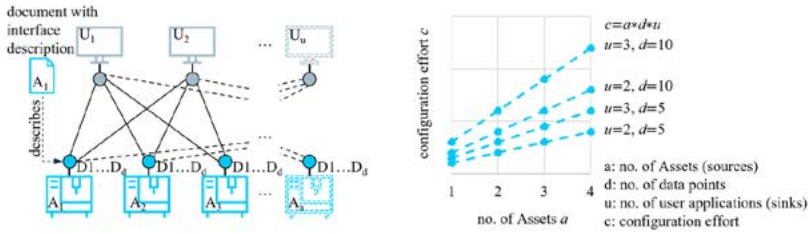

Figure 7: Integration example (left) and configuration effort (right) – providing configuration via documents.

4. AAS TECHNOLOGY TO ADDRESS THE CHALLENGES

AAS technology is characterised by open-source specifications, software development kits (SDK), simple interfaces and a community driving the interoperable data exchange standard. IEC 63278 [4] defines the *Asset Administration Shell* (AAS). The AAS consists of several open-source specifications and components relevant for this research (Figure 8):

- Asset: A virtual or physical product, machine or simple system of interest. The *Asset ID* is the globally unique identifier (ID) of an Asset.

- Asset Administration Shell [AAS]: Digital representation of an Asset. Each AAS is linked to one Asset by the Asset ID and reference to one or many *Submodels* [SM].
- Submodel [SM]: A data structure that is usually based on a *SubmodelTemplate* [SMT]. [SM] exist dynamically in a runtime as an object or statically as a .json or .xml format. Via the *AAS interface*, client applications are able to interact with a [SM] on a server. For this interaction, each [SM] has a unique *Submodel ID*. Each [SM] contains one or many *SubmodelElements* [SME].
- SubmodelElement [SME]: A structured data element. [SME] types relevant for this research are:
  - *SubmodelElementCollection* [SMC]: contains [SME]
  - *SubmodelElementList* [SML]: contains [SME] of the same type and definition
  - *Property* [PROP]: single value data element
  - *ReferenceElement* [REF]: defines a logical reference to another element
  - *RelationshipElement* [REL]: defines a relationship between two elements, contains two [REF] First and Second
- SubmodelTemplate [SMT]: A specified data structure. Each [SMT] has one unique *semantic ID*. For this research the two IDTA Submodel Templates *AssetInterfacesDescription* (AID) and *AssetInterfacesMappingConfiguration* (AIMC) are used.
  - [SM] AssetInterfacesDescription (AID) (IDTA 02017 [5]): It contains the description of the communication interfaces. Besides general information (URL, protocol type), a description of a specific property like the href or browse path, the unit, the data type or min and max values.
  - [SM] AssetInterfacesMappingConfiguration (AIMC) (IDTA 02027 [6]): It contains several [REL], that reference a property from the source [SM] AID to a property of the sink [SM] AID.
- AAS interface: A server hosting [AAS] or [SM] provides a specified REST API. For this research, the [SM] repository API with the following method is used: GET {URL}/submodels/{[SM]ID64}. Where the {URL} is the server address of the [SM] repository and the {[SM]ID64} is the base64 encoded [SM]ID.
- AAS user application: An application that communicates with the AAS or SM via the AAS interface.

[AAS] and [SM] data can be exchanged as a static file, a .json, .xml or within the .aasx package format (AAS Type 1) or, hosted on a server, via an API (AAS Type 2).

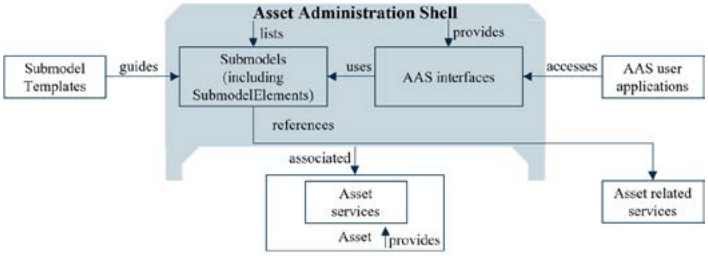

Figure 8: Relevant components of the Asset Administration Shell (based on IEC 63278 [4]).

4.1. Concept to apply AAS

The following concept is developed to apply the AAS technology in regards to the four challenges of the vertical data integration.

Challenge 1: Find the right interface description for the Asset.

The [AAS] is linked via the Asset ID to one Asset and refence the [SM] containing the information describing the Asset. An [SM] based on an [SMT] contains the semantic ID of the [SMT]. The AAS standard includes discovery, registry and repository specifications. Knowing the Asset ID and discovery URL (e.g., from the product type plate following the ID-Link standard (IEC 61406 [10])) as well as the semantic ID of the [SMT] AID, the [SM] AID can be retrieved automatically.

Challenge 2: Use the interface description to configure the service.

The [SM] AID contains all data relevant to configure a service to communicate with an Asset or Asset related interface. For each protocol, the [SM] structure follows a standard. The [SM] AID and its [SME] are accessed in a machine-readable way. Once the logic of the [SMT] is integrated in an application, the configuration process can be automated.

Challenge 3: Decouple and reuse code and configuration.

The communication interfaces can be described via [SM] AID and the mapping of the source-sink relationship via [SM] AIMC. With this concept, the configuration is provided in a neutral, standardised .json format and can be used by several applications.

Challenge 4: Understand the data.

The [AAS] represents with the [SM] different views on the Asset along its lifecycle. AAS technology is capable of structuring information that describes the Asset like provision of documentation or provision simulation models. Another aspect are relationships between Assets e.g., the connection of a valve with a pump. Here the RelationShipElement [REL] and ReferenceElement [REF] of the AAS are used. Furthermore, the context of different perspectives like production data of a part manufactured on a machine can be structured as well. In case of timeseries data, the time stamp is the main reference to synchronize different data sources.

This research is conducted as part of the funded project Fluid 4.0 [7][6]. Components to automate the communication channel between a runtime and an Asset interface are currently under development. An AAS API client [8], as well as a standard parser [9], including a handler for the [SM] AID and [AIMC], have already been published.

5. AAS TEST SET-UP, IMPLEMENTATION AND PROCESS

To evaluate the vertical integration of energy data by using an Asset Administration Shell (AAS) architecture, a test set-up was designed and implemented. The building blocks of the architecture are described in chapter 5.1. The processes to initiate and perform the two tasks "Store real-time data in a database" and "Read time-series data from a database" are described in chapter 5.2.

NOTE: for this research all software components are running on a local Windows 11 machine.

5.1. Building blocks

The AAS architecture consists of three building blocks, "Asset", "AAS Infrastructure", "Runtime" (Figure 9) that are described in more detail below.

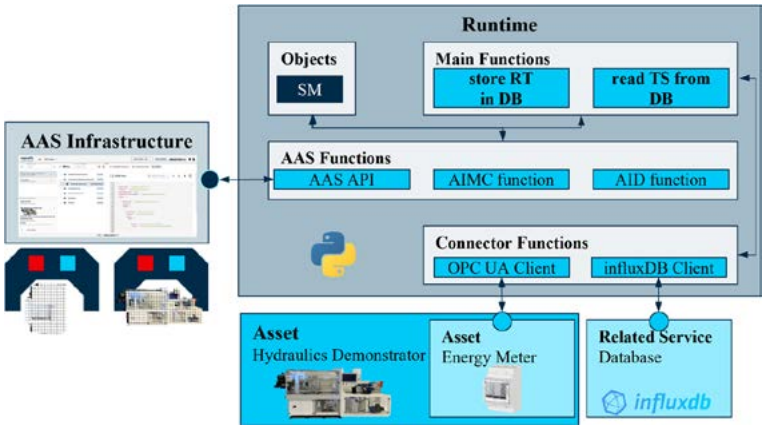

Figure 9: AAS architecture consists of three building blocks: "Asset" (bottom), "AAS Infrastructure" (left), "Runtime" (centre).

Asset

An hydraulics demonstrator of an injection molding machine from Bosch Rexroth [1] is modelled as the main Asset. The hydraulics demonstrator has an energy meter integrated, modelled as another Asset. The energy meter is providing real-time data of voltage, current and power via an OPC UA [2] interface (Figure 9, bottom). The OPC UA server is defined as an Asset service.

For the detailed testing of the AAS implementation, an additional virtual environment was established. In a local python environment, the OPC UA server of the energy meter is running with simulated data.

An InfluxDB 3 Core [3] database is storing the real-time data from the energy meter and providing the time-series data via a SQL interface. The influxDB is not part of the demonstrator and thus an Asset related service.

AAS Infrastructure

The AAS infrastructure is the Eclipse BaSyx Java implementation [11] running inside a local Docker [12] environment (Figure 9, left) The [AAS] are initialised by .aasx package files. There is one [AAS] for the hydraulics demonstrator and one for the energy meter. The AAS infrastructure offers several APIs. For this research, only the following AAS SM repository API method is used: GET {URL}/submodels/{[SM]ID64}. The return is a .json payload.

Design Decision: There is an API method to retrieve a specific [SME] inside the [SM] by a specific path: GET {URL}/submodels/{[SM]ID64}/submodelelements/{PATH}. To keep the number of requests between the runtime and the AAS Server to a minimum, the [SM] itself is retrieved as a single .json payload.

Figure 10 shows the concrete relationship between the Assets, the [AAS] and the [SM]. The [AAS] Hydraulics Demonstrator contains the [SM] AID to describe the influxDB interface. The [AAS] Energy Meter contains the [SM] AID to describe the OPC UA interface. Furthermore, the [AAS] Hydraulic Demonstrator contains the [SM] AIMC that refers to [SMC] inside the two [SM] AID.

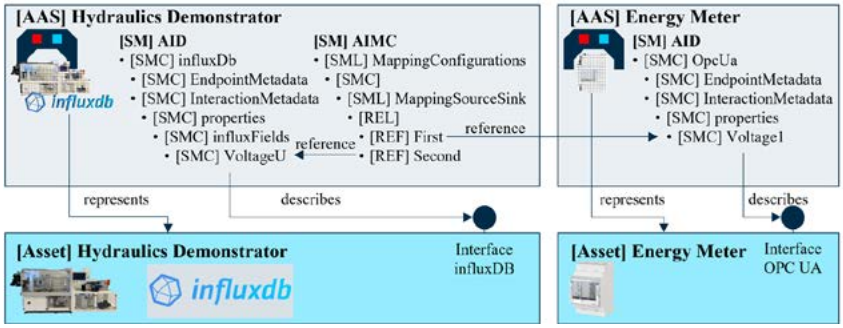

Figure 10: Relationship between Assets, AAS and Submodels.

Runtime

The runtime is implemented with Python. It contains three function modules “Main Functions”, “AAS Functions”, “Connector Functions” and the [SM] object storage (Figure 9, centre).

The functions and the object storage are described in more detail.

Main functions that fulfil the main tasks:

- Store real-time data in a database: this function starts the process to read from the source (OPC UA server) and writes to the sink (influxDB).
- Read time-series data from a database: this function starts the process to read from the source (influxDB).

AAS functions to interact with [AAS] and [SM] repository API and [SM] specific functions.

- AAS API: client to interact with the [AAS] and [SM] repository API. Relevant for this research: GET {URL}/submodels/{[SM]ID64}. The status code and the .json payload is returned.
- AIMC function: process the [SM] AIMC to set up two mapping vectors with information from the source and sink [SM] AID.
- AID function: process the [SM] AID to configure the clients.

Connector functions to set-up communication to the interfaces:

- OPC UA client: service to read data from an OPC UA server.
- influxDB client: service to write to and read from an influxDB.

SM object storage to store [SM] as a python object:

- The .json payload, returned from the [SM] repository server, is transformed via the AAS Core Works Python SDK [13] to a python object. The runtime interacts with this object instead of performing several API calls to the [SM] repository server.

5.2. Processes

NOTE: it is assumed that the suppliers or integrators, that set-up the interface and data structure offered by these interfaces, provide the interface descriptions as [SM] AID, as well as the URL to the corresponding repository and the ID of the [SM].

Task 1: Store real-time data in a database

The overall process to “store real-time data in a database” is described in Figure 11. The user effort for the configuration is limited to define the [SM] AIMC. That incudes to add for each mapping a [REL] element. The [REF] First points to the [SMC] within the [SMC] influxFields containing the description of the source element (e.g., [SMC] VoltageU in Figure 10). The [REF] Second points to the [SMC] within the [SMC] properties containing the description of the sink element (e.g., [SMC] Voltage 1 in Figure 10). To initiate the computing process, the user calls the runtime main function “Store Real-Time Data in Database” with the ID of the [SM] AIMC, the [SML] index of the [SMC] containing the concrete mapping and the URL of the corresponding repository.

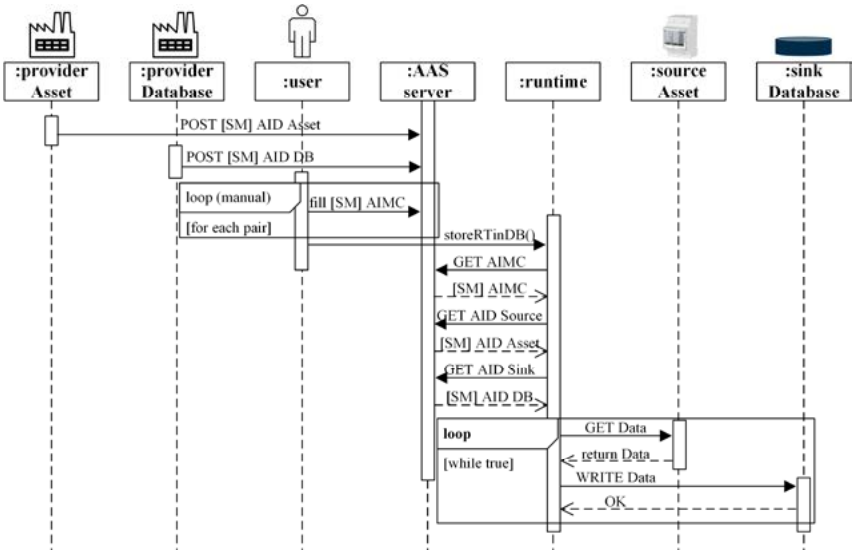

Figure 11: Process to initiate and perform task 1 with AAS: Store real-time data (RT) in a database (DB).

Task 2: Read time-series data from a database

The overall process to "Read time-series data from a database" is described in Figure 12. To initiate the computing process, the user calls the runtime main function "Read Time-Series Data from Database" with the ID of the [SM] AID, the name of the [SMC] for one concrete interface of the Asset (e.g., "OpcUa" in Figure 10) and the URL of the corresponding repository.

NOTE: it is assumed that all properties in the [SMC] for one concrete interface need to be integrated.

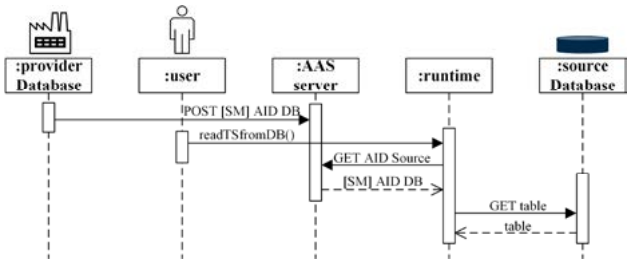

Figure 12: Process to initiate and perform task 2 with AAS: Read time-series data (TS) from a database (DB).

6. EVALUATION

The four challenges (chapter 3) of the vertical integration of energy data are evaluated based on the implemented test set-up of the Asset Administration Shell (AAS) architecture (chapter 5) in chapter 6.1.. It is important to note that the AAS is used in this evaluation to provide the static configuration information. The AAS is not used to handle the dynamic data directly. The data handling is done by runtime clients designed to communicate with the specific interface standards (e.g., OPC UA) directly. In chapter 6.2, the example from chapter 3.5 used again to show the potential of the AAS approach.

6.1. Evaluation of challenges

The evaluation focusses on the manual steps that a user needs to perform for the configuration and the interpretation of a communication interface. For each challenge, the limitations of the implementation are shown as well. The progress in the field of Artificial Intelligence (AI) will lead to new solutions in IoT applications. These opportunities in combination with the developed AAS approach are discussed as further potential.

Challenge 1: Find the right interface description for the Asset.

The process is reduced from searching the interface description in different supplier documents and websites to the search for the [SM] ID and URL of the Submodel repository. Furthermore, when [AAS] discovery and registry mechanisms are implemented, the Asset ID (following the ID-link standard) is sufficient to find and choose the right [SM]. The Asset ID can be encoded e.g., in the QR-code on the Asset.

Further potentials:

To scale this approach, it is necessary that a broad range of vendors create and provide AAS for their Assets. If vendors offer an AAS API, customer applications could retrieve the AAS automatically. As this is not yet common standard the scaling is an open question.

An AI approach could help transforming the data from a vendor specific standard, or a document to the AAS specification. This would reduce the initial effort for each participant. Otherwise, AI might search for the interface descriptions on websites and in documents – even without AAS, but with a risk of misinterpretation and recurring controlling efforts by a user in each case.

Challenge 2: Use the interface description to configure the service.

The process is reduced from taking over the configuration information manually into the application to a fully automatic configuration. This is due to the standardised machine-readable and vendor-independent .json format for the [SM] AID.

Further potentials:

Consuming applications could provide a ready-to-use service that configures the communication to the Asset services automatically based on the [SM] AID and [SM] AIMC.

The AAS specifications can be developed further to describe more different kinds of interfaces.

An AI approach would be suitable to take over the mapping process providing the [SM] AIMC, based on the source and sink [SM] AID.

Challenge 3: Decouple and reuse code and configuration.

Redundant integration effort is reduced significantly as a typical use case set-up and software services can be reused easily. Once the interface descriptions and the mapping are provided as [SM] AID and [SM] AIMC and the software can interpret the standard structure, the complete content can be transferred to different Assets. Changing or upgrading a single Asset within an IT infrastructure is possible with little implementation effort.

Further potentials:

The development of further open-source components for AAS is ongoing [8], [9], [11], [13], [14]. This enables different users and applications to adopt the AAS technology faster in their use cases.

Challenge 4: Understand the data.

The AAS provides easier access to structured information beyond the basic sensor measurement values. Information like units, valid ranges, accuracy, semantic IDs and additional descriptions can be used by different applications and use cases. Client applications are able to retrieve additional information when needed.

The AAS forms a framework in which the information of different domains is structured semantically and handled together. Therefore, the enrichment of a single use case with other perspectives can be conducted easily. The access via an API is also key for the interaction with AI-based applications. To gain deeper insights, information about the Assets, the manufacturing process or the production plan shall be combined.

Further potentials:

Today, [SMT] are able to describe location and relation information (topology) as well as process data and information about the Asset that is currently produced. By this, a big data ecosystem is evolving over time that supports information sharing. A concept how Assets, Submodels, AAS infrastructure and applications shall be structured and interact efficiently is needed, as well as the associated data ownership and privacy. Deriving [SMT] fitting to specific use cases would lead to data redundancy (also to other established standards like OPC UA companion specifications). To keep the framework efficient and comply with the single source of truth principle is still a challenge for cross-vendor interoperability.

6.2. Evaluation example of the implementation effort – AAS compared to document

To demonstrate the different integration effort when the communication interface description is provided as the AAS [SM] AID instead of a document for each Asset, the

integration example from chapter 3.5 is used again. When implementing the logic to process the [SM] AID, not every data point (D) needs to be configured manually anymore. For this reason, the number of data points (d) has no impact on the configuration effort (c). However, there is an initial effort to integrate the logic behind the [SM] AID. Therefore, to provide a meaningful comparison between [SM] AID and the document-based configuration effort, the initial configuration effort for the [SM] AID implementation has a positive offset of c_0.

The overall configuration effort (c) changes from $c=a*d*u$ (document-based interface description), to $c=a*u+c_0$ (AAS [SM] AID based interface description). This example visualizes that the integration effort rises with a higher number of Assets (a) and user applications (u), but more slowly by using the AAS [SM] AID in comparison to use a document-based interface description. Nevertheless, the break-even in the vertical integration of energy data is depending on the use case specific effort for the implementation. When software vendors start to implement the logic behind the AAS [SM] AID, the offset c_0 is assumed to decrease and the break-even is reached earlier.

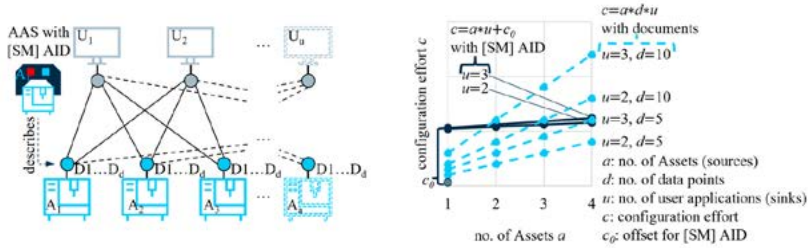

Figure 13: Integration example (left) and configuration effort (right) – providing configuration via [SM] AID (continuous lines) and via documents (dashed lines).

7. SUMMARY

This research addresses the significant manual effort involved in the vertical integration of energy data from diverse industrial Assets, a crucial bottleneck for optimizing economic and ecological performance. We investigate the Asset Administration Shell (AAS) as a framework to standardize and streamline this process. Our methodology involves developing and testing a practical AAS architecture for energy monitoring, focusing on two key tasks: “Store real-time data in a database” and “Read time-series data from a database”. Key findings demonstrate that AAS significantly reduces manual configuration and interpretation efforts by providing machine-readable, vendor-independent interface descriptions and enabling the reuse of code and configuration across different Assets. The AAS framework also facilitates a better understanding of data through structured metadata and contextual information. The main conclusion is that while AAS holds substantial potential to automate energy data integration, its widespread adoption by hardware and software suppliers is essential for scalability. The study also highlights promising future directions, particularly integrating Artificial Intelligence to further enhance configuration and data interpretation within the AAS ecosystem.

8. ACKNOWLEDGEMENT

This work has been funded by the European Union (EU) and supported by the German Federal Ministry for Economic Affairs and Energy (BMWE) in the project Fluid4.0 – Revolutionizing Fluid Engineering: Implementation of digitalization for fluid power 4.0 in the cross-industry and cross-manufacturer data space using asset administration shells, submodels and demonstrators (project number 13IK039L). 10. BIOGRAPHIES

Fabian Geibel received his master's degree in mechanical engineering from RWTH Aachen University in 2019. After working as a research assistant at the Institute of Power Plant Technology, Steam and Gas Turbines in Aachen, he started a graduate program at the Bosch Rexroth AG. His profession is in the field of standardised data exchange and the application of digital twin technologies in industrial use cases.

Dr. Karin Tischler received her Diplom in Mechanical Engineering from the Universität Karlsruhe (TH) in 2002 followed by a Doktorin der Ingenieurwissenschaften from KIT after serving as a Research Assistant in the Department for Measurement and Control Systems. Her foundational work was focussed on information fusion for autonomous driving. Since 2008, she has held various positions at Bosch Rexroth AG, including Project and Group Manager for Innovation and System Application in Mobile Controls. Responsible leader in the central development of systems & solutions she is a recognized expert in system optimization. As Innovation Cluster Owner she drives new business initiatives solving challenges regarding energy transition and digitalization.

System Simulation Meets Asset Administration Shell – Potential and Challenges of Standardized, Model-Based Development of Fluid Power Systems

Abstract.

Dynamic simulation is an established tool in the development of fluid engineering systems. In combination with the Asset Administration Shell (AAS), new potential arises for more efficient, standardized, and automated modeling and parameterization. Using the example of a hydraulic forming press, this article shows how AAS-based data structures accelerate system simulation and improve its quality – and where existing AAS standards still need to be expanded in order to meet the requirements of fluid technology practice.

Keywords: Fluid 4.0, digitalization, asset administration shell (AAS), collaborative engineering, dataspace, sub-models, industry-relevant use cases

1. INTRODUCTION

The *dynamic system simulation method* [1], has established itself as a recognized tool in the development of technical systems. It enables complex physical relationships between individual components and their interactions to be visualized early in the development process – long before prototypes can be built or components procured. This means that digital prototypes are available for testing during the development phase. As a result, functional principles can be evaluated, design decisions can be validated, and potential system problems can be identified at an early stage.

1.1. Significance of dynamic system simulation in fluid technology

Despite its well-known advantages, system simulation has not yet been established as a standard tool in everyday development work in many companies. Instead, it is often used only selectively, for example to analyze specific issues that arise during the commissioning of a plant, but not continuously throughout the entire development process.

1.2. Challenges in practical application

One of the main reasons for the limited use of simulation-based methods is the high barrier to entry when it comes to model creation. In practice, the construction of simulation-capable models still involves considerable manual effort. In particular, the selection of suitable model components, their correct parameterization, and the documentation of relevant assumptions and simplifications require experience, specific domain knowledge, and a considerable amount of time.
These challenges not only affect the efficiency of the simulation process but also make it difficult to trace and reuse models. Decisions made during model creation are often implicit and inadequately documented, which makes it considerably more difficult to reuse or adapt existing models later on.

1.3. Administration shell as an enabler for automated simulation

Against this backdrop, the combination of dynamic simulation and Asset Administration Shell (*AAS*) [2] offers new perspectives for simulation-based development processes. AAS is a central concept of Industry 4.0 and enables the standardized digital description of technical assets throughout their entire life cycle. *Ritz* [3] explains the potential advantages and several norms and standards to be considered for the application of the administration shell throughout the product life cycle for hydraulic systems.
The structured and semantically described provision of information and metadata in machine-readable form allows numerous steps in model creation that were previously performed manually to be automated or at least systematically supported. This not only facilitates the initial model setup, but also improves the consistency, traceability, and reusability of simulation models across different use cases.

1.4. Objective and structure of the article

This article examines the interaction between system simulation and administration shells from a practical perspective. Using the example of simulating a hydraulic forming press, it shows how fluid power drive systems can be converted into a simulation-capable model in a largely automated manner with the help of AAS-based data structures. **Figure 1.1** shows the press in the simulation environment on the left side of the image and the list of administration shell submodels used in the application example on the right side. The legend distinguishes between submodels that have been standardized by the *IDTA* [4] and those that have been newly developed or expanded as part of the *Fluid 4.0* research project [5].
Using a simulation workflow from the *Fluidon Cube* development environment [6], the sequence of transformation steps from the machine's administration shell to the simulation model, its application in the design of the hydraulic system, and the return of results and models to the administration shell are explained.

Figure 1.1. Fluid 4.0 example simulation of a hydraulic forming press

In addition, the article highlights where existing AAS standards are currently reaching their limits and which additional semantic descriptions and submodels are required to comprehensively support simulation-based engineering processes. The concepts developed in the Fluid 4.0 project are intended to provide impetus for the further development of existing AAS standards and contribute to establishing digital system simulation as a universal tool in mechanical and plant engineering.

2. STATE OF THE ART IN THE SIMULATION OF FLUID TECHNOLOGY SYSTEMS

2.1. Starting point: Fluid engineering circuit diagram and system complexity

In practice, a simulation project usually begins with a fluid technology circuit diagram containing all the components required to perform the drive task – often far more components than would be necessary for the actual simulation. One reason for this is that circuit diagrams are also used to generate the parts list. Accordingly, they contain additional components that are required for secondary functions but have no relevant influence on the dynamic behavior of the system.

2.2. Model design and selection of relevant system components

Figure 2.1 shows the typical steps in a simulation project, based on published descriptions [7], [8], [9].
Starting from the problem (see Figure 2.1-1) to be solved by means of simulation, the project engineer first has to ask himself the following question in the design phase (see Figure 2.1-2): Which components are actually relevant for solving the respective problem with the help of simulation?

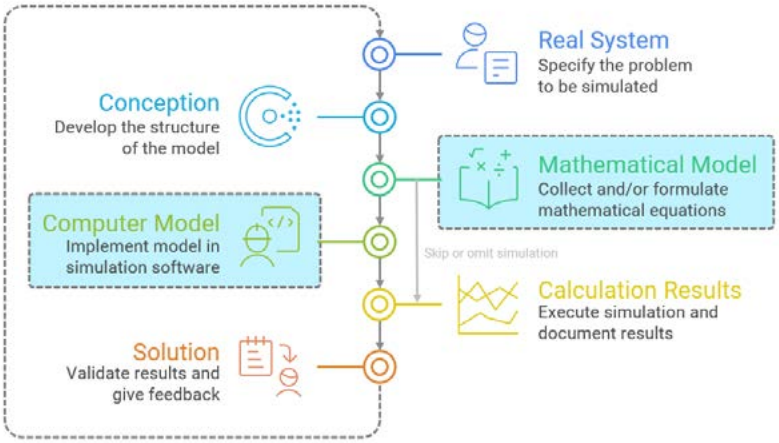

Figure 2.1. Sequence of work steps in a classic simulation process

This selection requires not only a deep understanding of the system but also experience in using the simulation environment and its model libraries and elements. In practice, this often leads to two typical error patterns. Either too many components are taken from the circuit diagram, resulting in unnecessarily large, computationally intensive, and numerically demanding models, or important components are omitted, meaning that crucial physical effects are not represented in the simulation.

2.3. Classic model creation process

Once the model concept has been defined, the classic simulation process begins with the creation of the mathematical model (see Figure 2.1-3) – regardless of whether a simulation will be performed later or not. The underlying equations are also required if the system is to be evaluated manually or with the aid of simple computer-aided design scripts, sometimes in the form of spreadsheets. In the past, the subsequent preparation of the equations for numerical calculation on a computer using a dedicated simulation program (see Figure 2.1-4) presented an almost insurmountable hurdle for many project engineers. As a result, simulations were often not used.

2.4. Modern simulation environments and model libraries

Nowadays, designers no longer have to manually create and code simulation models, as modern simulation environments take care of this task. Their model libraries contain many ready-made component descriptions that represent the dynamic properties of common components. These two process steps are therefore highlighted in color in Figure 2.1.

However, the designer must check whether the required components are available in the model library and whether their mathematical description meets the requirements. There is a high potential for error here, especially for occasional users, as it is usually difficult to choose between similar model types without in-depth background knowledge. Occasional users therefore often carry out additional, time-consuming test simulations to verify the behavior of individual component descriptions before using them in the overall system.

2.5. Parameterization of model components as a critical step

Another time-critical and error-prone step is the parameterization of the model (see Figure 2.1-5). As a rule, the required parameters must be manually researched and transferred from data sheets. For components that are mainly described by their geometry – such as cylinders – this can be done quickly. However, parameterization is much more complex for components with their own dynamics, such as control valves, regulated variable displacement pumps, or pilot-operated pressure valves. In practice, parameters such as step response times or frequency responses are often only available in graphical form. Their use in simulation therefore requires manual interpretation and conversion of the information obtained from diagrams, some of which are logarithmically scaled, into suitable model parameters.
In practice, this regularly leads to a time-consuming search for technical documentation on manufacturer websites and the need for internal consultations and validations using test simulations. However, the problem remains that some parameters and values are not provided by the respective manufacturers.

2.6. Motivation for an AAS-based simulation approach

The steps described above illustrate that, despite powerful simulation tools, the current state of the art in the simulation of fluid technology systems continues to be strongly influenced by manual activities, implicit expert knowledge, and individual decisions made by the project engineer. In particular, the selection of relevant system components, the interpretation of manufacturer information, and the parameterization of complex components are time-consuming and error-prone process steps.
At the same time, much of the information required for this – such as system structure, parts lists, or technical specifications – is available in digital form, but is often not structured consistently, lacks a unique semantic description, or is not linked in a machine-readable form. As a result, the consistent, automated use of this data throughout the entire simulation process has been limited to date. Concepts such as AAS open up new perspectives for data-driven, consistent, collaborative, and reproducible system simulation.
The following chapter shows how administrative shell data can be used to automate key steps in modeling and parameterization and to systematically support the simulation process.

3. SYSTEM SIMULATION REIMAGINED: AAS-BASED

In order to establish dynamic simulation as a standard tool across a wide range of fluid technology development processes, model design, model construction, and subsequent parameterization must be automated to a much greater extent and systematically supported. Only in this way can the full potential of simulation-supported development be exploited – both in early concept phases and in the detailed design and optimization of complex fluid engineering systems, as well as in the later further development of series products and the updating of machines designed in "batch size 1" for special applications.

The AAS-based approach opens up new possibilities here by structurally accessing existing engineering data and making it directly usable for the simulation process. **Figure 3.1** provides an overview of the essential steps in the AAS-based simulation process.

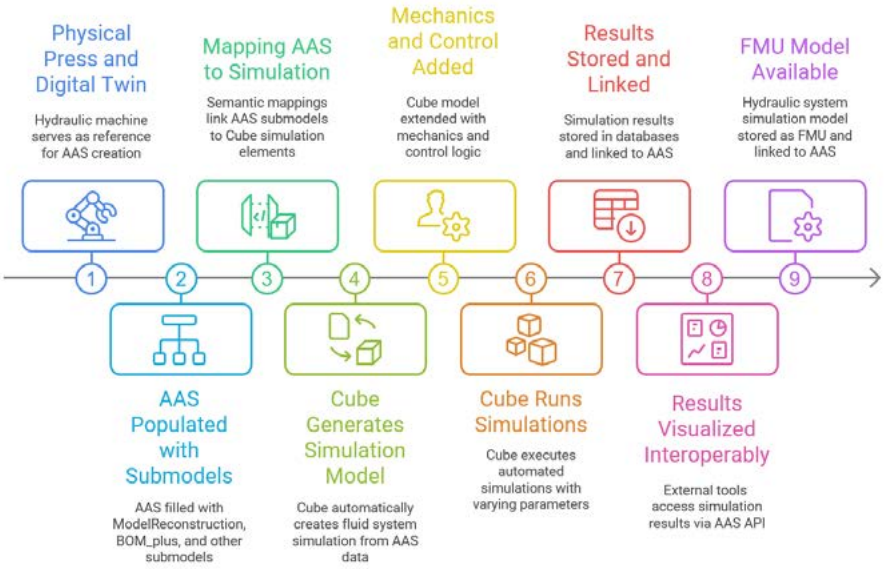

Figure 3.1. Digital Twin Workflow for a Hydraulic Forming Press

3.1. AAS-based system description

The starting point for the AAS-based simulation process here is, for example, the administration shell of a hydraulic forming press (see Figure 3.1-1), which the designer can use to access all relevant submodels. In addition to standardized submodels, the submodels newly developed or expanded in the *Fluid 4.0* project are also used (see Figure 3.1-2). This is necessary because existing IDTA submodels currently only provide incomplete simulation-relevant information.

The *ModelReconstruction* submodel plays a central role within the process. It contains the classification of components standardized in *ECLASS* [10] as well as their interconnection via hydraulic connections, thus defining the underlying system structure. The submodel is also linked to the parts list, which is mapped in the *BOM_plus* submodel. The *BOM_plus* submodel is the extension of the already standardized *BOM* submodel [11] proposed in the *Fluid 4.0* project.

The system structure and parts list for the application example were created using an external project planning tool (see [12]) and then stored in the administration shell of the hydraulic forming press. **Figure 3.2** shows the view of the *BOM_plus* submodel of the administration shell on the AAS repository server of the *Fluid 4.0* research project.

In the *BOM_plus* submodel, all components of the system are referenced to real existing components. The associated administration shells of these components in turn contain the parameters, model information, and settings required for simulation. This ensures that simulation-relevant information is always clearly assigned to a real, physical asset and can be used consistently across different engineering tools.

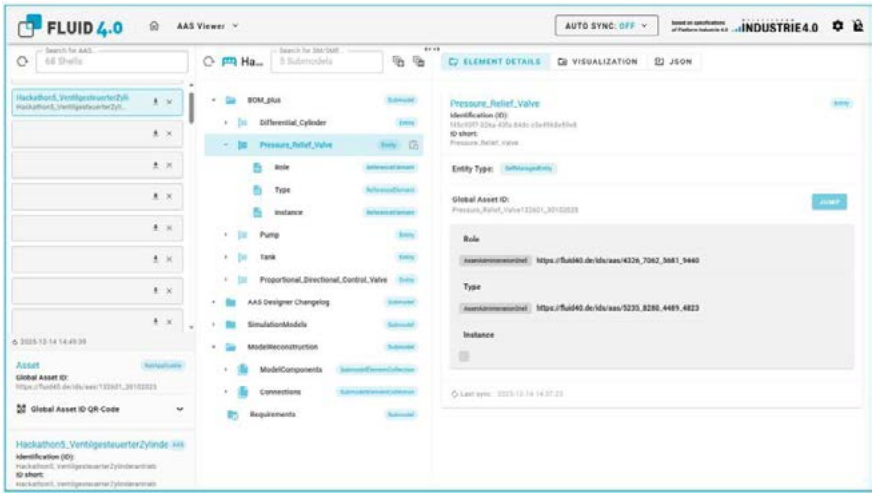

Figure 3.2. Administration shell of the hydraulic forming press

The classification into *role*, *type*, and *instance* describes the respective level of detail of a component in the development process. *Role* refers to an abstract component that merely represents the generic component class assigned in the *ModelReconstruction* submodel, for example, a pump. *Type* concretizes this abstract description to a real existing variant of the component class, for example, a gear, vane, or piston pump, which can be assigned to a specific type in a specific design from a manufacturer. If specific settings are then defined for such a component by the designer, this results in an *Instance* that is later integrated into the administration shell of the specific, real component. This shell is uniquely associated with a real, physical component with a unique serial number.

3.2. Mapping component behavior in the simulation

For each component contained in the system, there are basically two ways to map its fluid technical behavior in the simulation model:

1. **Direct model provision by the manufacturer:** A Functional Mockup Unit (*FMU*) [14] provided by the manufacturer can be loaded via the submodel *ProvisionOfSimulationModel* [13]. This contains an encapsulated mathematical description of the component and its parameterization and enables its use in the simulation – while preserving the manufacturer's know-how.
2. **Parameterization based on technical data:** If no FMU is available, the necessary parameters can be read from the *TechnicalData* submodel [15] and applied to a generic model from the library of the simulation environment used, which maps the real dynamic behavior as accurately as possible.

In the application example, the second option was deliberately chosen in order to demonstrate how flexibly technical component data can be assigned to existing generic mathematical model descriptions. **Figure 3.3** shows the *TechnicalData* submodel of the administration shell of a pump as an example. The parameters *NominalRotationalSpeed*, *Displacement,* and *MaxOperatingPressure,* among others, are relevant for the simulation.

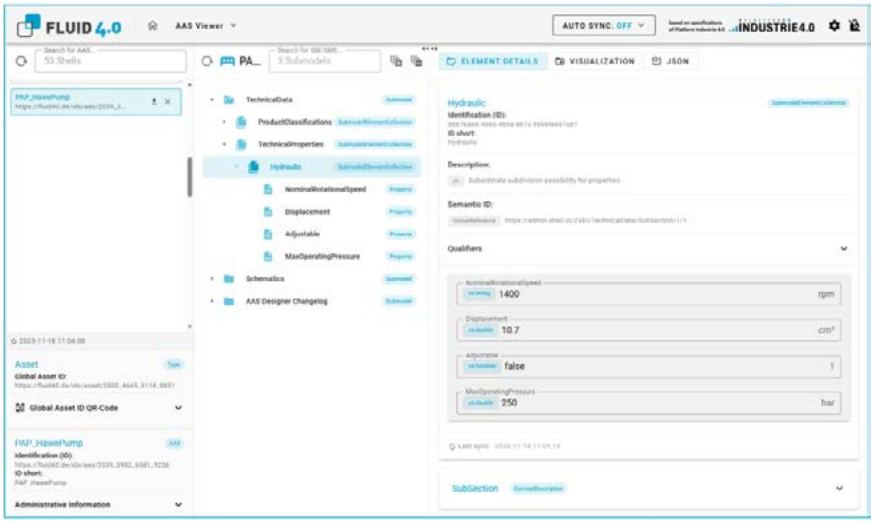

Figure 3.3. TechnicalData submodel of the administration shell of a pump

Access to this information and its further processing in the simulation workflow are explained in more detail in **Figure 3.4**.
First, the administration shell submodel is retrieved from the AAS server, read, and temporarily stored (see Figure 3.4-1). *ComponentName* references the unique component name from *ModelReconstruction*. In addition to name, value, and unit, each entry also contains a *GlobalReference* as an ECLASS-based semantic IRDI [16].

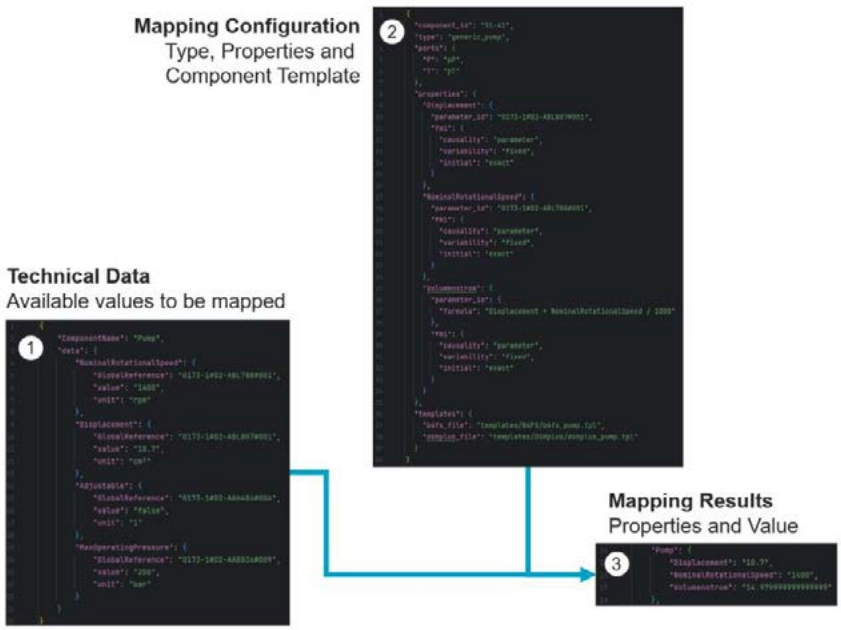

Figure 3.4. Mapping of technical data to the simulation model component

The declarative assignment of a real component type to a component from the simulation environment library is done via a mapping configuration (see Figure 3.4-2). In this configuration, the ECLASS IRDI is assigned to a simulation parameter as *parameter_id*.
Each parameter listed in the *properties* section also contains the semantic information *causality*, *variability,* and *initial*, whose meanings correspond to the definitions in the FMI standard [14].
The *templates* section references possible components of the simulation environment that can mathematically map the real component. The abbreviation *B4FS* refers to components that were developed in the *BaSys4FluidSim* project [17] to integrate component FMUs into the system simulation.

3.3. Formula-based parameter derivation in the mapping process

In the example of the pump, the real component is mapped to the simplest available pump model in the component library, which only provides a constant volume flow. However, the volume flow value required for this is not directly contained in the *TechnicalData* submodel. To enable consistent parameterization nonetheless, the Python-based mapping script allows formula-based derivation of missing parameter values (see Figure 3.4-2, line 27). Assuming that the pump is operated at its nominal speed, the required volume flow for the selected simulation model can be calculated in this way. The calculation rule for this is stored directly in the mapping configuration.
The results of this mapping step are again temporarily stored (see Figure 3.4-3) and transferred to the simulation model in a later process step.
Corresponding mapping configurations were created for all other components of the example system. For components not yet covered, users can independently define comparable mapping templates and integrate them into the workflow. Once created, these are then directly available for automatic model generation.

3.4. Automated model construction in the simulation environment

The actual model construction takes place within the *Cube* simulation environment (see Figure 3.1-4). A workflow script analyzes the structural information from the *ModelReconstruction* submodel, generates a network plan from it, and transfers it to a parameterized simulation model structure.
The entire process – from accessing the AAS repository to the fully parameterized simulation topology – is AAS-supported and requires no manual intervention. The hydraulic part of the simulation model is then immediately available for further analysis.

3.5. Extension to the multidisciplinary simulation model

However, for a meaningful evaluation – for example, in terms of energy efficiency, performance, or cycle times – the hydraulic simulation model must be supplemented with additional control and mechanical components. This extension is carried out manually by the user within the cloud environment (see Figure 3.1-5).
In the future, however, other domains, such as mechanics and control engineering, should also be mappable via corresponding administration shell submodels, so that fully automated multidisciplinary model generation will be possible at a later date.

3.6. Use of the generated model for simulation and optimization

With the completed simulation model (**Figure 3.5**), different simulation scenarios can then be carried out (see Figure 3.1-6). These range from the analysis of individual work cycles to automatic variant comparisons and optimization runs.

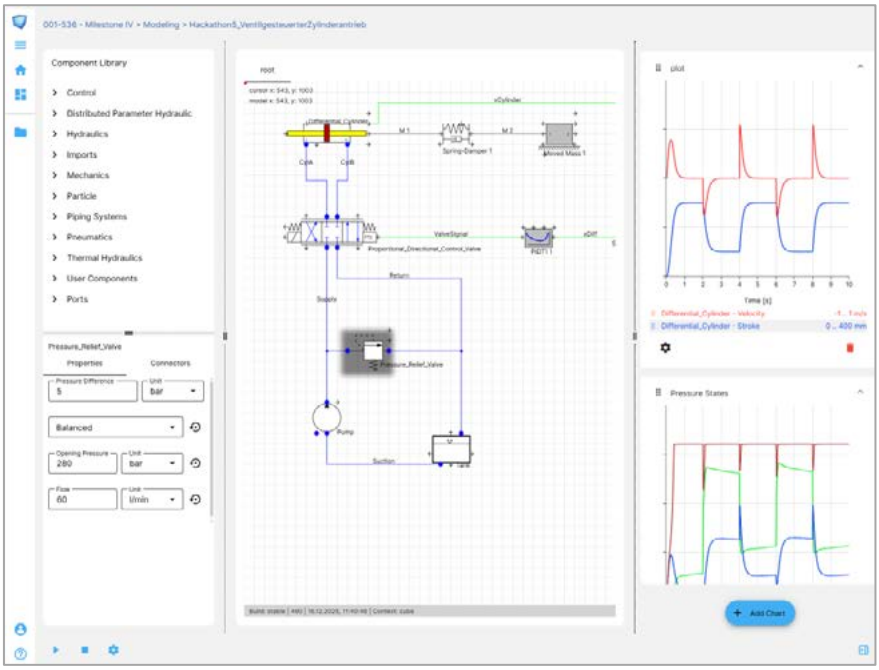

Figure 3.5. Simulation of the cylinder drive of the hydraulic forming press

The goal is to identify a system configuration that achieves the desired behavior while taking all technical constraints into account. At the same time, the simulation model should remain available as a consistently documented digital model in the AAS data ecosystem.

4. FEEDBACK OF RESULTS BACK TO THE ADMINISTRATION SHELL

Following the simulation, the simulation results are automatically checked and evaluated (see Figure 3.1-7).

4.1. Consistency check of the model parameters

A key step in this process is to check whether parameters that originally came from administration shells have been changed by the user. This check is made possible by the additional semantic information stored in the mapping configuration (see Figure 3.4-2). A distinction is made between *fixed product parameters* (e.g., piston diameter of a cylinder) and *freely adjustable settings* (e.g., opening pressure of a pressure valve or preload pressure of a hydraulic accumulator).
If the user changes parameters that are declared as *fixed*, the workflow generates a warning because the parameterization no longer matches the real component designed in *BOM_plus*. In the future – and already tested in a prototype as part of the *Fluid 4.0* research project –

the workflow can support an automated search for a component that matches the changed parameters. If a suitable alternative is found, *BOM_plus* can be updated accordingly so that the simulation and real project planning are consistent with each other again.

4.2. Rule-based verification of the system configuration

Beyond pure consistency checks, the Python scripts integrated into the workflow enable a rule-based evaluation of the system configuration. This checks whether parameter values comply with system-wide constraints and component-specific limits. **Figure 4.1** shows an example of this using the opening pressure of a pressure relief valve.

	ComponentName	MaxOperatingPressure	CrackingPressure
0	Differential_Cylinder	210	
1	Pressure_Relief_Valve	315	280
2	Proportional_Directional_Control_Valve	350	
3	Pump	250	

Figure 4.1. Checking the pressure resistance as a function of the selected system pressure

The opening (cracking) pressure is declared as *a variable* in the mapping configuration and can be set individually for each system by the project engineer in the real system. In the application example, a value of 280 bar was selected. However, a comparison with the maximum permissible pressure of the planned components shows that this value is not permissible for the cylinder and pump (see Figure 4.1).
Such rule-based checks could in principle also be implemented in today's project planning or circuit diagram creation tools, provided that they interact with the administration shell and use its data. In system simulation, however, this approach represents an innovation, as much of the component information required for it is not available in the classic simulation process. It is not necessary for numerical calculation and is therefore usually not represented in conventional simulation models.
In conjunction with dynamic simulation, the improved data available from the administration shell enables more advanced approaches to automated system evaluation. One example is the evaluation of the simulated cylinder speed, which checks whether permissible speed limits – for example, from the administration shells of the installed cylinder seals – are adhered to during the simulated work cycle.
Another example is the detection of critical pressure peaks in the simulated pressure curves, which can occur as a result of rapid reversal processes, for example. Such pressure peaks lead to material fatigue in hose lines or component housing. Based on the analyzed pressure curves, projections can be made regarding the number of critical load cycles in production operation. This information can in turn serve as a basis for condition-based maintenance strategies (predictive maintenance) or for analyses within the scope of the ongoing work on the Fluid 4.0 project on *the smart circular economy for the fluid industry* [18].

4.3. Feedback of results and models into the AAS data ecosystem

Once all tests have been successfully completed, the relevant results are automatically fed back into the administration shells. This includes, among other things:

- **Simulation documentation**, which is stored in the *HandOverDocumentation* submodel [19] and can be viewed by sales or the customer

- **Time series-based simulation results**, which are persisted in a time series database (e.g., *InfluxDB* [20]) and made available for detailed analysis via the *TimeSeriesData* submodel [21]
- **Settings determined in the simulation**, which are transferred to the *OperationalData* submodel developed specifically for this purpose as part of Fluid 4.0 and assigned to the instance AAS of the respective component so that they are available to the project engineer during commissioning
- **The generated simulation model**, which is stored as an FMU [14] on a Nextcloud instance [22] and referenced in the machine's AAS via the *ProvisionOfSimulationModel* submodel [13]. From there, it can be used, for example, for controller development or simulation-based optimizations.

The consistent feedback of all relevant data to the AAS ensures that digital project planning can be seamlessly integrated into downstream engineering processes. Project planning tools can then access the verified system configuration and its parameters to fully detail the plant – including all components required for implementation, such as screw connections, shut-off valves, or safety elements.
The administration shell thus functions as a continuous data hub between simulation, documentation, and actual machine construction.

5. CLASSIFICATION AND OUTLOOK

5.1. Simplification of the simulation process through AAS integration

The AAS-based system simulation presented in this article shows how the classic simulation process described in Chapter 2 can be fundamentally simplified and systematized. Many tool-specific and experience-based work steps that were previously performed manually are removed from the actual simulation process through the use of the administration shell and converted into standardized, interoperable data structures.
Figure 5.1 presents this new AAS-based simulation process, in which the remaining manual steps of the classic simulation process from Figure 2.1 are replaced by the automated steps presented in Chapter 3 and Chapter 4.

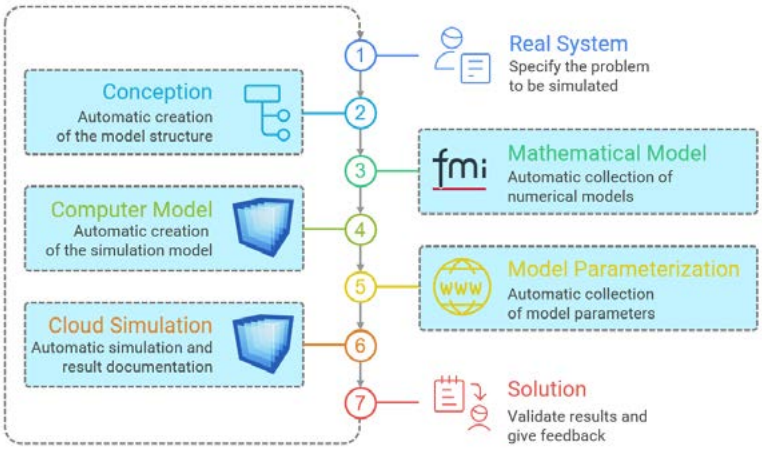

Figure 5.1. Automated simulation process with administration shell interaction

The central element of this simplification is the clear separation between *engineering data management* and *numerical simulation*. Information on the system structure, parts list, technical parameters, and semantic relationships is explicitly stored in the AAS and is available to the simulation workflow in a structured and machine-readable form. This makes model construction and parameterization largely automated and reproducible.
An example from the *Fluid 4.0* project (**Figure 5.2**) quantifies the difference to the classic approach (cf. Figure 2.1): A project engineer was tasked with researching, interpreting, manually reading, verifying component by component through test simulations, and transferring all component information required for the simulation from publicly available manufacturer data sheets based on the circuit diagram and parts list of the existing hydraulic forming press. The time required for this was recorded and forms the basis for comparison with the new AAS-based approach.

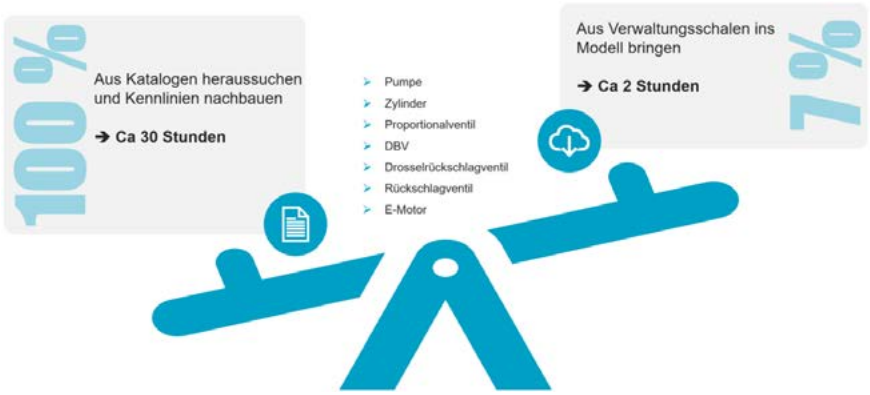

Figure 5.2. Time required for parameterization of components

Thanks to the AAS-based approach, the project engineer was able to begin his actual task – solving the problem or optimizing the system design – almost immediately after communicating the problem with the existing system design.

5.2. Insights gained

The practical implementation of the AAS-based simulation workflow in the *Fluid 4.0* project provides several important insights:

- Firstly, it shows that the combination of administration shell and dynamic system simulation goes far beyond mere automation of model creation. Feeding simulation results, settings, and models back into the AAS creates a consistent digital data space that links simulation, project planning, commissioning, and operation.
- Second, the improved data situation enables rule-based verification of the system configuration, which classic simulation approaches cannot achieve. Limit violations, inconsistent parameterizations, or potentially damaging operating conditions can already be identified and evaluated on the basis of simulated time sequences. This expands the scope of simulation from pure behavior analysis to an integral tool for system validation.
- Third, the AAS-based approach significantly improves the traceability and reusability of simulation-based development work. Decisions, assumptions, and results

are explicitly documented and clearly referable. This facilitates both internal collaboration and the transfer of engineering knowledge to downstream processes or external partners.

5.3. Gap analysis and contribution to standardization

The experience gained during the project reveals the following challenges and areas where action is needed:

- Available AAS submodels reach their limits in their current form and must be expanded in order to consistently map simulation-relevant information. For certain requirements – documentation of the system configuration or storage of plant-specific settings – there are currently no standardized submodels.
- The current AAS data situation for fluid engineering components is still insufficient. Many features relevant to simulation (e.g., efficiency data or characteristic curves) are either not included in current administration shells or are not described in the required granularity. In some cases, suitable semantic keys are missing in existing classification systems.

These gaps were closed in the *Fluid 4.0* project by means of project-specific extensions and newly developed submodels. All identified shortcomings and extensions deemed necessary will be systematically communicated to the IDTA and ECLASS after project completion so that they can be incorporated into future standardization activities. Among other things, the authors are already contributing their findings to the relevant IDTA submodel groups (Automation Engineering) or have already promoted the establishment and management of relevant working groups (Characteristic Curves) as a result of the project.

6. SUMMARY

This article shows how the dynamic system simulation of fluid power drive systems can be rethought and systematically simplified through the consistent use of the Asset Administration Shell. Based on the challenges of classic simulation processes, an AAS-based workflow was presented that integrates model design, parameterization, simulation, and result feedback in a continuous digital process.

Using the example of a hydraulic forming press, it was demonstrated how administration shell data can be used for automated model generation and how simulation results, validated settings, and simulation models themselves can be fed back into the AAS data ecosystem. This creates a consistent digital data space that establishes simulation not as an isolated tool, but as an integral part of modern engineering processes.

The results of the *Fluid 4.0* project highlight both the considerable potential of AAS-based system simulation and the need for further development of current standards. The insights gained and prototypical enhancements provide concrete impetus for standardization and contribute to establishing simulation-supported development as an integrated tool in mechanical and plant engineering.

7. ACKNOWLEDGEMENT

This work has been funded by the European Union (EU) and supported by the German Federal Ministry for Economic Affairs and Energy (BMWE) in the Fluid4.0 project – Revolutionizing Fluid Engineering: Implementation of digitalization for fluid power 4.0 in the cross-industry and cross-manufacturer data space using asset administration shells, submodels, and demonstrators (project numbers 13IK039E, 13IK039J, and 13IK039L). Biographies

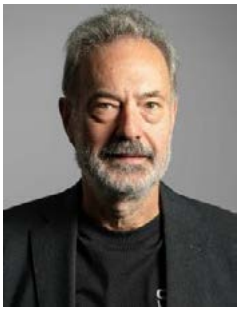
Heiko Baum studied mechanical engineering at RWTH Aachen University and completed his doctorate in 2001. Since 2001, he has been the managing director of FLUIDON GmbH, where he focuses on model-based engineering, digital twins, and automated simulation workflows for hydraulic and pneumatic systems. His long-standing experience in the simulation and development of fluid power systems bridges industrial applications and research projects in the context of Industry 4.0 and the Asset Administration Shell.



Micha Koebele received his M.Sc. degree from RWTH Aachen University in 2021. Since 2024, he has been working at FLUIDON GmbH as a development engineer, focusing on dynamic system simulation, model-based engineering, and automated simulation workflows for hydraulic and pneumatic systems. His work particularly addresses the integration of simulation models with digital twin concepts and Asset Administration Shell–based data structures in the context of Industry 4.0.

Denis Ritz completed his mechanical engineering studies at TU Dresden in 2018 and is currently a research assistant at the Chair of Fluid Mechatronic Systems at TU Dresden. His

research at centers on control strategies and the development of mobile hydraulic drive systems, with a strong emphasis on systems engineering. Prior to his academic studies, he completed vocational training as a farmer, providing him with practical insights into mobile machinery.

Jürgen Weber studied mechanical engineering at TU Dresden and successfully completed his doctorate in 1991. Until 1997, he was the active senior engineer at the former chair of Hydraulics and Pneumatics. This was followed by an approximately 13-year industrial phase. He was active in various positions in the R&D department of the agricultural and construction machinery manufacturer CNH. Effective March 1, 2010, Dr.-Ing. Jürgen Weber was appointed university professor and chair of Fluid-Mechatronic Systems (Fluidtronics) at TU Dresden. Since July 2018, he has been the head of the Institute of Mechatronic Engineering. He is also one of the founders and managing director of Construction Future Lab gGmbH.

Heiko Röcher is the managing director of Röcher GmbH & Co. KG, a family-owned company specializing in hydraulic presses and custom forming machinery. He combines engineering expertise with entrepreneurial leadership and is responsible for the strategic and operational development of the company, focusing on high-performance hydraulic press systems and customer-specific machine solutions.

Unlocking Semantic Interoperability in Industry with Large Language Models

Barkha Sharma, Malte Becker, Constantin Meier, Katharina Schmitz

RWTH Aachen University, Institute for Fluid Power Drives and Systems (ifas), Campus-Boulevard 30, 52074 Aachen, Germany

Abstract.

The digitalization of industrial processes within Industry 4.0 depends on the reuse of technical product data across systems, organizations, and lifecycle stages. In practice, the main challenge is not often the availability of data, but their heterogeneity, which prevents automated interpretation and semantic interoperability. This paper presents an automated pipeline for incrementally transforming existing heterogeneous technical data into interoperable representations. The approach builds on available industrial data and combines Large Language Models, retrieval-augmented generation, and the Asset Administration Shell to align manufacturer-specific descriptions with standardized vocabularies such as ECLASS. Using fluid power datasheets as an exemplary data source, the pipeline is introduced to demonstrate how heterogeneous engineering data can be made interoperable. The focus is on the pipeline concept itself, which aims to reduce manual mapping effort and support a gradual transition toward Industry 4.0-compliant digital engineering environments, rather than on the processing of datasheets. While demonstrated in the fluid power domain, the approach is transferable to other technical domains facing similar data heterogeneity challenges.

Keywords. Semantic Interoperability, Asset Administration Shell, ECLASS, Large Language Models, Retrieval-Augmented Generation, Digital Twin, Industry 4.0

1. INTRODUCTION

The ongoing digitalization of industrial processes has led to a steadily increasing availability of technical product data. In industrial practice, however, the fundamental challenge not the lack of data, but their significant heterogeneity. Technical data already exists in large volumes, yet it is described, structured, and maintained differently across departments, IT systems, and organizations. As a result, data cannot be automatically interpreted or reused, as a shared semantic basis is missing. Within the context of Industry 4.0, this lack of semantic interoperability limits the integration of technical product data into digital twins, automated engineering workflows, and cross-company data exchange [1].

Within companies, technical product data are typically distributed across ERP systems, PLM systems, engineering tools, spreadsheets, and document-based formats. Different departments often describe identical technical properties using varying terms, units, or levels of detail. Across organizational boundaries, this heterogeneity increases further due to

All Open Access articles are peer-reviewed, distributed under the Creative Commons Attribution-Non Commercial 4.0 International

manufacturer-specific conventions and documentation practices. Although the underlying physical properties are equivalent, digital systems are unable to recognize these relationships [2]. Consequently, engineers are required to manually interpret, compare, and harmonize data, which leads to significant effort, introduces errors, and does not scale with increasing data volumes.

This challenge is particularly evident in the fluid power domain. Technical characteristics such as nominal pressure, maximum operating pressure, or flow rate are described inconsistently by manufacturers and even within individual organizations. For example, the maximum pressure of a hydraulic motor may be specified “maximum pressure”, “maximum operating pressure”, “p_max”, “peak pressure”, or “pressure limit”. While these descriptions refer to the same physical quantity, their semantic equivalence cannot be derived automatically. This lack of semantic interoperability significantly complicates the integration of fluid power components into digital engineering workflows, digital twins, and Industry 4.0 environments [3].

Standardized concepts such as the Asset Administration Shell (AAS) and semantic dictionary like ECLASS define suitable target structures for interoperable technical data. In practice, however, the transformation of existing heterogeneous data into these standardized representations remains largely manual. Industrial organizations cannot replace their existing data sources or enforce new data models across all systems. Instead, approaches are required that build on available data and enable a gradual transition toward semantic interoperability [4], [5], [6]. At the same time, recent advances in artificial intelligence, particularly Large Language Models (LLMs), have demonstrated the ability to capture semantic relationships within heterogeneous and partially unstructured data [7]. These capabilities provide new opportunities to support the semantic alignment of technical data without requiring fundamental changes to existing data sources [8], [9].

Against this background, this paper presents an automated pipeline that acts as an enabler for semantic interoperability. The proposed approach deliberately starts from existing technical data and allows organizations to retain their current data formats and structures. Using fluid power datasheets as a practical entry point, the pipeline combines LLMs, Retrieval-Augmented Generation (RAG) [10], and the AAS to incrementally align manufacturer-specific descriptions with standardized vocabularies such as ECLASS. In doing so, existing technical data can be progressively transformed into interoperable representations that support further digitalization efforts. While the approach is demonstrated in the fluid power domain, it is not limited to this field and can be transferred to other technical domains facing similar challenges related to heterogeneous product data.

The remainder of this paper is structured as follows: Chapter 2 discusses the theoretical foundations of the work. Chapter 3 reviews the state of the art and outlines the motivation for this work. Chapter 4 details the proposed methodology and implementation variants. Chapter 5 presents and discusses the evaluation results. Finally, Chapter 6 summarizes the findings and provides an outlook on future research directions.

2. THEORETICAL BACKGROUND

Achieving semantic interoperability is essential for digital manufacturing systems, allowing consistent data exchange and interpretation across heterogeneous environments. This

chapter introduces the theoretical foundations and core principles that form the basis of the proposed approach.

2.1. Interoperability

Interoperability is a key prerequisite for integrating heterogeneous systems in industrial and digital environments, enabling machines, software, and organizations to exchange data and effectively use the transferred information. In the context of Industry 4.0, interoperability supports collaboration across technical, organizational, and domain boundaries and forms the foundation of data-driven manufacturing [3].

As illustrated in Figure 1, interoperability can be understood as a layered concept in which higher-level coordination depends on capabilities provided by underlying layers.

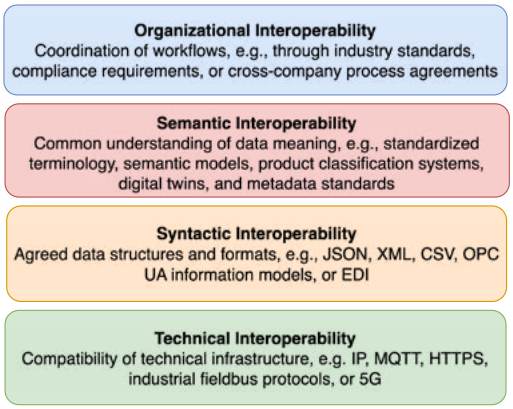


Figure 1. Levels of Interoperability [11]

At the organizational level, interoperability enables coordinated business processes and workflows across company boundaries. This coordination relies on semantic interoperability, which ensures that exchanged data conveys a consistent meaning across heterogeneous systems through shared vocabularies and semantic models [11].

The lower levels, namely technical and syntactic interoperability, provide the prerequisites for connectivity and structured data exchange but do not ensure a shared interpretation of information [11]. Consequently, semantic interoperability represents the critical transition from mere data exchange to meaningful information integration. This work therefore focuses on the semantic layer and explores how LLMs can support semantic alignment between unstructured technical data and standardized vocabularies.

2.2. Asset Administration Shell

The AAS is a core concept of Industry 4.0 that provides a standardized digital representation of physical or virtual assets. It acts as an interface between the physical and digital worlds, enabling interoperable management and exchange of asset-related data across the lifecycle. Within the Reference Architecture Model Industry 4.0 (RAMI 4.0) [12], the AAS constitutes the technical basis for digital twins. Its internal structure is defined by a formal metamodel specified by the International Digital Twin Association (IDTA) [4].

As illustrated in Figure 2, an AAS consists of one or more Submodels (SMs), each describing a specific aspect of an asset. Submodels are composed of SubmodelElements (SMEs), which represent individual data points or relationships. Core SME types include Properties, Files, ReferenceElements, and Ranges, which may be grouped using SubmodelElementCollections to represent complex structures. This hierarchical organization supports modular and scalable modeling of assets, ranging from individual components to complete systems [13], [14]y

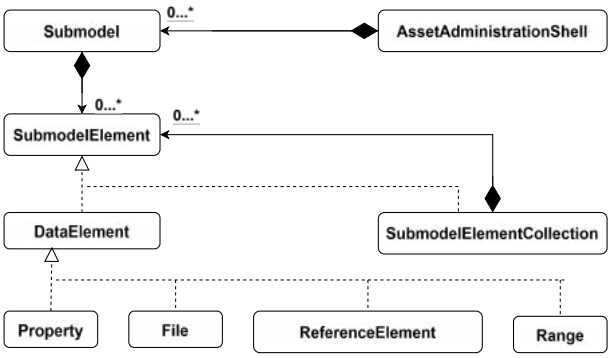

Figure 2. AAS hierarchy according to [5]

Depending on their functionality, AAS implementations can be categorized into three types:

- **Type 1 - Passive AAS:** Provides static information for documentation purposes.
- **Type 2 – Active AAS:** Enables automated data exchange via standardized interfaces.
- **Type 3 – Interactive AAS:** Supports bidirectional communication and autonomous behavior, effectively realizing a digital twin.

With increasing AAS maturity, both the volume and dynamics of exchanged data grow significantly. Consequently, consistent naming conventions and standardized semantic identifiers become essential to ensure reliable interoperability across tools and organizational boundaries, a requirement that is already becoming evident in fluid power research and industrial applications [15].

2.3. ECLASS Semantic Dictionary

Semantic interoperability requires a shared understanding of technical information across systems and organizations. A widely adopted approach to achieve this is ECLASS, a standardized framework for the classification and description of products and services. ECLASS provides language-independent, machine-readable representations of technical and commercial data, ensuring consistent interpretation across heterogeneous systems [15].

As illustrated in Figure 3, ECLASS organizes product information within a hierarchical classification structure, ranging from general product groups to specific classes, such as axial piston motors in the fluid power domain. Each class is associated with standardized properties and identified by International Registration Data Identifiers (IRDIs), enabling persistent and uniquely identifiable referencing of products, characteristics, and values across systems.

This structure supports interoperable and reusable data for applications such as digital twins, automated engineering, and cross-enterprise workflows.

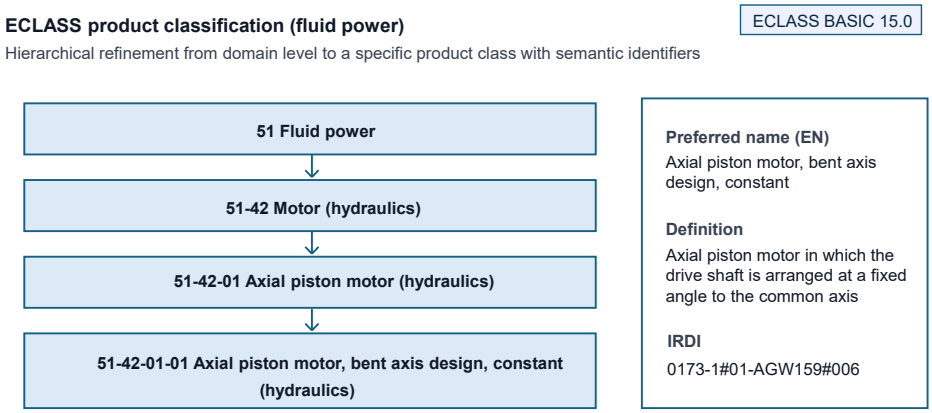

Figure 3. Example of hierarchical structure within the ECLASS classification [15]

Compared to conceptual standards such as IEC 61360 [16], which define general principles of data modelling, ECLASS provides a practical, domain-specific implementation that operationalizes these concepts for industrial use. Owing to its maturity and established adoption in domains such as fluid power, ECLASS serves as the semantic backbone for the semantic mapping approach presented in this work, particularly in the context of AAS. Further details on the internal ECLASS data model are outside the scope of this paper and are documented in the official ECLASS specifications [15].

2.4. Large Language Models

LLMs are based on the transformer architecture, which was introduced by Vaswani et al. [17]. The core element of this technology is the self-attention mechanism, in which each word is related to all other words in a text. As a result, it is possible to identify not only long dependencies but also complex semantic relationships [8], [10].

The development of LLMs is characterized by various fundamental learning approaches [18]:

- **Supervised learning:** Learning from labelled examples (e.g., a sentence is annotated with a category).
- **Unsupervised learning:** Learning from unstructured data without labels, only through pattern recognition.
- **Self-supervised learning:** The model generates the learning tasks itself, for example by predicting the next word or filling in missing text passages.

The development of LLMs typically follows three consecutive learning stages. First, during pretraining, the model learns general linguistic structures and statistical patterns from large volumes of text data using self-supervised objectives such as next-token prediction. Second, in the fine-tuning stage, the pretrained model is adapted to specific domains or tasks through supervised learning with curated datasets. Finally, in the alignment stage, instruction tuning or reinforcement learning from human feedback (RLHF) is applied to optimize the model's

responses for usefulness, safety, and factual accuracy. Together, these stages enable LLMs to combine broad language understanding with domain-specific reasoning capabilities [7], [9].

Although LLMs develop a broad understanding of language, they remain limited in two respects: Firstly, their knowledge is frozen at the level of the training data, and secondly, they may hallucinate information when context is insufficient. This is particularly problematic in industrial scenarios, such as when assigning technical data to standards, where precision and timeliness are crucial.

2.5. Retrieval-Augmented Generation

RAG is used to overcome these limitations. It extends a LLM with an external knowledge source that is consulted for every query, ensuring access to up-to-date and verifiable information. The RAG process follows three sequential steps [2], [19]:

1. **Retrieval:** In the first step, the user query is converted into a vector representation. This vector is compared against a knowledge base, such as technical documentation, standards, or AAS data sheets, to identify the most semantically similar text passages [19].
2. **Augmentation:** In the second step, the retrieved document excerpts are provided to the LLM as additional context. This augmented input serves as a factual reference for the model, anchoring its subsequent reasoning [19].
3. **Generation:** In the final step, the LLM produces an answer by combining its internal language knowledge with the externally retrieved information [19].

In this way, RAG combines two strengths: the language processing and generalization capabilities of LLMs with the timeliness and traceability of external knowledge sources. Transparency is particularly important in an industrial context as RAG allows answers to be provided with source references, which facilitates verification.

3. RELATED WORK

Achieving semantic interoperability remains a central challenge for realizing the Industry 4.0 vision. Reference architectures such as RAMI 4.0 and concepts like the AAS establish structured frameworks for linking physical assets with their digital representations. While these frameworks define harmonized data models and interfaces, the transformation of manufacturer-specific documentation into standardized vocabularies such as ECLASS or IEC remains largely manual in practice [12], [15]

In the fluid power domain, this challenge is particularly pronounced due to the high number of suppliers and the strong reliance on manufacturer-specific documentation practices. Hydraulic and pneumatic components are described using diverse terminologies, parameter definitions, and documentation formats. Although standards such as ISO 18582 and ECLASS define structured property sets for pumps, valves, and actuators, their consistent application across vendors is limited. As a result, semantic inconsistencies persist, hindering automated data integration, digital twin creation, and cross-company data exchange, which are key objectives of Industry 4.0 [20].

Recent research has explored the use of artificial intelligence to reduce manual effort in semantic mapping and interoperability tasks. LLMs, often combined with RAG, have

demonstrated the ability to extract, interpret, and structure data from unstructured technical documents [21], [22]. Xia et al. proposed an LLM-based approach for generating AAS from unstructured asset descriptions, showing that technical attributes can be identified and standardized with reduced manual intervention [14]. De Bellis investigated how semantic relations are encoded within LLM representations and how these can support ontology alignment tasks [23]. Wang et al. introduced Unify, a system for deriving structured semantics from heterogeneous industrial documents using LLMs [24]. In infrastructure engineering, Hoeltgen et al. demonstrated the enrichment of technical condition data through LLM-based semantic processing, illustrating the applicability of these methods beyond manufacturing domains [8].

In parallel, research on knowledge graphs and linked data emphasizes structured semantic representations as a foundation for interoperability across engineering systems [11]. While these approaches provide robust mechanisms for representing standardized relationships, they typically rely on manually curated data and predefined schemas, limiting their scalability and adaptability to heterogeneous legacy documentation.

Despite these advances, most existing approaches remain largely domain-agnostic and do not sufficiently address the specific terminology, parameter sensitivity, and contextual dependencies inherent to fluid power systems. Given the domain's reliance on precise physical parameters and cross-vendor component integration, automated semantic alignment tailored to fluid power documentation remains underexplored.

This work addresses this gap by proposing a domain-specific methodology that builds on existing heterogeneous technical data and supports their gradual transformation toward semantic interoperability. By combining retrieval-based context, LLM-supported reasoning, and established standards such as ECLASS and the AAS, the approach enables manufacturers and system integrators to retain their current data sources while systematically aligning fluid power documentation with standardized semantic models. In doing so, the methodology reduces manual mapping effort and supports digital twin creation and lifecycle-oriented data integration in accordance with Industry 4.0 principles.

4. METHODOLOGY AND RESULTS

This chapter introduces the proposed workflow for achieving semantic interoperability between unstructured industrial datasheets and standardized digital representations. The methodology is executed in parallel for a cloud-based and a fully local pipeline, both following the same processing stages and differing only in the execution environment.

The pipeline was implemented in Python due to its extensive ecosystem for document parsing, vector computation, and model integration. Its modular design supports flexible deployment in scalable cloud environments as well as local setups where data confidentiality is required. Figure 4 summarizes the shared workflow, consisting of five main stages described in the following subsections.

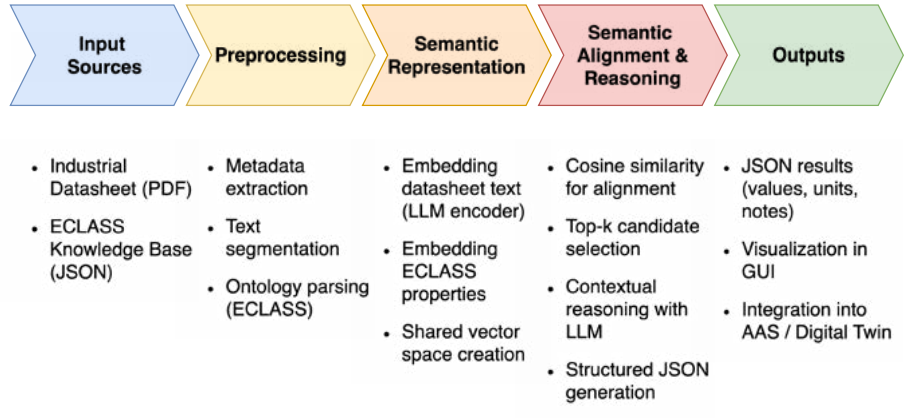

Figure 4. Workflow for achieving semantic interoperability

4.1. Input Sources

The workflow integrates two complementary data sources:

- **Technical datasheets (PDF):** These documents contain manufacturer-specific data on hydraulic and pneumatic products, such as nominal pressure or flow rate, but differ strongly in terminology, and structure. This heterogeneity makes automated processing difficult and motivates the need for a domain-independent mapping method.
- **ECLASS semantic knowledge base (JSON):** Using ECLASS ensures that the extracted data can be semantically aligned with established industrial standards and reused across systems, e.g., in AAS Submodels.

Integrating both sources forms the foundation for semantic interoperability. The datasheet delivers real-world technical content, while ECLASS defines the target semantic schema that standardizes its meaning.

4.2. Preprocessing

The preprocessing stage converts both the unstructured datasheets and the structured ECLASS ontology into machine-readable form. The workflow begins with data acquisition, where technical datasheets, usually PDF files containing textual descriptions, tables, and diagrams, are processed page by page. Text and metadata such as document titles or product identifiers are extracted using the Python library pdfplumber.

In the cloud-based setup, the same operation is performed through LangChain's PyPDFLoader, which supports API-driven processing. All extracted content is saved in JSON format, ensuring that each segment can be traced back to its original page and reused in later stages without reprocessing.

In parallel, the ECLASS ontology is loaded as a JSON file, providing the hierarchical structure of classes and standardized property definitions that serve as the reference vocabulary for later semantic alignment. Following extraction, the textual data undergoes normalization to correct common formatting issues in industrial PDFs, such as broken lines, hyphenations,

and layout artifacts. The cleaned text is then divided into overlapping sections using LangChain's RecursiveCharacterTextSplitter.

Unlike rule-based segmentation by headings or tables, this character-based approach is robust to inconsistent layouts and ensures that related data, such as a parameter and its corresponding unit, remains within a single segment. By the end of this stage, both sources are harmonized and structured, providing a consistent foundation for the embedding and semantic mapping steps.

4.3. Semantic Representation

In the third stage, the workflow converts textual and structured data into numerical vector representations, known as embeddings. This step allows semantic comparison between expressions even when they differ linguistically.

Each text segment t_i from the datasheet and each property s_j from ECLASS is mapped into an n-dimensional vector space through the embedding function:

$$E_T: T \to \mathbb{R}^n, E_S: S \to \mathbb{R}^n$$

where $E_T$and $E_S$represent the encoder functions for the datasheet and the semantic model, respectively.

Two embedding methods were implemented: The cloud-based pipeline employs the OpenAI model "text-embedding-3-large", which offers high semantic precision and context sensitivity. The local variant uses the Sentence Transformers library, specifically the model "all-mpnet-base-v2", which generates 768-dimensional embeddings and runs entirely offline. Both approaches use cosine similarity as their underlying measure of semantic proximity. Embeddings were selected over keyword-based methods because they capture conceptual meaning rather than literal matching. This enables the system to identify equivalent terms such as "pmax", "maximum pressure", and "max. operating pressure", even when phrased differently across manufacturers.

4.4. Semantic Alignment and Reasoning

In this stage, the embedded datasheet segments and ECLASS properties are compared within the shared vector space to identify semantic correspondences.
The similarity between a text segment $t_i$and an ECLASS property $s_j$is computed using the cosine similarity:

$$\text{sim}(a, b) = \frac{a \cdot b}{\| a \| \| b \|}$$

where $a = E_T(t_i)$ is the embedding vector of the text segment, and $b = E_S(s_j)$ is the embedding vector of the standardized property.
A higher value of $\text{sim}(a, b)$indicates a stronger semantic relation between both expressions. For each property, the top-k most similar text segments (typically $k = 3$-5) are selected as candidates for interpretation. Cosine similarity was chosen because it is scale-invariant and well suited for comparing high-dimensional sentence embeddings, providing more robust matches than keyword-based methods. The selected text segments are then processed by a LLM to extract structured data such as values, units, and contextual notes. This reasoning

step converts semantically aligned evidence into standardized outputs. In the cloud-based setup, reasoning is performed by OpenAI's gpt-4o-mini, while the local variant uses Meta-Llama-3-8B-Instruct with quantization for efficiency. Prompts follow a fixed JSON schema, ensuring syntactic consistency and easy post-processing. Together, the embedding and reasoning stages combine semantic precision with contextual understanding, enabling accurate and verifiable mappings between unstructured datasheets and standardized interoperability models.

4.5. Output

The workflow produces structured, machine-readable outputs that capture both the extracted data and its traceability. All results are stored as JSON files, each entry containing the standardized property, extracted value, physical unit, contextual notes, and a link to the corresponding page in the original datasheet. This design ensures that every mapping remains verifiable and can be reused for further processing.

4.6. Case Study

To evaluate the proposed framework, a case study was conducted using several publicly available datasheets from the fluid power domain. The documents originate from different manufacturers and describe hydraulic components using heterogeneous terminologies and specification formats. All datasheets were processed using the workflow described in Sections 4.1- 4.5. While multiple datasheets were used to assess general robustness, the quantitative evaluation focuses on one representative reference datasheet for which a fully manually curated ground truth mapping to ECLASS properties was available. This reference document comprises 114 technical features and enables a transparent and reproducible assessment of mapping quality.

Table 1 presents correctly mapped examples extracted from this reference datasheet, illustrating successful semantic alignment of heterogeneous fluid power specifications, where the data extraction and mapping were performed using an OpenAI-based variant (gpt-4o-mini).

Extracted Feature	**Assigned ECLASS Feature**	**ECLASS ID**	**Similarity Score**
Maximum operating pressure: 250 bar	Maximum operating pressure	0173-1#02-BAF016#005	0.90

Table 1. Selected examples illustrating correct semantic alignment of heterogeneous fluid power datasheet descriptions with standardized ECLASS properties.

During preprocessing, textual content was extracted and normalized. Semantic embeddings were generated and compared with ECLASS feature embeddings using cosine similarity, and selected candidates were structured into feature–value representations by the reasoning

stage. A qualitative comparison with the expert reference confirmed that most mappings were technically plausible.

In addition to the qualitative assessment, the similarity scores obtained during the retrieval stage were analyzed in relation to the manually curated ground truth. Across all 114 mapped features, the average cosine similarity was 0.72. It was observed that correctly mapped features generally exhibited higher similarity values, while incorrect mappings occurred predominantly at lower similarity levels. Mappings with similarity scores above approximately 0.85 were found to correspond almost exclusively to correct semantic alignments with the expert reference. This value was not predefined as a hard decision threshold but emerged empirically from the evaluation as a high-confidence region, indicating stable semantic correspondence between heterogeneous datasheet descriptions and standardized ECLASS properties.

Despite the overall high mapping quality, mismatches and omissions were observed in specific cases. These can be attributed to the following factors:

- **Complexity of data extraction from industrial datasheets:** Fluid power datasheets often contain complex layouts, diagrams, characteristic curves, and hydraulic schematics that are not reliably captured by text-based extraction. Relevant features may therefore be partially extracted or missed before semantic mapping.

- **Variability in LLM reasoning performance:** Closely related technical concepts may be misinterpreted when contextual data is weak. A recurring example observed during evaluation is the confusion between nominal pressure and maximum operating pressure. Such cases were identified during qualitative comparison with the reference mapping and are not reflected in the correctly mapped examples shown in Table 1.

Overall, the case study demonstrates that automated semantic alignment of heterogeneous fluid power datasheets is feasible using the proposed workflow, while highlighting data extraction and reasoning robustness as key areas for further improvement.

5. DISCUSSION

This chapter discusses the main outcomes of the proposed approach, emphasizing its advantages, limitations, and validation perspective in the context of industrial data interoperability.

5.1. Advantages

The proposed workflow demonstrates that semantic data alignment in industrial domains can be automated largely without sacrificing interpretability. By embedding both datasheet content and ECLASS descriptors into a shared semantic space, the system can automatically recognize and assign technical data such as pressure, flow rate, or mounting type to standardized properties. This capability replaces a traditionally manual, time-intensive process with a consistent and reproducible mapping strategy. As a result, human involvement shifts from repetitive data entry to higher-level validation and quality assurance, which substantially increases efficiency and reduces the likelihood of human error.

Another notable strength lies in the method's scalability and robustness. Because the matching process operates on semantic similarity rather than keyword overlap, it generalizes well across heterogeneous datasheet formats, varying manufacturer terminology, and even multilingual documentation. The integration of ECLASS as a reference ontology ensures that the resulting data is compatible with AAS and digital twin implementations, thereby supporting interoperable data exchange across different systems and organizations.

Equally important is the flexible system architecture, which supports both cloud-based and local execution. The OpenAI-based configuration provides high inference speed and strong contextual understanding, making it suitable for rapid prototyping or large-scale processing. In contrast, the local pipeline based on Meta-Llama-3-8B-Instruct enables confidential, fully offline deployment, which is essential in regulated or security-critical industrial settings. Together, these two configurations demonstrate the approach's adaptability to different operational environments and data governance requirements.

5.2. Challenges

Despite the advantages of the proposed workflow, several challenges remain that affect its reliability. The most critical limitation is not the semantic mapping with LLMs itself, but the extraction of technical data from industrial datasheets. In practice, datasheets often contain complex layouts, scanned content, diagrams, characteristic curves, and hydraulic schematics that convey essential data but are not directly accessible through text-based extraction methods. As a result, relevant data may be partially extracted or missed entirely, which directly impacts all downstream processing steps.

Although preprocessing techniques such as OCR, normalization, and recursive text segmentation alleviate some of these issues, non-textual and weakly structured content remains a major source of errors. Improving document understanding at this stage therefore represents a key prerequisite before further improvements through larger or more advanced reasoning models can be expected.

Beyond data extraction, interpretive behaviour of LLMs constitutes an additional challenge. While larger, higher-parameter models generally improve contextual understanding and reasoning stability, they do not fully eliminate misinterpretations when technical descriptions are ambiguous. Moreover, increased model size introduces trade-offs in inference latency, computational cost, and deployment feasibility, particularly for fully local industrial deployments.

Finally, limitations in the coverage of existing interoperability schemas such as ECLASS can lead to unmapped attributes when manufacturer-specific or highly specialized parameters are encountered, highlighting the need for flexible hybrid approaches and future schema extensions.

5.3. Comparison and Validation Perspective

When compared to traditional manual annotation, the proposed workflow improves scalability and reduces processing effort. While manual mapping can achieve high precision for small datasets, it does not scale to large component portfolios or frequently updated documentation. The presented approach enables automated mappings that can be reviewed by domain experts in a human-in-the-loop setup, providing a practical balance between automation, reliability, and reduced manual effort.

Two deployment variants were evaluated: a cloud-based implementation using the OpenAI model gpt-4o-mini and a fully local open-source implementation based on Meta-Llama-3-8B-Instruct. The quantitative evaluation focuses on one representative reference datasheet with a complete manually curated ground truth comprising 114 technical features. Table 2 summarizes the quantitative comparison of both variants, including feature coverage, semantic similarity, inference time, and deployment-related aspects relevant for industrial application.

Criterion	OpenAI-based Variant (gpt-4o-mini)	Local Open-Source Variant (Meta-Llama-3-8B-Instruct)
Evaluated datasheet	1 reference datasheet	1 reference datasheet
Mapped features	114/114	114/114
Inference time per attribute	2.95s	5-10s
Total inference time per datasheet	5min 36s	10-19 min
Average Semantic Similarity	0.72	0.66-0.69
Data sovereignty	Requires external data exchange	Fully offline and confidential
Scalability	Easily scalable via cloud deployment	Limited by on-premise capacity

Table 2. Quantitative comparison of cloud-based and local deployment variants. Inference times reflect end-to-end execution and depend on deployment constraints.

Both deployment variants successfully mapped all 114 features contained in the reference datasheet. Mapping quality was assessed using three metrics. First, feature coverage was measured as the number of successfully detected and mapped features, resulting in full coverage for both variants. Second, semantic similarity was evaluated using cosine similarity during the retrieval stage. The cloud-based implementation achieved an average similarity score of 0.72, while the local implementation achieved values between 0.66 and 0.69. The observed differences in average semantic similarity between the cloud-based and local deployment variants are primarily caused by differences in the employed embedding models and execution configurations. The cloud-based variant utilizes higher-capacity embedding models with greater contextual sensitivity, while the local variant relies on smaller, quantized models optimized for offline execution. This results in slightly lower average similarity scores without fundamentally affecting mapping correctness for well-defined features.

Third, all generated mappings were compared against the expert reference. For clearly defined features, both implementations produced equivalent mappings, whereas differences primarily occurred for weakly specified or context-dependent attributes.

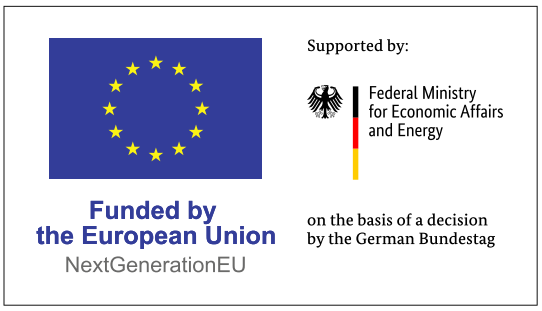
Correct mappings in both deployment variants were consistently associated with higher similarity values, while misassignments predominantly occurred in intermediate similarity ranges, particularly for closely related technical concepts such as nominal and maximum operating pressure. For the OpenAI-based configuration, similarity scores above approximately 0.85 emerged as an empirically observed high-confidence region for the evaluated

reference datasheet. This observation is model- and dataset-dependent and should not be interpreted as a strict or generally valid threshold. Future work will extend the evaluation to larger and more diverse datasets to further analyze similarity distributions and derive more robust confidence estimates.

Differences in inference time are primarily attributable to the execution environment rather than the semantic mapping methodology itself. The cloud-based variant benefits from highly optimized infrastructure, parallelized inference, and optimized model serving, whereas the local open-source variant prioritizes offline capability and data sovereignty and was executed on on-premise hardware with limited computational resources. Consequently, longer processing times represent an expected trade-off rather than a methodological limitation.

Overall, both deployment variants achieve comparable mapping quality for well-defined features. Differences are mainly observed in processing time and sensitivity to weakly specified input, indicating that stable semantic alignment depends not on model size alone but on the combination of structured preprocessing, retrieval-based context, constrained model interaction, and expert validation.

6. Conclusion and Outlook



This paper demonstrated that LLMs can support semantic interoperability in the fluid power domain, where heterogeneous datasheets and inconsistent terminology continue to limit automated data integration. By combining embedding-based similarity search with structured reasoning and standardized vocabularies, the proposed workflow enables the transformation of existing manufacturer documentation into machine-readable representations suitable for digital engineering applications. The modular architecture allows the approach to be applied in different deployment scenarios. A cloud-based implementation supports scalable processing with low inference times, while a fully local configuration enables offline operation and compliance with data protection requirements, which are common constraints in industrial environments.

At the same time, the evaluation highlights that the main limitation is not the semantic mapping itself, but the extraction of technical data from industrial datasheets. Complex layouts, diagrams, characteristic curves, and schematic representations remain challenging and directly affect the quality of downstream semantic alignment. Future work should therefore prioritize improved data extraction and document understanding, including multimodal approaches, before extending the reasoning models or scaling the framework further. Additional integration with established interoperability frameworks such as the AAS may further support practical adoption.

Overall, the presented approach provides a feasible step toward improving semantic interoperability in fluid power domain by systematically bridging unstructured technical documentation and standardized digital representations, contributing to more consistent and reusable industrial data in Industry 4.0 contexts.

7. ACKNOWLEDGEMENT

This work has been funded by the European Union (EU) and supported by the German Federal Ministry for Economic Affairs and Energy (BMWE) in the project Fluid4.0 – Revolutionizing Fluid Engineering: Implementation of digitalization for fluid power 4.0 in the cross-industry and cross-manufacturer data space using Asset Administration Shells, submodels and demonstrators. Danfoss Power Solutions GmbH & Co OHG, Krokamp 35, 24539 Neumünster, hlaffrenzen@danfoss.com

Abstract.

When selecting a hydrostatic transmission, there is a choice between load-dependent and load-independent pump control. With certain limitations, the load stiffness characteristics can be tuned using software, although this requires sensors. In addition, a system controlled by an ECU can cause a small but noticeable delay for the machine operator. Danfoss now introduces the Hybrid Load Control (HLC) that combines load-dependent and load-independent control characteristics in one control valve without additional actuators and sensors. This paper explains the functionality and design of this innovative control valve, as well as its switching mechanism.

Keywords. Pump control, servo system, hydrostatic propel system, mobile hydraulics

1. INTRODUCTION

When designing hydrostatic propel systems, mobile machine manufacturers must select the machine's fundamental driving behaviour. State-of-the-art systems are categorized into two types.

The first is a load-independent behaviour, also known as speed mode. This is used for constant-speed applications or for scenarios where the system load should not affect the driving behaviour.

The second type is a load-dependent behaviour, also referred to as torque mode. This approach utilizes the power of the prime mover by creating a ratio between flow and pressure. In this mode, the flow is dependent on the system pressure p_{L}, equation 1.1.

$$q(p_{\mathrm{L}}) = \frac{V_{\mathrm{g,\,max}} \cdot n \cdot \tan\alpha(p_{\mathrm{L}}) \cdot \eta_{vol}}{\tan\alpha_{\mathrm{max}}} \qquad (1.1)$$

A new control valve developed by Danfoss combines both control characteristics, allowing the driver to switch between load-dependent and load-independent control behaviour [1]. The control valve has the same interface as an EDC valve. Additionally, the essential control loops are working hydromechanical. In detail, this means:

- no additional actuator
- no additional sensors
- fast control behaviour

The basic idea of this 'hybrid control' was introduced in [1,4,5]. The current paper presents the design realization of this new type of control, compares it to existing controls and elaborates how each mode of the control offers specific advantages in certain applications. Chapter 2 and 3 provide the context by describing the designs of the load-independent and load-dependent controls. Chapter 4 explains the design and function of the hybrid control. Chapter 5 presents simulation results of drive scenarios on a vehicle-level in a realistic 3D environment. These simulations include the propel hardware and software, which is also a crucial component for the overall performance.

2. EDC FUNCTION (LOAD-INDEPENDENT / SPEED MODE)

The Electric Proportional Displacement Control (EDC) is a type of Displacement Control (DC) for closed-loop pumps. In an EDC system, swashplate angle of the pump, and therefore its displacement, is proportional to the input current. The flow output is ideally proportional to the pump displacement; however, volumetric efficiency deteriorates the precise relationship between the input signal and the resulting flow. Overall, when a variable pump with an EDC is used in a propel application, the vehicle speed is primarily dependent on the input signal of the operator, and the speed of the prime mover.

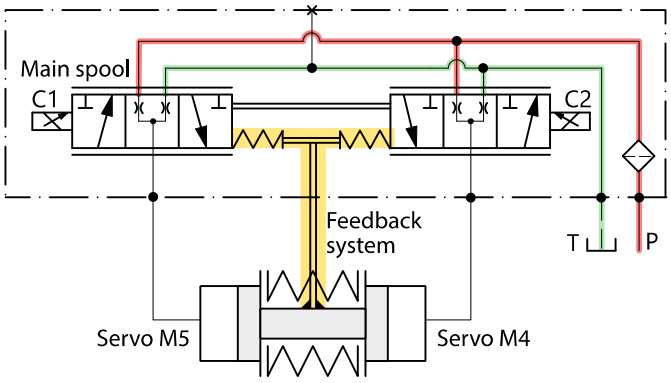

Figure 2.1: Schematic of EDC Control and servo system

The schematic of a Danfoss EDC control is depicted in Figure 2.1. The EDC incorporates a pair of proportional solenoids on either side of a common control spool, which is linked to the swashplate of the axial piston unit via a mechanical feedback system.

The solenoids convert the electrical input signal into force, moving the three-position, four-way control spool from its neutral position. This movement increases pressure on one side

of a double-acting servo piston, which rotates the swashplate until the forces from the mechanical feedback and the electrical input are balanced.

This hydro-mechanical feedback system is also referred to as a servo system. Figure 2.2 shows a schematic diagram of a servo system. Only one solenoid and one piston surface is depicted, sufficient to control displacement of the swashplate in one direction. The feedback spring is a soft spring intended to produce a force on the main spool equivalent of the swashplate displacement. In steady-state condition the main spool is closed and the solenoid force in perfect balance with the force produced by the feedback spring. The servo spring is a much stiffer spring, to make sure the swashplate angle returns to neutral at zero current condition. The axial piston unit produces reaction moments on the servo system which are dominantly pressure and speed-dependent but also vary with displacement and temperature. The force on the servo piston caused by swashplate reaction moments is shown as F_d.

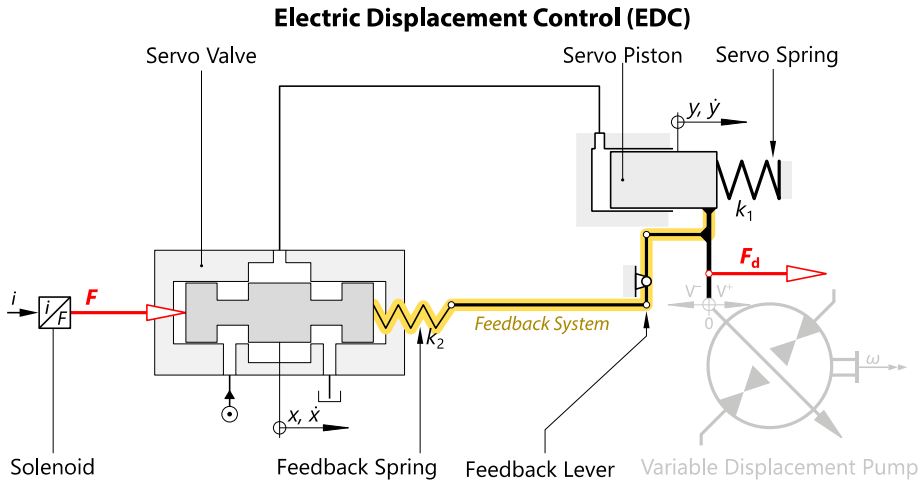

Figure 2.2: EDC with hydro-mechanical feedback system. The swashplate reaction force F_d is a disturbance.

3. NFPE FUNCTION (LOAD-DEPENDENT / TORQUE MODE)

The Non-Feedback Proportional Electric Control (NFPE) is a type of non-feedback control for closed-circuit pumps. It consists of two pressure control valves to control the pressure in each servo piston, see Figure 3.1. A simplified schematic is shown in Figure 3.2 with only one solenoid and a single servo cylinder chamber, which is sufficient to explain the action in one direction. It is clearly seen that there is no mechanical feedback between the servo cylinder and the control valve. The reaction force of the axial piston unit and the force of the servo springs result in a force F_d acting on the servo piston [2]. The preloaded servo springs produce a position-dependent force, and they are important for a fail-safe design to bring the pump back to neutral position. As a result, the servo system displacement is proportional to the valve current. However, because there is no mechanical feedback, the swashplate reaction moments can disturb the swashplate angle and render the pump load-dependent.

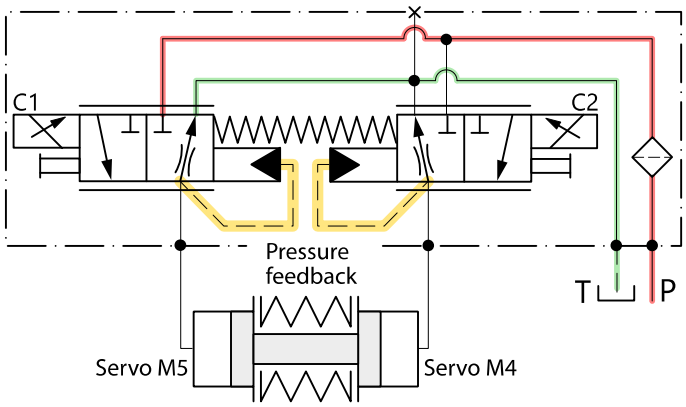

Figure 3.1: Schematic of NFPE Control and servo system

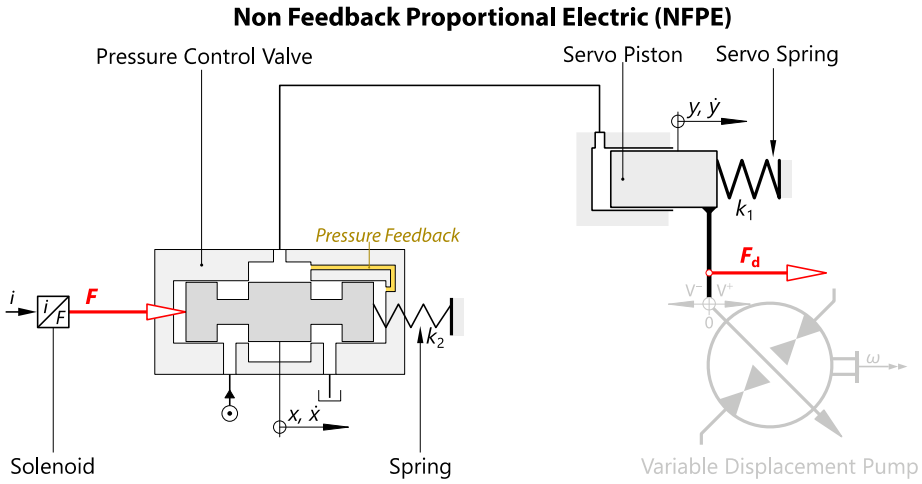

Figure 3.2: Simplified schematics of half of a non-feedback control system (NFPE). The valve realizes a pressure control. The servo piston finds an equilibrium position in relation to the external forces

If a variable pump with an NFPE control is used in a propel application, the oil flow and vehicle speed depend not only on the inputs of the operator. It is also influenced by the system pressure which affects the swashplate moments. The combination of system pressure and pump speed creates the load-dependent characteristic.

A pump with an NFPE control optimizes the use of available engine power by converting it into an ideal ratio of flow and pressure. This maximizes vehicle speed and tractive force without stalling the engine, making NFPE the preferred solution for applications with low engine power relative to the required corner power.

4. HYBRID LOAD CONTROL (HLC) FUNCTION

The patented Hybrid Load Control (HLC) is fundamentally an EDC with the added capability to create load-dependent behaviour, see Figure 4.1 [4,5]. It achieves this by allowing the servo pressure to superpose the mechanical feedback force. The primary difference between the HLC and a standard EDC is the control spool. It contains two nested inner spools. In their default positions, these inner spools open a passage for flow through an orifice cascade from the servo chambers M4/M5 to case. This orifice cascade acts as a pressure divider and lets the servo pressure produce a force on the control spool. On the side of the main spool which is pushed by the active solenoid the inner spool is pressed against the main spool and the orifice cascade is shut closed. It is the opposite side of the main spool, where pressure feedback can take place.

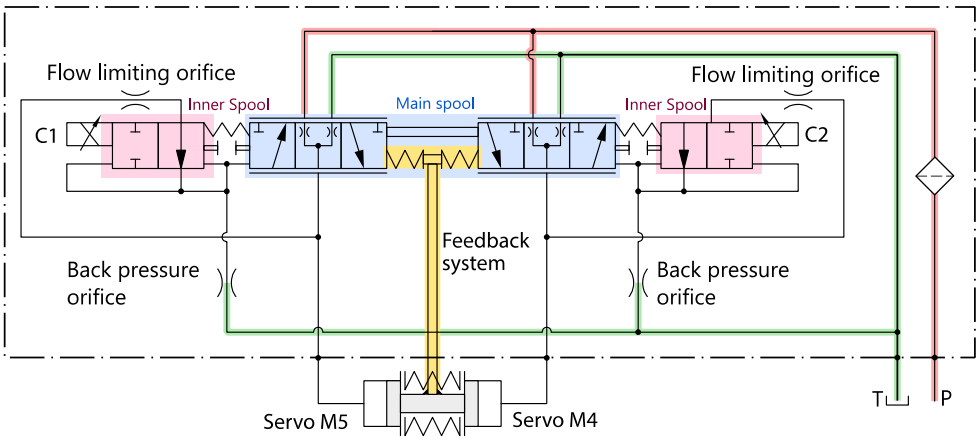

Figure 4.1: Schematic of HLC valve and system.

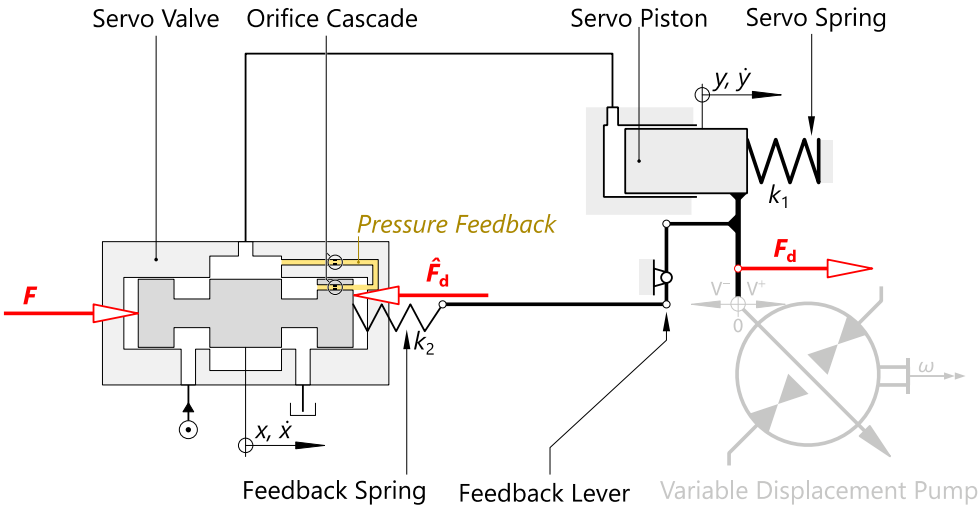

Figure 4.2: Simplified system schematic of half of HLC. In comparison with schematics of EDC and NFPE it includes both, pressure and position feedback. Pressure feedback can be switchted on or off.

The working principle can be explained by a simplified schematic in Figure 4.2. Here we consider the left side of the servo valve being pushed by the active solenoid. On the opposite side the orifice cascade ('pressure feedback') is seen, which transmits the servo pressure to the right side of the spool. It divides the servo pressure with a predefined ratio related to the ratio of orifice areas. The reduced servo pressure offsets the force produced by the solenoid and thereby reduces the set point of the servo control. Essential to the HLC is that the pressure feedback can be switched off. The orifice cascade is shut close, when the inner spool is slightly pushed against the main spool by the opposite (inactive) solenoid. It creates a disturbance for the active spool, but the force for closing the inner spool is small and can be easily compensated.

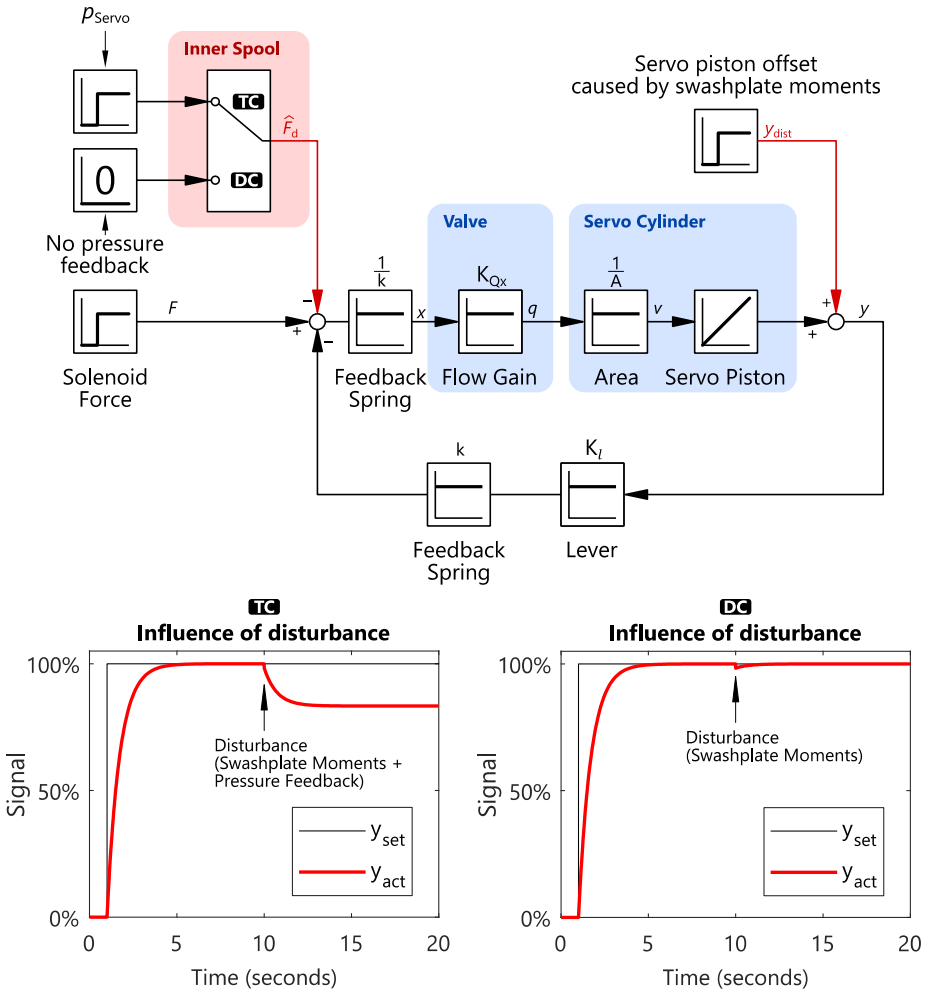

Figure 4.3: Block diagram of servo system with switchable pressure feedback and swash moment disturbance (top) and impact of disturbance (bottom).

Figure 4.3 shows a signal diagram of the control in the top. It can be used to derive the load stiffness with and without pressure feedback, compared in the bottom. For this analysis we

assume that the valve dynamics are much faster than the dynamics of the servo piston. Therefore, the valve is represented simply by a flow gain K_{Qx} that is proportional to the sum of the force components from solenoid, and mechanical and hydraulic feedback. The force component from the hydraulic feedback is indicated by the top left signal branch in red. Its switchable nature is indicated by the 'Inner Spool' switch. It is open in the default position.

In load-dependent mode, the reduced servo pressure is applied to the valve spool as a disturbance force $\hat{F}_{\mathrm{d}}$. It is a function of A_{Spool} spool area, and α ratio of the pressure divider:

$$\hat{F}_{\mathrm{d}} = A_{\mathrm{Spool}} \cdot \alpha \cdot p_{\mathrm{Servo}} \tag{4.1}$$

This disturbance force offsets the solenoid force and reduces the setpoint. As the servo pressure increases, the offset causes a de-stroking of the servo piston.

The closed-loop set-point transfer function can be written as

$$\frac{Y(s)}{F(s)} = \frac{\frac{K_{\mathrm{Qx}}}{kA}\frac{1}{s}}{1 + \frac{K_{\mathrm{I}}K_{\mathrm{Qx}}}{A}\frac{1}{s}} = \frac{\frac{1}{K_{\mathrm{I}}k}}{\frac{A}{K_{\mathrm{I}}K_{\mathrm{Qx}}}s + 1} \tag{4.2}$$

Where $F(s)$, $Y(s)$ are the Laplace transforms of spool force and servo position. The factor $\frac{A}{K_{\mathrm{I}}K_{\mathrm{Qx}}}$ represents the time constant of this first order transfer function. The steady-state relationship between force F and servo position y is given by

$$\lim_{s\to 0}\frac{Y(s)}{F(s)} = \frac{1}{K_{\mathrm{I}}k} \tag{4.3}$$

Therefore, the steady state relationship between servo pressure and servo displacement can be expressed as

$$\lim_{s\to 0}\frac{Y(s)}{p_{\mathrm{Servo}}(s)} = \frac{A_{\mathrm{Spool}}\alpha}{K_{\mathrm{I}}k} \tag{4.4}$$

And the load stiffness can be given as the inverse.

In load-independent mode, there is no disturbance by the servo pressure on the control spool. Or, in other terms, the orifice ratio α is 0. Reaction forces from the rotating unit that act directly on the servo piston do not affect the closed loop control.

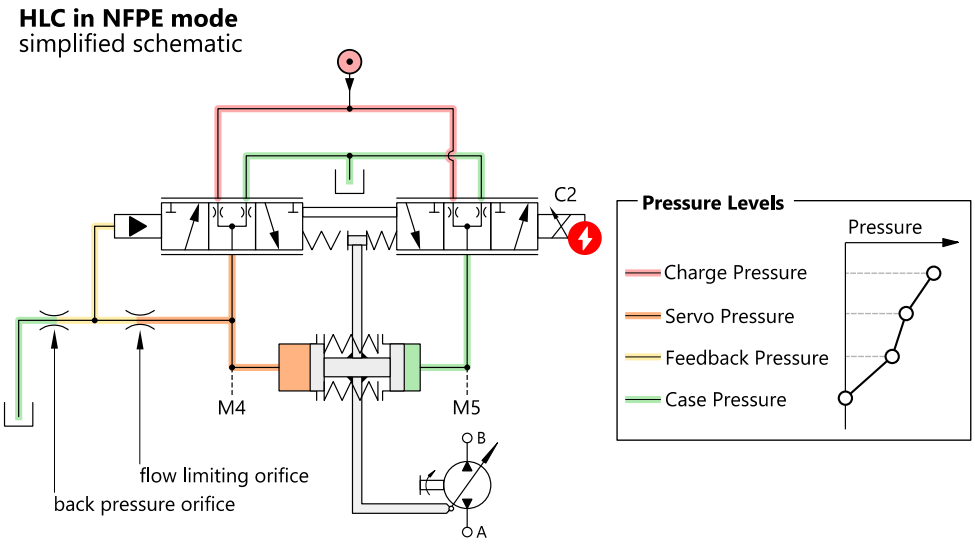

Figure 4.4: Pressure divider to superimpose reduced servo pressure on the valve spool.

Figure 4.4 shows a hydraulic schematic of the HLC, where solenoid C2 is activated. This leaves the orifice cascade on the opposite side open. Different pressure levels are indicated by colour. The servo pressure M4 is divided by the orifice cascade and produces a small force on the main spool. It opposes the force from solenoid C2. The set value is reduced, and as a result, the control behaves load-dependent.

To switch into load-independent (EDC) mode C1 is energized slightly with a current that does not affect the control action of C2 but is enough to close the orifice cascade via the small internal spool. The HLC does not require additional actuators or sensors to switch between modes. This is illustrated in Figure 4.5, which shows the control with both solenoids. The right solenoid is the active one and the left solenoid determines whether operation is in NFPE or EDC mode. The blue arrows indicate the current ranges when operating in load-dependent mode. The red arrows indicate the current ranges when operating in load-independent mode. The passive solenoid is given a small current that is below the dead-band threshold of the EDC control.

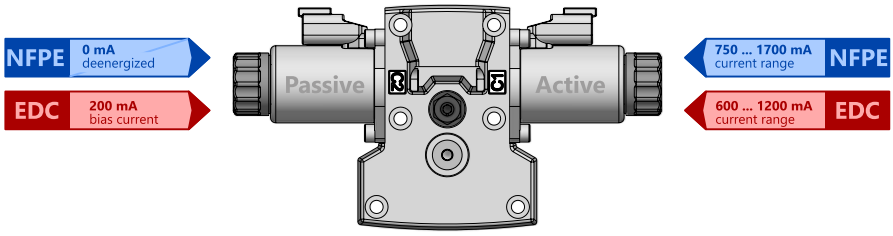

Figure 4.5: Actuation of Danfoss Hybrid Load Control

5. HLC OPERATION

Three driving scenarios are considered to illustrate the functionality of the HLC:

1. Driving a bucket into a pile of sand
2. Driving precisely over an obstacle
3. Downhill braking

For the first scenario, a load-dependent control characteristic is advantageous as this type of control prevents the diesel engine from stalling by de-stroking the pump. For the second scenario, a load-independent control characteristic is preferable because precise manoeuvring over an obstacle is required. A load-independent control characteristic regulates the displacement of the pump in a closed control loop, as mentioned above. The vehicle can thus maintain a nearly constant speed despite leaks. This enables precise manoeuvrability. In the third scenario, the braking behaviour between load-dependent control (NFPE) and HLC in load-dependent control mode is shown. It should be noted that load dependency is inactive during braking. During braking, the swashplate moment switches direction and now acts on-stroking. The control maintains the swashplate angle by pressurizing the opposite side. As can be seen from Figure 4.1 this opposite side cannot cause an offset to the servo spool because the orifice cascade is shut off by the active solenoid. To demonstrate the advantages of HLC in the scenarios mentioned above, a simulation was used that includes models of the hydraulic hardware, drive train components, a 3-D multi-body dynamic simulation of a vehicle and of the electrical control and software. Some parts of this real-time driver-in-the loop simulation setup are described also in [3]. The key data of the wheel loader and the drivetrain used in the simulation can be found in Table 1.

Table 1: Vehicle data.

Wheel rolling radius	0.6 m
Mass	8400 kg
Differential Gear ratio	16.51
Final differential gear ratio	15.24
Pump	H1P 89 cm³
Motor	H1B 160 cm³
Diesel engine max. power	103 kW

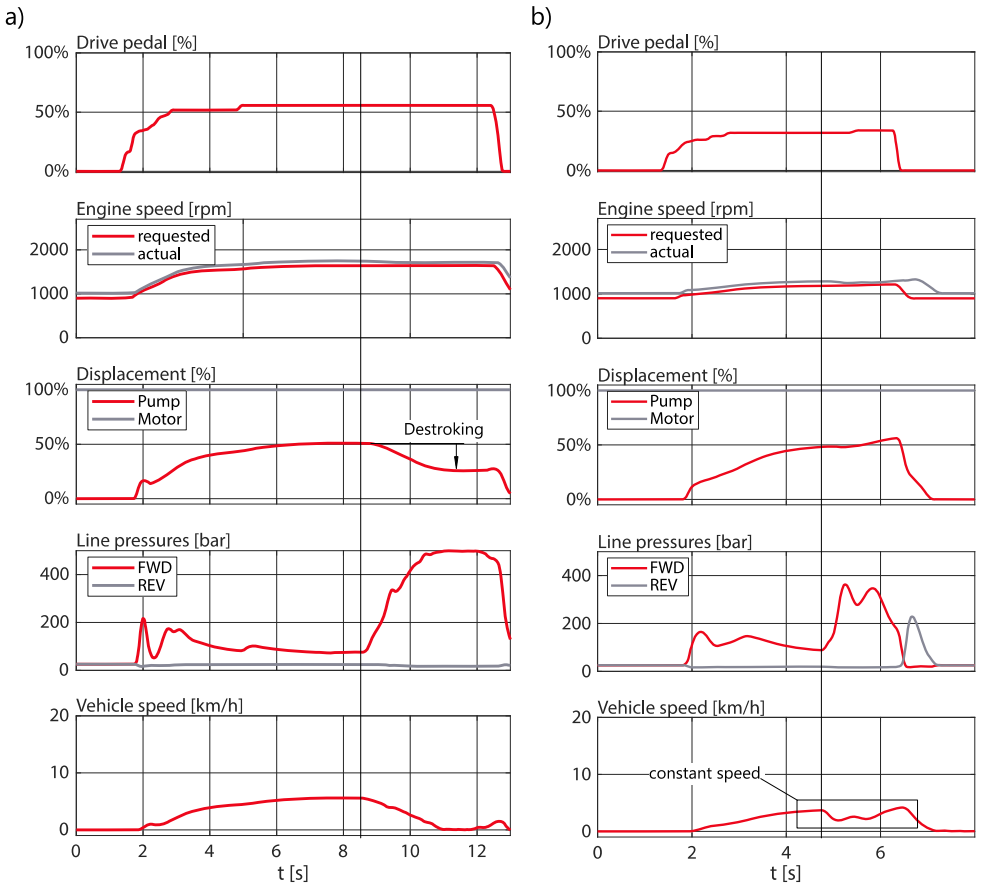

Figure 5.1: Simulation results showing two different driving scenarios with HLC operating in different modes. Left: Driving of bucket into pile (load dependent). Right: Precise maneouvre over obstacle (load independent)

Figure 5.1 shows simulation results for these driving scenarios. “Driving of bucket into a pile” (scenario 1) is shown on the left and “precise manoeuvre over obstacle” (Scenario 2) on the right. Considering scenario 1, the wheel loader approaches the pile of sand at almost constant speed. The drive pedal remains in approximately the same position until the bucket is full. As soon as the bucket reaches the pile of sand, the driving resistance increases, indicated by a steep rise in line pressure. Because of the servo pressure feedback, the pump de-strokes automatically and the diesel engine is protected from stalling.

In the second scenario, load-independent speed mode is selected because the driver wants to drive over an obstacle precisely and at almost constant speed. The corresponding signals are shown in Figure 5.1 on the right. As soon as the wheel loader reaches the obstacle, the load pressure increases. Due to the selected speed mode, the servo pressure cannot influence the control spool, and the vehicle speed remains approximately constant. The vehicle manoeuvres precisely over the obstacle.

The HLC provides a better braking performance, even in load-dependent mode. As stated before, the load-dependency is not active during braking. During braking the swashplate moments are on-stroking. Therefore, load-dependency, if it was active, would cause the pump to increase displacement during braking. This lowers the engine RPM and therefore reduces the available engine braking power. It can be demonstrated that with HLC, even in the load-dependent mode, braking performance is just as if the pump control was load-independent: fast and precise. Software can be used effectively to optimize the overrun operation of the diesel engine. Figure 5.2 shows a comparison of simulation results for downhill breaking between a vehicle that uses a standard NFPE pump control (left) and one that uses a HLC in load-dependent mode (right). The simulated vehicle is equipped with a 103 kW engine. Its braking power is the limitation for the achievable deceleration.

The driving scenario can be divided into three phases:

A. Acceleration on flat ground while approaching the incline,
B. Driving downhill a 10% slope,
C. Hydrostatic braking.

Braking starts at the same speed. As the upper plot in Figure 5.2 shows, with the HLC pump control, the software can better utilize the available engine braking power by controlling displacements to achieve maximum engine speed in the overrun operation. The vehicle with standard NFPE pump control stops after 9 s and 23.6 m, whereas the vehicle with HLC pump control stops after 7s and 20.8 m. It should be noted that the braking performance with NFPE control has also been optimized using software.

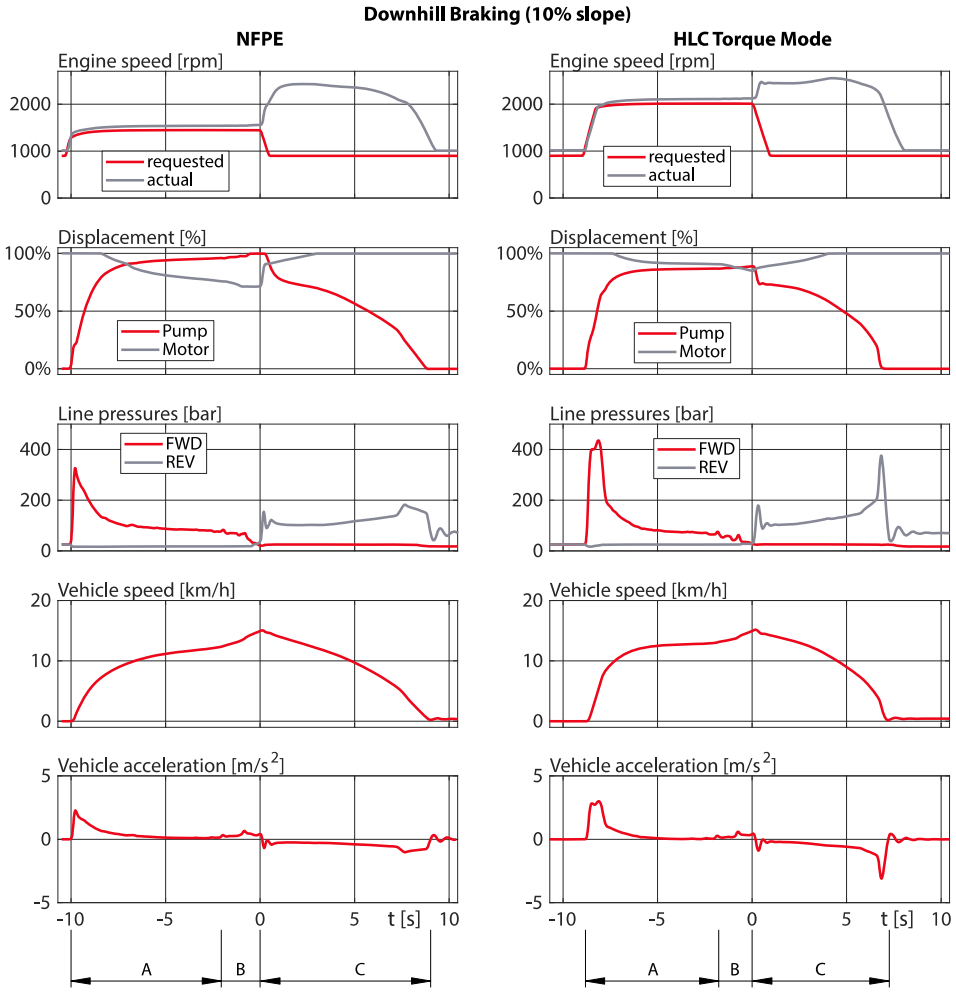

Figure 5.2: Simulation results of downhill braking. Left: Vehicle with standard NFPE pump control. Right: Vehicle with HLC pump control in load-dependent mode. A: acceleration on flat ground. B: driving downhill. C: hydrostatic braking.

SUMMARY AND CONCLUSION

The new Hybrid Load Control combines the best of both worlds, load-independent and load-dependent hydrostatic driving. By specifically using the dead band for a new function and making use of unused space, it was possible to combine two control valves into one. No additional actuators or sensors were required, nor was any additional space needed. The components that determine the characteristics of the control loops were adjusted so that the control characteristics of the HLC in the torque control mode are very similar to those of the current NFPE pump control. Since the control loops are still hydromechanical, the responsiveness of the established control valves is achieved and has been demonstrated on Danfoss Application Development Center. These validation results will be shown in a future publication.

NOMENCLATURE

Abbreviation	*Description*
DC	Displacement Control
EDC	Electric Displacement Control
FWD	Forward
HLC	Hybrid Load Control
NFPE	Non-Feedback Proportional Electric
REV	Reverse
TC	Torque Control

Variable	*Description*	*Unit*
A	Area	m^2
F_d	Disturbance force (from swashplate moments)	N
$\hat{F}_\mathrm{d}$	Force from pressure feedback	N
k	Spring constant	N/m
K_l	Feedback link ratio	-
K_Qx	Flow gain	m^2/s
p_Servo	Servo pressure	Pa
s	Laplace variable	s^{-1}
V	Volume	m^3
$V_\mathrm{g,max}$	Maximum displacement volume	$\mathrm{m}^3/\mathrm{rev}$
x	Set point	m

Dr. Rahmfeld completed his PhD on new displacement controlled hydraulic linear actuators at the Technical University of Hamburg-Harburg in 2002 under supervision of Professor Monika Ivantysynova, and his MSc in mechanical engineering at Duisburg University in 1996. He was also holding a postdoc position in fluid power for 2 years at the Technical University of Hamburg-Harburg and Purdue University, Indiana, USA. Dr. Rahmfeld represents Danfoss within the VDMA fluid power board and is also the chairman of the corresponding fluid power research fund with more than 60 member companies. He was awarded in 2024 by Purdue University with the *Monika Ivantysynova Medal* for technology advancements of hydrostatic units and their controls, and for leadership in fostering industry - academic initiatives to promote fluid power.

High efficient Hydraulic Actuator Valve Sensor Unit without dedicated hydraulic supply (HAVSU)

Ralph Wassermann & Florian Hölzle

MAGNET-SCHULTZ, info@magnet-schultz.de

Abstract

MAGNET-SCHULTZ, specialists for electromagnetic solutions, has combined the advantages of fluid-power with the energy efficiency of sustainable electrified drivetrains, since purely electric actuators often lack power density and robustness in the demanding environment of applications in powerful modern electric drivetrains (EV, BEV and PHEV).

The highly innovative development resulted in an Actuator-Valve-Sensor-Unit (HAVSU) like not seen before in the vehicle industry. Adapted to the specific environment and requirements of electric drive axles, such a unit can actuate functions like disconnect and park-lock mechanics and supplement or substitute purely electric actuators with their well-known weaknesses in regards of robustness and power density.

The unit can provide force and stroke to the mechanism of the axle with high power-density and speed of hydraulics and is fully scalable to many other mobile and stationary applications.

1. GOALS

The main goal was to create an actuator providing all necessary functions for the typical applications in modern drivetrains and beyond, combining the proven advantages of hydraulics, like high power density, speed and robustness with an innovative layout with significantly reduced complexity, most efficient use of resources and small CO_2 footprint from cradle to grave.

Precisely the goals were:

(1) Stronger than purely electric driven actuators
(2) Less complex than common hydraulic systems

All Open Access articles are peer-reviewed, distributed under the Creative Commons Attribution-Non Commercial 4.0 International

(3) Smaller and lighter than electric driven actuators
(4) More robust and durable in operation than electric actuators
(5) Less resource demanding, sustainable in production and more cost efficient
(6) Development according to the requirements of functional safety as defined by ISO26262
(7) Scalable to as many applications as possible (passenger car, truck & bus, off-highway, aerospace, defence, industrial)

2. INITIAL IDEA

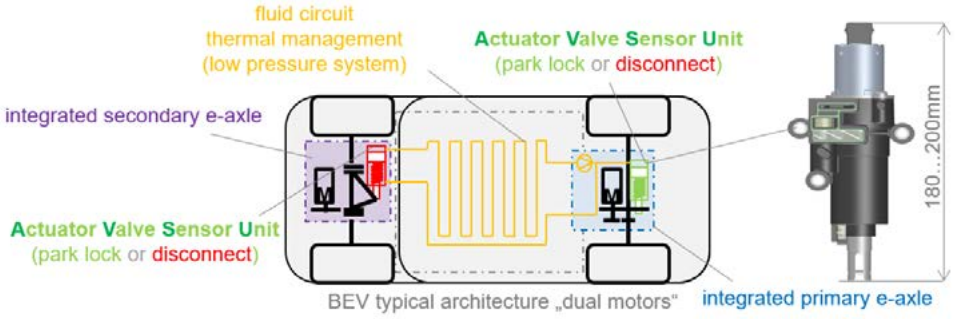

Figure 2.1: Typical architecture of a AWD EV

The invention has been inspired by the fact that e-axles generally need a thermal management or lubrication circuit to keep the system in an optimum state of operation. Thus, the creative idea was that exactly this fluid could be utilized in a second way to supply hydraulic actuators, even if initially not dedicated for this purpose.

But a major obstacle had to be overcome as a fluidic system primarily designed for thermal management is optimized to provide a high flowrate at low pressure levels and thus is not suitable to supply hydraulic actuators with sufficient pressure without boosting the fluid to higher pressure levels.

This innovative boost function is possible by blocking the hydraulic circuit for the very short actuation time of the actuator what leads to the pump working against a closed end. That on the one hand enables boosting the pressure up and on the other hand does not negatively affect the relatively slower responding thermal management system.

Once the actuator reaches its end position, the integrated solenoid-driven bistable locking mechanism is activated and secures the actuator stroke without the need of further supply pressure. After locking the actuator position, the integrated valve opens, and the thermal management is working freely with minimal pressure drop again.

To avoid an additional dedicated electrically operated pilot valve, the valve had to be part of the solenoid-driven locking mechanism, which is anyways necessary to lock the state of the hydraulically actuated cylinder. Thus, it became possible to actuate the bistable lockable hydraulic cylinder with the same solenoid as the pilot valve for pressure boosting. Summarized up and due to the dual use of the highly integrated subsystems, pressure boosting requires no additional actuation principle than the already existing from similar systems with a common hydraulic pressure supply.

3. FUNCTIONAL COMPONENTS

The unit consists of eight collaborating subcomponents.

(1) Hydraulic actuator, piston and cylinder rod – providing external stroke and force up to 800N (further scalable)
(2) Position sensor – monitoring the stroke-position of the cylinder rod
(3) Pilot valve – controlling the state of the main valve
(4) Main valve – switching the flow of the fluid in circuit ON/ OFF
(5) Locking mechanism – Locking the state of the hydraulic actuator
(6) Electromagnet – operating the pilot valve and locking mechanism
(7) Housing – providing mechanical interfaces and ensuring structural integrity
(8) Electrical connection – connecting all electrical subcomponents and building interface to the higher-level system (power supply, communication, sensing, diagnosis)

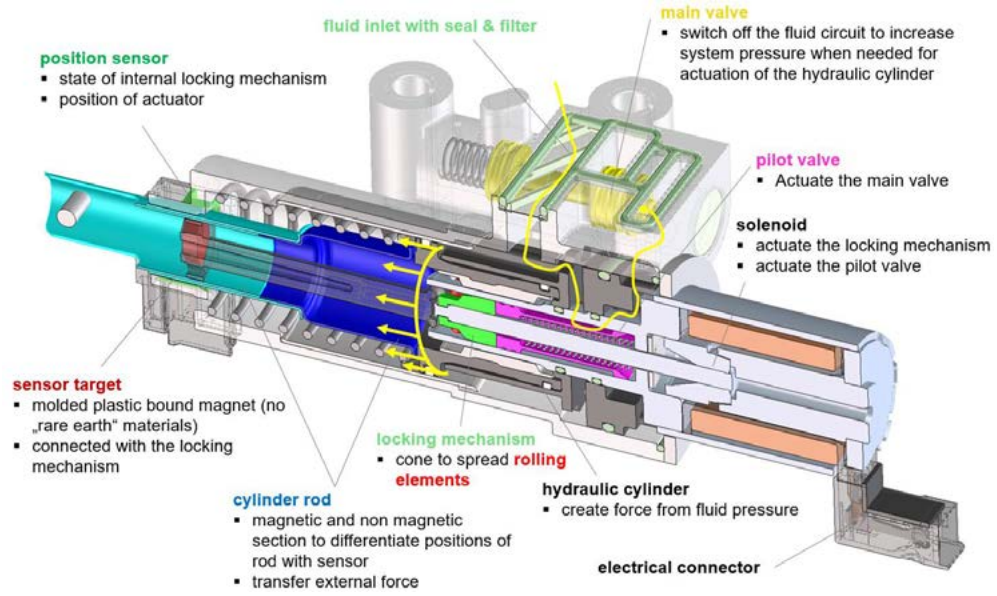

Figure 3.1: Integrated components and functions of the Hydraulic Actuator unit

The subcomponents are either controlled by the axle control unit (ECU) or with an onboard OBD-capable smart control unit as a ninth subcomponent.

All the required innovations of manufacturing technology to build those components were driven by MAGNET-SCHULTZ engineering. Especially the hybrid housing, spool valve and hydraulic manifold from thermoplastic materials and the two-component

ferromagnetic / non-ferromagnetic cylinder rod. All chosen materials have been selected to be free of per- and polyfluoroalkyl substances (PFAS).

The weight of the unit is 0.46kg with a length of 180mm in the retracted position of the cylinder rod.

4. FUNCTION

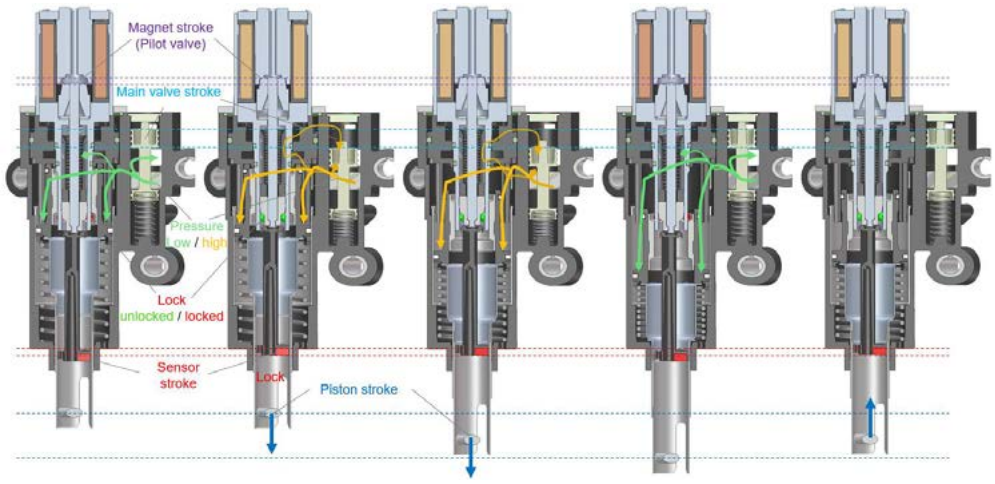

Figure 4.2: Main states of function of the Hydraulic Actuator unit

The HAVSU actuator can switch between five main states of operation.

First stage is the **Park State** (PS).

The solenoid is electrically OFF, no current flows through the coil. The locking mechanism is locked, the pilot valve is open. Pressure in the fluid circuit is low, and pressure drop in the main valve is very low, even if the pump is working at high flowrates. The hydraulic piston-rod remains retracted.

Second stage is the **Pressure Boost State** (PBS).

The solenoid is electrically ON, current is drawn. The locking mechanism, driven through the same armature rod as the pilot valve, is thereby released (unlocked) simultaneously with the opening of this pilot valve. Fluid is drawn from the main line and pilot pressure is applied to operate the main valve. The main valve closes to block the main circuit. Now the pump is triggered for increased performance to work against the dead end (closed line) what causes the pressure to rise immediately.

Third stage is the **Extraction State** (ES).

As soon as the pressure reaches the level needed to overcome the force of the return spring mounted on the cylinder rod, this cylinder rod starts to extract till its end stop. During this movement the boost pressure reaches its maximum.

Fourth stage is the **Drive State** (DS).

After the cylinder rod hits its end stop, the solenoid is switched OFF. The locking mechanism toggles to locked and the pilot valve releases the pilot pressure from the main valve; both through spring pretension. The cylinder rod is locked in the extracted position to remain in drive without pressurizing what means the boost pressure is no longer needed and falls back to normal mode.

Fifth stage is the **Retraction State** (RS).

If the retraction of the cylinder rod is desired, the first cycle “Boost stage” is repeated but with the pump switched OFF, so that the pressure reliefs. The locking mechanism is opened by the energized solenoid. With decreasing pressure and thus hydraulic force the return spring can retract the piston together with the cylinder rod to the retracted position. Afterwards the actuator returns to park or idle stage. With the solenoid OFF, the piston locked in retracted position, fluid passes the main valve with very low pressure drop if the pump is activated again to fulfill its supposed dedication.

Important note: Because thermal processes are slow compared to the few hundred milliseconds needed to extract the cylinder, this is usually easily acceptable for the main fluid circuit of the cooling-system to be interrupted for this short boost and extraction phase. This is why usually easily accessible cooling or lubrication systems are often appropriate for utilizing a HAVSU.

Dual Sensor Solution

Both independent strokes, the solenoid stroke (corresponds to locked / unlocked) including pilot valve state and that of the piston rod (park / not park) are monitored by only one 2D hall-effect position sensor with only one permanent magnetic sensor target. In known applications two separate sensors with two separate targets for each sensing function were necessary what offers plenty of advantages beginning from the often difficult supply chains of rare earth material for sensor targets or the chips itself and ending with quality by design.

This innovative design becomes possible, because the sensor target is connected to the solenoid on the one hand as well as to a tailored multi-material cylinder rod on the other hand. This cylinder rod is made of materials with different magnetic properties along its longitudinal axis, what enables it to act as a varying magnetic shield between the permanent magnetic sensor target, and the opposite positioned hall-effect sensor. Thus, the hall sensor is exposed to a stroke-dependent magnetic field as illustrated below:

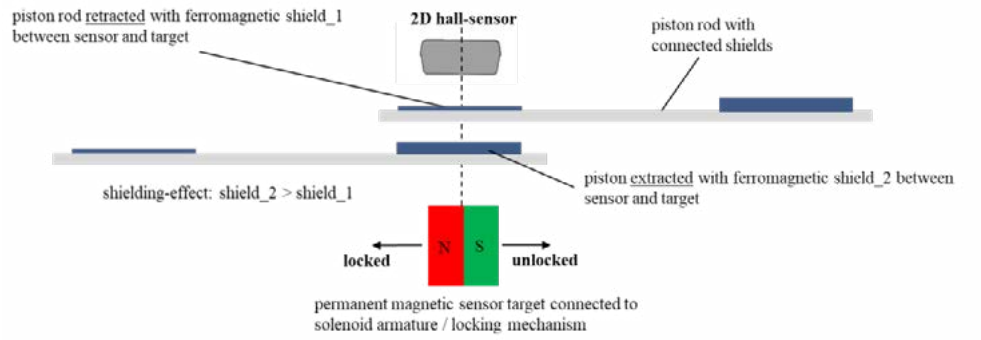

Figure 4.2: Dual sensor principle

To gain two independent positions signals of the 2D hall sensor, it is necessary to evaluate the sensor signal in two different ways. 2D hall sensors can measure the magnetic field strength in two planes perpendicular to each other (Bx, Bz; illustrated below), what is important for the dual sensor principle.

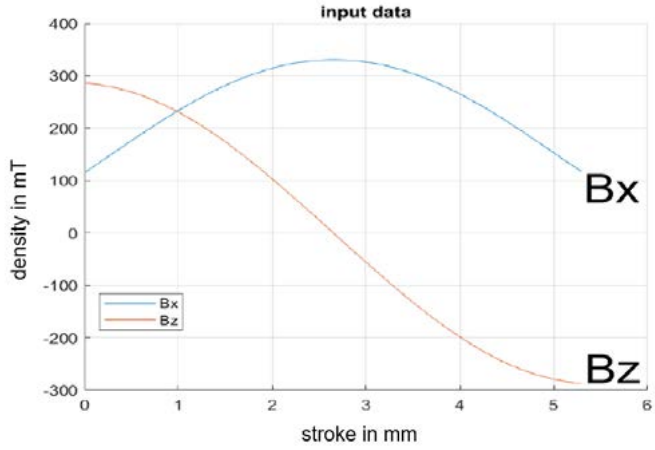

Figure 4.3: Raw sensor signal

For the evaluation of the stroke of the piston rod (retracted / extracted) it is necessary to calculate the stroke-dependent (through varying shield effect) absolute field strength of the target, which corresponds to the vector sum of the two evaluation planes of the 2D hall sensor:

$$B_{abs} = \sqrt{{B_x}^2 + {B_z}^2}$$

For the evaluation of the stroke of the solenoid (locked/ unlocked) it is necessary to calculate the stroke-dependent (through varying shield effect) angle between field strengths of the two perpendicular to each other evaluation. This angle is fully independent from the absolute field strength and thus from the shielding effect which is necessary for the before mentioned evaluation for the position of the piston rod. The angle corresponds to the trigonometrical relationship:

$$\alpha = atan2(B_x; B_z)$$

The Dual-Sensor Solution as well as the whole system Actuator-Valve-Sensor-Unit are patent pending.

5. PERFORMANCE DATA AND TEST RESULTS

The test results with the mock-up samples of the actuator-unit showed great success. The tests included basic functional test, durability test, environmental testing from -40 to +150°C and in-system tests.

The following figure 5.1 shows a typical operating cycle and table 5.1 gives an overview of the technical data measured.

Durability tests confirmed the expected life-length and environmental testing showed no malfunctions, e.g. in thermal cycling or under vibrations and mechanical shocks acc. to well-known automotive standards like LV124.

The successful results have been confirmed by the system-level test and were honored by customers.

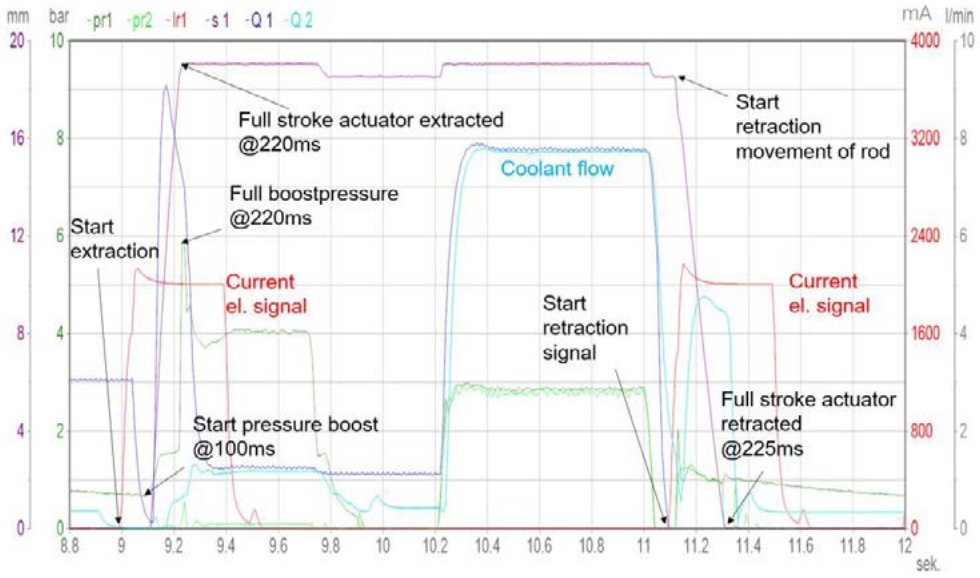

Figure 5.3: Measurement el. current, flow-rate, pressure and stroke over time @ 45°C

Characteristic	Unit	Typical spec.	MSM-HAVSU
Supply Voltage	V	24 / 48	24 / 48
Operating current	A	<3	1.5
Pull in current	A	<3	1.5
Holding current	A	<0,6	0.2
Switching time solenoid (locking mech.)	ms	<50	<20
Pressure build up time (boost)	ms	-	100
Stroke hydraulic	mm	15…50	19.5
Piston area (specific type; scalable at will)	mm²	-	780
Force potential (scalable at will)	N/bar	-	78
Burst pressure	bar	>60	>60
Max. operating pressure	bar	-	20
Max Force (scalable at will)	N	1000	1560
Switching hydraulic (extracting)	ms	<300	<100…220(T)
Switching hydraulic (retracting)	ms	<300	<100…220(T)

Flow-rate main valve (e.g. cooling circuit)	l/min	-	8…15
Pressure drop	bar	<0,1	<0,1
Leakage idle mode @ 1 bar	ml/min	-	<5
Leakage during extracting phase @ 10 bar	ml/min	-	<50
Weight (specific type)	kg	-	0.46

Table 5.1: Summary technical data

The actuator meets all typical specifications regarding dynamic stroke behavior. Especially the very low leakage in idle mode results in very high efficiency.

6. EXAMPLES FOR APPLICATIONS

Lockable linear actuator units including position feedback are highly suitable for applications requiring:

(1) High force density without a full hydraulic infrastructure.
(2) Precise positioning and closed-loop control.
(3) Fail-safe locking for safety-critical systems.
(4) Energy efficiency through bistable lockable hydraulic cylinder which only needs hydraulic actuation for change of state.

The unique advantage of this system is the operation without a dedicated high-pressure hydraulic supply through utilizing an existing low-pressure fluid circuit, e.g., for cooling or lubrication. Dedicated on-demand pressure boosting makes these actuators perfect for modern architectures in many next-generation platforms (e.g. trucks, buses, aerospace, defense, automotive) by moving towards more electric systems and reducing or removing centralized hydraulic supplies.

However, certain functions still require high forces that pure electromechanical actuators struggle to deliver efficiently. By tapping into an existing low-pressure circuit (e.g. 1–3 bar) and locally boosting pressure (e.g. up to 10–50bar), the actuator eliminates the need for a full hydraulic system with reduced weight, complexity and costs as well as minimizes leakage risk and maintenance combined with the typical high force capability and power density of hydraulic actuators.

Possible application fields and examples:

Automotive

- **Transmission Actuation**, Gearshift or clutch actuators in hybrid/EV drivetrains where no hydraulic system exists.
- **Parking Lock Mechanisms**, securely locking the driveline without relying on mechanical-only solutions. Figure 6.1 illustrates the HAVSU in one of our already a realized application.
- **Active Aerodynamics**, spoilers or air flaps that need high force and locking at extreme speeds without adding hydraulic complexity.
- **Cooling on Demand** solutions where the airflow through radiators is a controlled for expample by air flaps to optimize overall aerodynamic drag losses.

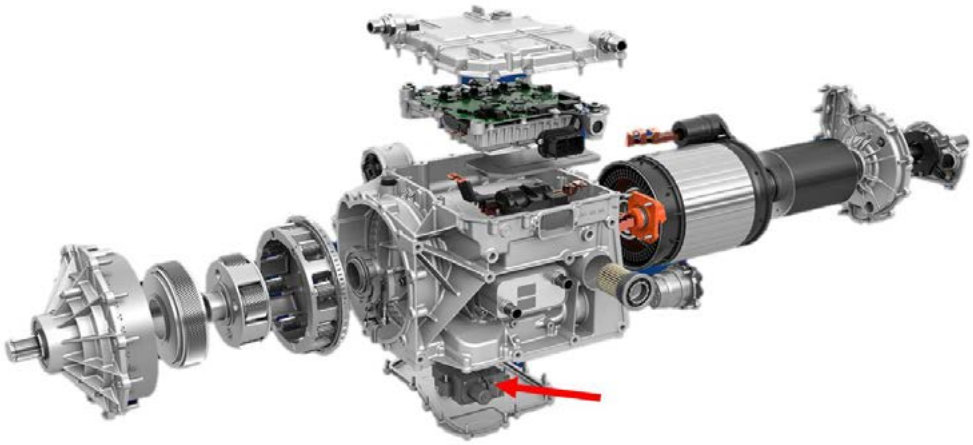

Figure 6.1: Actuator as park-lock-application in e-axle, image courtesy of ZF Friedrichshafen AG [1]

Truck & Bus, Rail and other On- and Off-Highway applications

- **Steerable Axles and Axle Locks,** for controlling auxiliary steering axles and lock them at highway speeds without a central hydraulic system.
- **Suspension Height Adjustment**, for suspension systems, actuators can provide precise height control and secure locking during loading and unloading.
- **Heavy-Duty Doors and Ramps**, passenger doors or wheelchair ramps require strong actuation and safe locking, ideal for local hydraulic boosting.
- **PTO clutches** for distributing mechanical power to auxiliary units.
- **Thermal flow control** especially for large heating circuits, e.g. bus passenger compartments

Aerospace

- **Door-actuators** could extend/ retract and lock doors in position, leveraging low-pressure cooling circuits for energy supply.
- **Flight Control Surfaces**, high-force actuation with fail-safe locking for flaps or stabilizers in "More Electric Aircraft" designs.
- **Cargo Doors**, large and heavy doors require strong actuation and locking, perfect for local pressure boosting.

Defense

- **Weapon Stations**, positioning and locking of turrets or launchers without a full hydraulic network.
- **Armored Vehicle Hatches and Ramps**, heavy hatches need secure locking and high force in compact systems.
- **Stabilization Systems,** radar, missile or laser weapon platforms requiring precise positioning and locking under harsh conditions.

7. BENEFITS OF THIS INNOVATION

The integration of all necessary functions is successfully combining the proven advantages of hydraulics (high power density, robustness) with an innovative layout providing significantly reduced complexity and CO_2 footprint of supply chain, system manufacturing and system operation.

The key advantages versus purely electric actuators can be summarized as follows:

(1) Higher force density: Hydraulic boosting enables compact actuators to handle heavy loads.
(2) Fail-safe locking: Integrated hydraulic lock ensures safety even in power loss scenarios.
(3) Energy efficiency: Uses existing low-pressure fluid, reducing electrical power demand.
(4) Simplified architecture: No need for centralized hydraulic systems, ideal for electrified platforms.

The benefit also includes the reduction of weight, overall size, number of parts and assembly steps as well as improved efficiency of electric energy and use of material resources in the system and whole supply chain.

The lean design with highly integrated functions result in a significant cost reduction compared to alternative systems that combine actuators with separate, external valves and sensors.

At least one electromagnetic valve and one sensor could be saved compared to alternative and less integrated solutions, even without taking the pump and further components of a dedicated system into account.

The innovation is showing great benefits and uniqueness for the markets by bridging the gap between great power density provided by hydraulics, functional robustness, energy-savings and cost effectiveness compared to standard actuator technologies.

Further the innovation has the potential to provide substantial competitive advantages in the mass market of next generation electric vehicles (NGEVs) launched in the second half of the decade and beyond, to make such cars affordable to a broader customer base.

The actuator is fully scalable to different force and stroke requirements as well as environmental conditions in automotive, all mobile or industrial applications.

Thus, a high degree of innovation has been achieved and provides high flexibility for additional applications and future innovations and platforms in a variety of industrial sectors.

EHAs in mobile machinery: Experimental validation of a high-speed EHA with recuperation and load-holding capability

Felix Figge, Katharina Schmitz

RWTH Aachen University, Institute for Fluid Power Drives and Systems (ifas)

felix.figge@ifas.rwth-aachen.de

Abstract.

The electrification of mobile machinery is advancing, with more machines now featuring battery-electric power sources. However, this shift often results in reduced energy availability and shorter operating hours before recharging is needed. This has led to increased interest in efficient systems driven by the need for energy conservation and emission reduction, alongside relevant legislation.

Traditional hydraulic systems in mobile machinery have demonstrated poor energy efficiency [1,2], highlighting significant improvement potential. Decentralized electro-hydraulic actuators (EHAs) consume less energy than conventional load-sensing systems [2,3], yet their adoption remains limited, possible due to higher costs, unwanted oscillations from mode switching, and increased spatial requirements.

To address these issues, an EHA with a high-speed internal gear unit and electronically controlled valves was developed. The design enables energy recuperation and load-holding while keeping costs low by using a single prime mover and hydraulic unit. High operational speeds reduce installation volume, and the used electronic valves facilitate a control strategy that synchronizes motor speed and valve positions as best as possible. Active hysteresis control and throttling minimize cylinder velocity deviations.

This paper presents the functional model of the EHA and its experimental validation through a hardware-in-the-loop (HiL) test rig. Predefined synthetic test cases are utilized to analyze quadrant switching, demonstrating effective velocity tracking, with minor deviations during transitions. Additionally, measured load cycles of an excavator indicate sufficient position tracking and high efficiency, especially when implemented on the boom.

Keywords. EHA, 4Q-operation, electrification, active throttling, hysteresis control

1. Introduction & State of the Art

Substituting the combustion engine is arguably the most significant change in mobile hydraulics in recent decades. Historically, most machines have utilized a centralized hydraulic pressure supply, with power distributed through fluid lines and valves to various

All Open Access articles are peer-reviewed, distributed under the Creative Commons Attribution-Non Commercial 4.0 International

actuators. While this approach is cost-effective in terms of initial component cost, it is relatively inefficient in terms of energy consumption. The different pressure levels required by the actuators during operation, combined with a single pressure supply, inherently result in significant throttle losses. This contradicts the common understanding of the need to conserve energy and reduce emissions, particularly in the context of the lower energy density and higher costs associated with alternative energy sources. Therefore, the hydraulic system of mobile machinery must become more efficient and sustainable.

Decentralized electro-hydraulic actuators (EHAs) can significantly reduce energy losses by using a dedicated pump for each actuator, eliminating throttling losses between varying pressure levels. However, despite their increasing use in stationary industrial applications, EHAs have not yet gained traction in mobile machinery. This is mostlikely due to higher initial component costs, increased installation space requirements, reduced damping linked to lower system losses, and more complex control software. The additional prime mover and hydraulic unit contribute significantly to the higher costs, while the larger footprint complicates integration into existing machines. Latter can be partly counteracted by an increase in rotational speed, reducing the volume of the electric motor and the displacement volume of the pump. Some research even attempted to increase the motor speed further by use of an intermediate gear [4]–[8].
Consequently, this research aims to develop a high-speed closed-circuit EHA for mobile machinery, featuring recuperation and load-holding capabilities, while also establishing the foundation for the necessary software implementation [9]–[12].

Closed-circuit electro-hydraulic actuators (EHAs) with a single pump may display undesirable behavior during quadrant transitions, such as oscillations and frequent mode switches. Pressure feedback is often used to increase the overall damping of the system [13,14], which is typically too low for optimal performance. Williamson and Ivantysynova [15] developed a predictive observer for feed-forward control of pump displacement in skid-steer applications, addressing excessive phase lag that hampers feedback control during mode-switching oscillations. They identified the interaction between moving mass and compressible fluid as a key issue, comparing it to a mass-spring-damper system [13,14].
To mitigate oscillations and prevent mode switches, increasing system damping through pressure feedback is recommended. Michel calculated maximum allowable acceleration to further prevent mode switches [14]. Wang et al. [16] employed electrically actuated proportional valves with a control algorithm to introduce leakage under critical conditions, selectively enhancing damping at low loads. Çalışkan et al. proposed a mechanical solution using an underlapped shuttle valve instead of electrical component [17]. Imam et al. introduced the ‘limited throttling valve’ designed to restrict cylinder outflow at low loads near critical operating conditions, demonstrating no oscillations in simulations [18,19]. This valve is designed to restrict cylinder flow only at low loads near critical operating conditions. Their simulation results show no oscillations under any operating conditions. They also demonstrate that applying different charge pressures to both sides of the cylinder can reduce the critical zone and oscillation amplitudes [19]. Costa and Sepehri [20] introduced a new four-quadrant definition based on cylinder load pressure rather than pressure difference over the pump. They concluded that this was the primary reason for the poor performance of previous circuits and introduced a new circuit that implements their quadrant definition.

However, Gøytil et al. [21] showed that the proposed circuit can still experience unwanted mode switches under certain conditions due to dynamic factors. They recommend using a software-based observer to calculate a modified force estimate, which determines valve states and mitigates these switches. This approach excludes forces from valve switching and acceleration but requires a minimum accumulator pressure of 30 bar to prevent cavitation, which may not be feasible for all circuits. Kärnell and Ericson [22] investigated hysteresis control to prevent unwanted mode switches. They concluded that pressures should be sensed so that the difference remains unchanged after a mode switch. Nevertheless, switches can still occur, but active hysteresis control reduces the risk if the reservoir pressure is sufficient.

The control approach discussed in this paper, first introduced in [9], utilizes the cylinder load pressure definition from Equation 1.1 [17,20] and implements active throttling [19,22] to enable complete coverage of the four quadrants for excavators. To minimize mode switches caused by minor pressure fluctuations, active hysteresis is incorporated [22]. Additionally, the approach minimizes cylinder velocity spikes during quadrant transitions by decoupling the cylinder from the pump using the load-holding valves.

$$p_{load} = p_{pist} - \alpha \cdot p_{rod} \tag{1.1}$$

The paper is structured as follows: Section 2 presents the circuit layout and functional model of the EHA, along with a summary of the control scheme. Section 3 introduces the experimental validation setup, and Section 4 presents the results and discussion.

2. DESIGN & CONTROL OF EHA

In this section, first, the design of the developed EHA and the assembled functional model are introduced. Secondly, the hardware-in-the-loop test rig used for validation of the EHA in all quadrants (Q1 to Q4) under a wide range of operational conditions is presented.

2.1. EHA Design

The EHA design under investigation, introduced in [9], is specifically tailored for mobile machinery integration, particularly excavators. Key requirements included minimizing initial costs, achieving a wide range of operating conditions with high efficiency, and enabling complete stoppage of the prime movers. As shown in the circuit layout at the top of Figure 2.1, the design features only a single prime mover, one pump, and a standard differential cylinder. The accumulator stores the differential cylinder volume by switching the 'differential' valves ($Diff_{pist}$ and $Diff_{rod}$). Load-holding capability is realized by two electric actuated proportional valves denoted LH_{pist} and LH_{rod}. The use of proportional valves is required to allow throttling of the cylinder outflow and thereby expanding the range of Q1 and Q3 operation, as detailed in [9]. Otherwise, throttling losses from the load-holding valves prevent high velocities in combinations with low assistive loads, compromising full four-quadrant operation essential for mobile machinery's variable working conditions.

The functional model of the EHA is shown at the bottom of Figure 2.1, with key components labeled. A PMSM electric motor was chosen for its low operating voltage (48 V) and maximum rotational speed of 7,200 rpm, constrained by inverter dual-use regulations. Due to the limited availability of motors that meet these criteria, the motor is oversized with a continuous power rating of approximately 10 kW. In contrast, the peak power output during

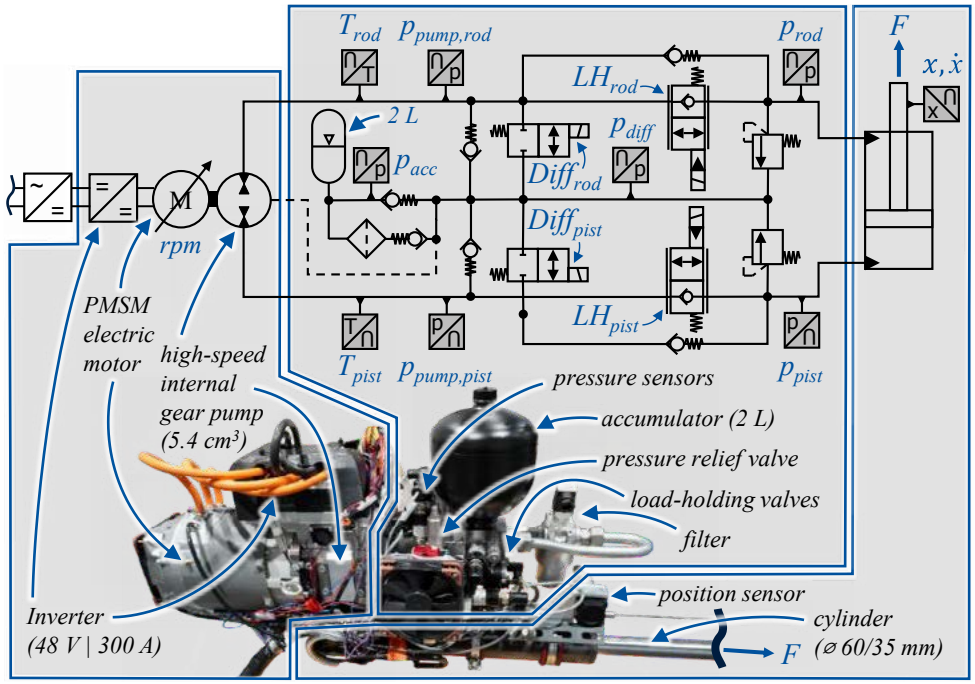

Figure 2.1. Circuit layout and functional model of the high-speed EHA

a dig and dump cycle on a 1.8-ton excavator's arm is around 4 kW. Consequently, software limits the motor's output to 6 kW to account for power losses. The hydraulic unit features an internal gear design with a displacement volume of 5.4 cm³ and is optimized for operation up to 10,000 rpm. The pump is flange-mounted to the valve block, compactly interconnecting it with the valves, sensors, and accumulator hydraulically. Additionally, check valves parallel to the load-holding valves prevent cavitation in the cylinder while another pair near the filter and accumulator directs flow through the filter.

To achieve high rotational speeds without cavitation, a minimum absolute inlet pressure of 1.2 bar is required at the pump. The accumulator serves two functions: it stores the cylinder's differential volume (0.358 L) and maintains this minimum pressure. However, the pump shaft seal limits the maximum pressure to 10 bar. To operate within a temperature range of -10°C to +60°C, the accumulator needs a nominal volume of 2 L, achievable only if check valves between the accumulator and pump inlet have minimal pressure drop. Higher pressure drops reduce the effective pressure difference, necessitating a larger accumulator volume for storage. Therefore, check valves are installed parallel to the load-holding valves to minimize pressure drop, allowing for a lower minimum accumulator pressure and increasing the maximum pressure difference, which reduces the required nominal volume.

2.2. Control scheme

The control scheme is presented and evaluated using simulations in [9]. The most important features are summarised briefly below.

The operating boundaries, which are shown in Figure 2.2, are based on cylinder friction ($p_{bound,fric}$), accumulator pressure ($p_{bound,acc}$), and the pressure drop over the load holding

valve ($p_{bound,valve}$) due to the circuit layout. The latter is problematic during motor operation due to the minimum pressure required for a given flow rate. High velocities cannot be achieved under low loads. However, since mobile machinery is used under a wide range of operating conditions that cannot be predicted in advance, an inoperative load-velocity combination is unacceptable. Therefore, the load pressure operating range of pump operation (Q1 and Q3) is expanded by actively throttling the cylinder outflow using proportional valves, in a manner comparable to metering-out systems. This enables displacement control in regions where valve losses would otherwise limit it. The aim is to maintain a fixed pressure difference over the load-holding valves using a characteristic field in combination with a PI controller. By engaging this only in regions close to the boundary, the influence on efficiency is minimized.

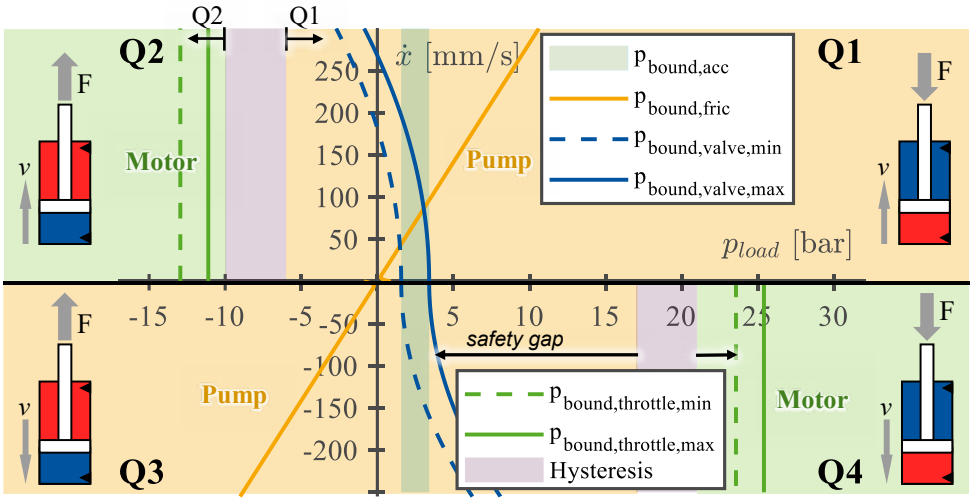

Figure 2.2. Quadrant definition used by the new control approach

However, switching from displacement to valve control still occurs at higher loads. This is denoted as the throttle boundary ($p_{bound,throttle}$) in Figure 2.2, where the 'min' and 'max' indices indicate dependency on the corresponding accumulator pressure limits. If the load pressure exceeds the current limit, the constant pressure difference request of the load-holding valves will cause the cylinder to accelerate. Therefore, switching to motor operation beforehand is necessary. Active hysteresis, marked in violet in Figure 2.2, is used to determine when the quadrant switch must be executed. During cylinder extension, mode Q1 is selected if the load pressure is above -10 bar. If the load pressure falls below this threshold, the system switches to mode Q2. Switching back to mode Q1 requires an increase in load pressure exceeding -6 bar. The positioning and width of the hysteresis band depend on the specific application and the optimization of performance. The configuration shown is for an excavator arm. Therefore, the hysteresis band is placed closer to the throttle boundary because the centre of mass generally does not cross top dead centre. This means that switches Q1→Q2 or Q3→Q4 generally do not occur. This placement enables operation under all working conditions and maximizes the safety gap, corresponding to the time between reaching a hysteresis edge and its corresponding boundary, during switches from Q2→Q1 and Q4→Q3. Thereby allowing more time for adjustment of valve positions.

The control scheme features two state machines. One determines the current operation quadrant based on the quadrant definition with active hysteresis, as shown in Figure 2.2. The other synchronizes motor speed and valve positions during quadrant switches. The hydraulic unit's volumetric efficiency, pressure feedback, and valve controllers are implemented to enable the different required valve modes, as well as to provide overload protection for the electric motor. A more detailed description is given in [9]. As described there, the control scheme used in this paper was improved to also allow for smooth transitions Q1↔Q3 with recuperation and improved pre-pressurization before motor operation.

3. EXPERIMENTAL VALIDATION

Experimental validation is performed using a hardware-in-the-loop test rig. The tests include synthetic test cases that focus on the quadrant switches, as well as different load cycles that validate the application's performance in excavators. Additionally, a quadrant-based efficiency map and the efficiencies under different load cycles are calculated.

3.1. Hardware-in-the-loop test rig

The hardware-in-the-loop (HiL) test rig, introduced in [23], primarily consists of two load cylinders and associated servovalves, as shown in Figure 3.1. The load cylinder rods are mechanically linked to the EHA cylinder rod via a movable crossbeam, enabling the application of pulling or pushing forces. The actual force on the EHA differs from the hydraulic force due to friction, which is measured by a load cell. While the friction forces from the load cylinders increase system damping compared to excavator applications and the moving mass of the Hil of roughly 100 kg is lower than that of an excavator arm, the HiL setup allows for repeatable and adjustable testing conditions for the EHA.

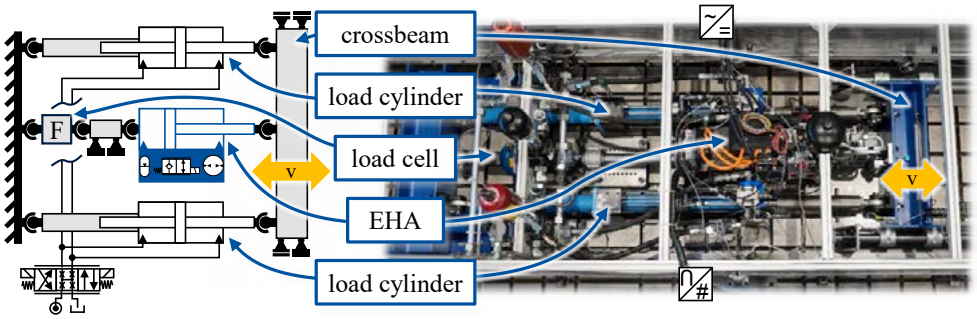

Figure 3.1. Hardware-in-the-loop (HiL) test rig (simplified hydraulic circuit layout)

Although controlling the HiL test rig is not the focus of this paper, a few important notes are provided below. The system is rather stiff due to the hydraulic tension between the load cylinders and the EHA, which complicates force control. Small errors in the flow rate of the valve-controlled cylinders result in significant force changes due to the system's high stiffness, which is caused by the bulk modulus of the oil. To achieve acceptable force control, it is necessary to predict the cylinder flow rate, and thus, cylinder velocity, to enable feed-forward control of the rough valve position. A PID controller then fine-tunes the position to achieve good force accuracy. However, for feed-forward control, simply calculating velocity by differentiating the position signal introduces lag due to the required

filtering. This lag results in temporary, large differences between the required and actual valve positions, leading to significant force deviations. Therefore, an approach is necessary that predicts cylinder movement based on pump speed and valve actuation. Valve actuation must be considered separately due to temporary switching to valve control of cylinder speed, for example, when stopping. A perfect prediction still was not achieved.

3.2. Synthetic test cases

The synthetic test cases examined are depicted in Figure 3.2 and are identical to those previously analyzed through simulations. The first test case is called 'velocity reversal', representing quadrant switches by reversing the direction of movement under constant load force F. The second test case entails a force reversal, which linearly alters the load force during movement at a constant velocity. Here, F_{mean} represents the midpoint of the hysteresis band, and ΔF is half the change in force over a duration of 0.5 seconds.

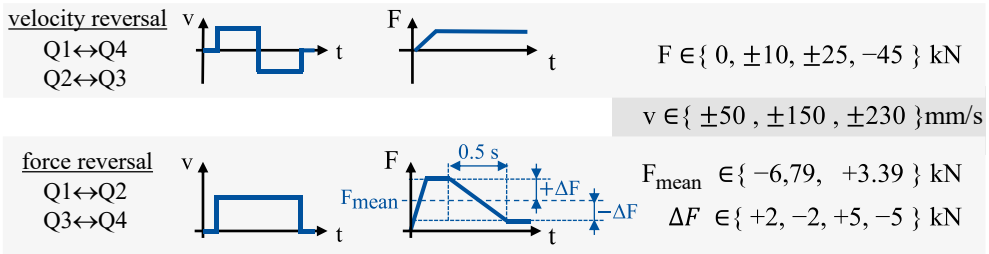

Figure 3.2. Synthetic test cases

3.3. Load cycles

The authors had access only to a measured dig and dump load cycle of a 1.8-ton excavator. To evaluate the EHA under a broader range of working conditions, load cycles from the STEAM research project were scaled to fit within operational limits:

1. The load pressure profile is scaled to not exceed the maximum operational pressure.
2. The cylinder position is filtered and differentiated to obtain the velocity profile, which is then scaled to remain within the maximum operational velocity.
3. By integrating the scaled velocity profile, a new cylinder stroke profile is generated.
4. If the cylinder end stops are reached, the time is adjusted to reduce the duration of EHA movement, thereby decreasing the maximum stroke.

It is important to note that this approach modifies not only the absolute values of the profiles but also their gradients. However, these profiles remain related to the measured data, and such alterations appear acceptable given that profiles can vary significantly between different machines as well as depending on current work conditions and operator actions.

4. RESULTS & DISCUSSION

The cylinder velocity in the following results is calculated by filtering the measured position signal. A significant challenge in evaluating performance is achieving operator acceptance during EHA operation, which is inherently subjective. The authors were unable to identify a meaningful method to assess this type of acceptance for mobile machinery and strongly recommend that it be evaluated separately. Consequently, the performance rating in this paper is based on the calculated velocity and the authors' considerations.

4.1. Test cases

Figure 4.1 displays the results of the velocity reversal test case. The results are divided into six subgroups based on the initial velocity. The top graph in each group displays the cylinder velocity, and the bottom graph shows the calculated hydraulic force based on the load pressure and the cylinder piston area. Positive force values represent a pulling force at the cylinder.

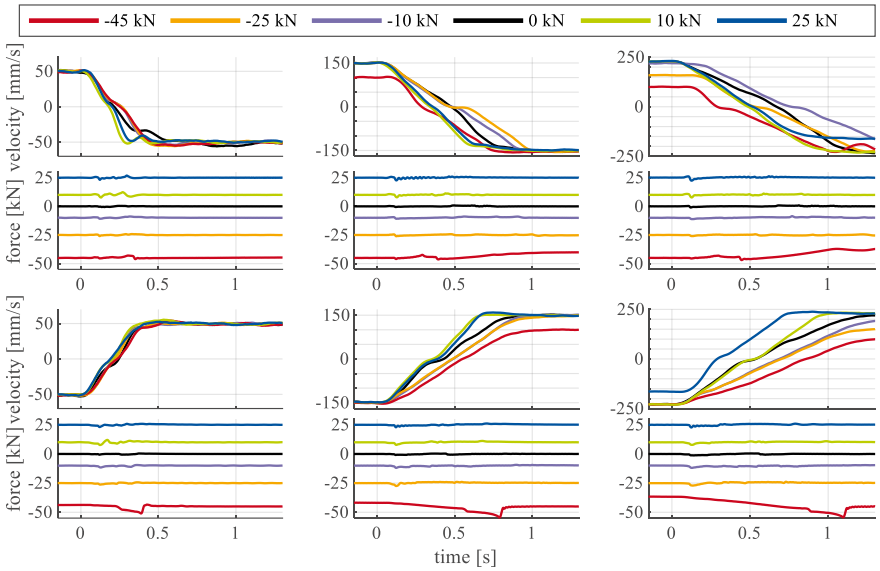

Figure 4.1. Experimental results for test case 'velocity reversal' (force based on p_{load})

As intended, the forces during the reversal are constant, except for the -45 kN case, which shows smaller deviations. As can be seen from the velocities, high velocity and load combinations result in a power limitation of the motor and, therefore, a smaller-than-requested cylinder velocity. Negative forces correlate with a loaded piston side, requiring higher flow rates and rotational speeds. Therefore, the torque capacity of the electric motor is reduced further, resulting in slower acceleration and deceleration. The top group of graphs represents positive initial velocities. As expected, a linear velocity change is achieved for positive pulling forces (Q2→Q3) and zero load (Q1→Q3). For negative forces (Q1→Q4), the designed rest phase, which allows time for LH_{rod}, $Diff_{rod}$, and LH_{pist} to open and close, respectively, can be seen at about zero velocity.
The bottom group represents negative initial velocities. For these, a negative pushing force (Q4→Q1) results in a linear velocity change. Positive forces (Q3→Q2) and no load (Q3→Q1) demonstrate the intended rest state, allowing time for LH_{pist} to open and LH_{rod} and $Diff_{rod}$ to close.

In conclusion, the velocity reversal test cases show the desired and expected behaviour. The velocity reversal is smooth and does not show strong oscillations.

The results for the 'force reversal' test case are displayed in Figure 4.2, grouped by the corresponding quadrant switch. The graphs on the left side show results for zero load. In contrast to the velocity reversal, larger deviations from the set force (dashed black line) are

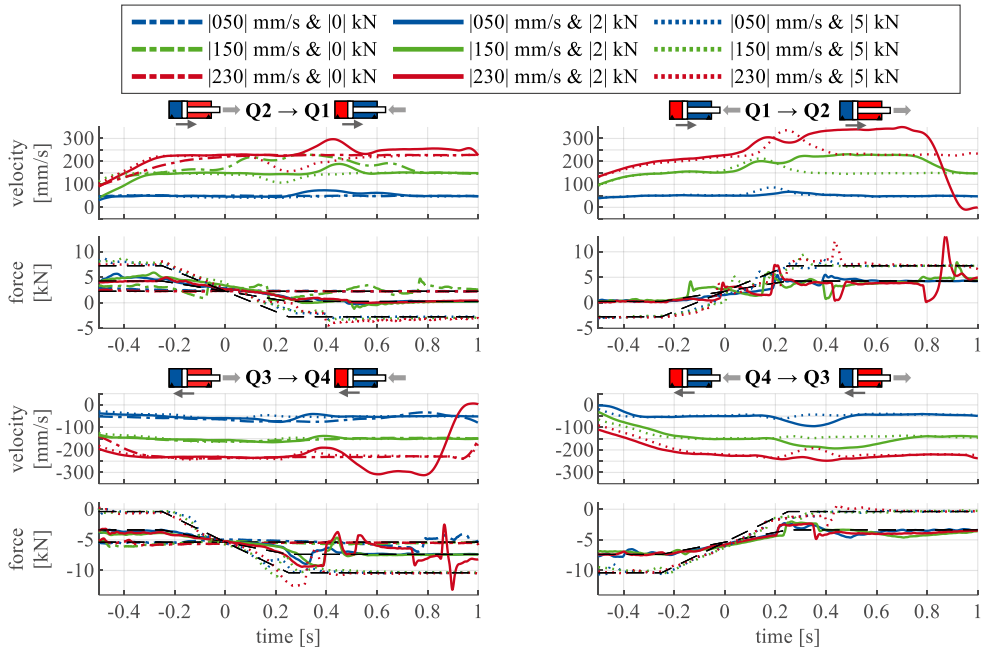

Figure 4.2. Experimental results for test case 'force reversal' (force based on p_{load}) (set force marked with a black dashed line)

evident in some test cases, particularly during Q1→Q2 and Q3→Q4 at high velocities. The interaction between the EHA and force control of the HiL during initial switches leads to deviations so significant that they can trigger additional switches.
As previously mentioned, force control in the HiL is challenging due to system stiffness combined with changing valve states, making it difficult to accurately identify the root cause of these deviations. However, despite these challenges, good velocity tracking is achieved when examining the velocity graphs of cases with effective force tracking.

For switches Q2→Q1, the no-load case at 150 mm/s stands out as an outlier in terms of velocity tracking, which can be attributed to mode switches resulting from poor force tracking. In contrast, the other no-load test cases demonstrate good tracking. When force changes of 2 kN occur, short and minor overshoots are observed due to the motor speed increasing while still supporting some cylinder load, coupled with the valve not being in the correct throttling position because of its dynamics. At higher change rates, the force begins to slow down the cylinder sooner, and the pump speed fails to increase quickly enough to supply the required power. Consequently, deviations increase with rising cylinder velocity due to heightened friction.
During the Q1→Q2 switches, initial overshoots are observed due to the assistive load accelerating the cylinder before displacement control is reestablished through a slowdown of the hydraulic unit. Faster force changes lead to greater deviations because of increased acceleration, while not under displacement control.
Q3→Q4 switches show small negative deviations at lower velocities and smaller load changes. This is attributed to the assistive load still being applied while the valve lags before throttling and slowing down the cylinder.

For Q4→Q3 switches, overshoots appear for small force change rates, again due to assistive load being applied and valve lagging before throttling can slow down the cylinder. The prolonged deviation at -150 mm/s with 2 kN can be traced back to an extended adjustment period of the valve position by the PI controller, likely resulting from inaccuracies in the characteristic field that necessitate longer adjustments.

The results for most cases qualitatively match the simulation results presented in [10]. Exceptions include the Q2→Q1 switches with slow change rates, which show an overshoot instead of the simulated undershoot, and the Q1→Q2 switches with slow change rates, where experimental results reveal an overshoot while simulations indicate almost no deviation. These discrepancies may stem from differences in moving mass and friction between the simulation and the hardware-in-the-loop (HiL) test rig.

In conclusion, the force reversal test cases demonstrate that quadrant switches, excluding those with problematic force application due to coupling between HiL and EHA, can be executed with only short and limited deviations in the velocity profile. Although perfect tracking is unattainable due to valve lag and rotational speed adjustments, it has been demonstrated that the developed control scheme can effectively mitigate the severity of these issues.

4.2. Efficiency map

Figure 4.3 shows the efficiency map of the EHA, which was calculated based on measurements taken under quasi-stationary conditions. The cylinder is loaded, accelerated, and stopped again. Due to the limited cylinder stroke, the 400 ms period before deceleration is evaluated. The efficiency is interpolated between the marked measurement points, resulting in anomalies at the outer edges of the efficiency field due to the algorithm used. Additionally, reduced motor performance is evident at higher speeds in Q1, Q3, and Q4. Efficiency is calculated using Equation 4.2, which considers mechanical (Equation 4.3), electrical (Equation 4.4), and hydraulic energy from the accumulator (Equation 4.5). Therefore, all system losses, including those of the inverter, electric motor and cylinder, but excluding those of the valve actuation, are considered. Depending on the sign of the total transferred energy, the different parts are considered output or input in Equation 4.2.

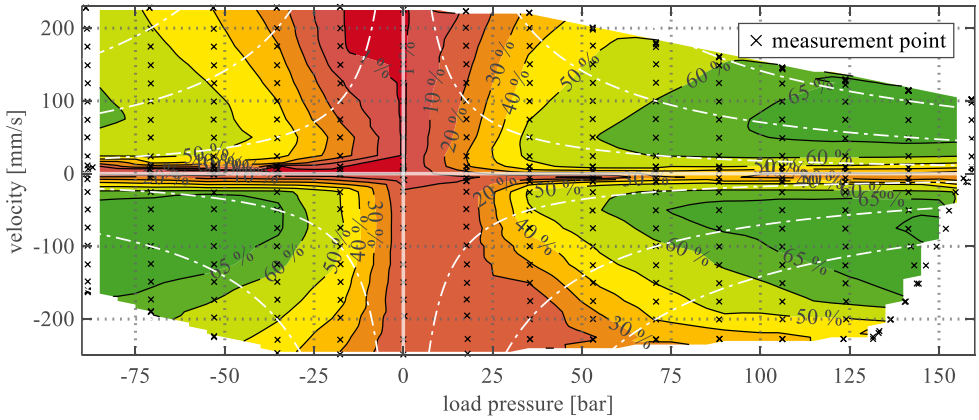

Figure 4.3. Efficiency map of the EHA (isolines for cylinder power neglecting friction of 0.5, 2 & 4 kW)

$$\eta = \frac{E_{out}}{E_{in}} \tag{4.2}$$

$$E_{mech} = \int F_{cyl} \cdot v_{cyl}\, dt \tag{4.3}$$

$$E_{elec,powersupply} = \int U_{sup} \cdot I_{sup}\, dt \tag{4.4}$$

$$E_{acc} = \int Q_{acc} \cdot p_{acc}\, dt \quad \text{with} \quad Q_{acc} = (A_{pist} - A_{rod}) \cdot v_{cyl} \tag{4.5}$$

Except for Q2, the highest efficiencies per quadrant exceed 65% for moderate velocities and high loads. The added isolines for cylinder power outputs of 0.5 kW, 2 kW, and 4 kW indicate that areas with poor efficiency correlate with low power transfer, resulting in minimal absolute power loss. The regions of low efficiency at low loads in Q2 and Q4 correspond to the expanded areas in Q1 and Q3, where a significant portion of energy input is lost due to active throttling. In Q2 at high velocities, there is no power output from the cylinder due to friction; instead, all power input from the pump and accumulator is converted to heat. In contrast, Q4 exhibits higher efficiency because the accumulator is charged.

The impact of load-holding valve losses, along with cylinder and pump friction at higher speeds, is evident. The pressure difference across the load-holding valves is particularly relevant in Q1 and Q3, as it remains constant, leading to linear increases in losses with increasing cylinder velocity. Interestingly, efficiencies in Q1 and Q4 are comparable; however, this is not the case for Q2 and Q3. This discrepancy most likely arises from the interplay between the hydraulic unit's efficiency and the efficiency of energy storage in the accumulator. In Q2, these effects negatively combine, while in Q4, the higher efficiency of energy storage counteracts the lower motor operation efficiency.

4.3. Load cycles

Figure 4.4 shows the results of the 1.8-t dig and dump cycle. The results are limited to the first 13 seconds to allow for a higher level of detail. A simple outer PI controller was added to adjust the requested speed, which was calculated offline beforehand, based on the deviation between the requested and current position during the tests. These values, as well as accumulator pressure, are shown in graph 1 (see grey box in Figure 4.4). A maximum RMSE of 75.45 mm and an ITAE of 34 ms^2 are achieved over the 55 second cycle. The deviations can be traced back to the cylinder velocities shown in graph 5. There is a delay between the request and the actual velocity. Examining the deviation between the cylinder velocity based on the actual pump speed, neglecting volumetric efficiencies (f(rpm)), and the current cylinder velocity, it can be concluded that the displacement control is functioning as intended. However, especially during deceleration phases, which are not subject to delays by the control scheme, a delay of up to 200 ms can be observed between the cylinder speed request and the rotational speed adjustment. Approximately 50 ms of this delay is related to the time between the speed request and the motor's rotational speed adjustment.

Graph 2 illustrates the pressures in the cylinder chamber and the hydraulic unit ports. Following each entry into a quadrant (as shown in Graph 3), higher pressure levels are initially observed due to the delayed adjustment of the load-holding valve position. This phenomenon is further evidenced in graph 4, which displays the adjustment of current over

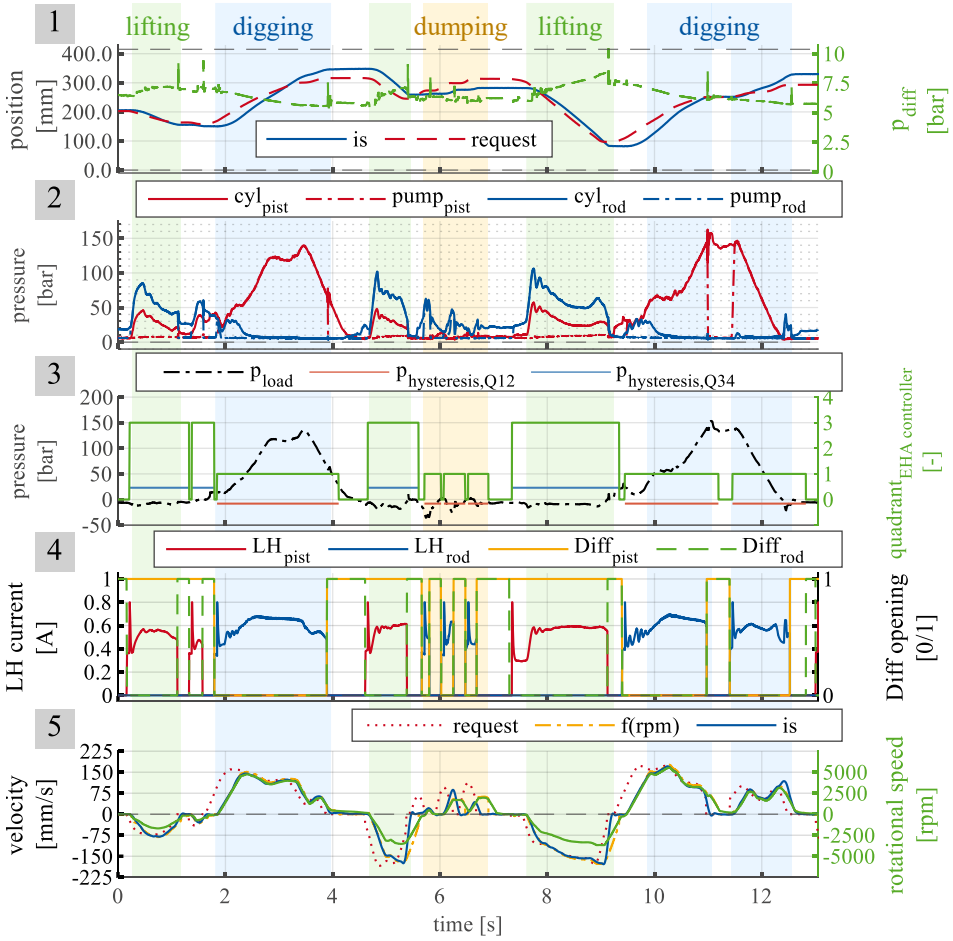

Figure 4.4. Experimental results of the 1.8-t excavator dig and dump cycle with outer position controller

time alongside the actuation signal of the differential valves. The initial peak in the actuation signal for the load-holding valves at maximum current is designed to open the valve promptly, preventing hydraulic tensioning of the cylinder caused by obstructed outflow.

Shortly after 6 seconds and again at 12 seconds, peaks in the cylinder velocity request are observed. At these moments, the cylinder speed exceeds that based on pump speed, indicating a loss of displacement control. During these instances, the load pressure drops below the hysteresis band between Q1 and Q2, as shown in Graph 3. This triggers a mode switch towards the motoring quadrant (Q1→Q2), which is associated with an overshoot, as previously illustrated in Figure 4.2.

It is important to note that the load cycle was measured in a valve-controlled system. The measured load is applied based on time without feedback from the cylinder position. Consequently, some working conditions may differ when implemented on a real excavator due to changes in system response. Nevertheless, the overall tracking of the reference load

cycle is achieved, albeit with some deviations primarily attributed to initial delays inherent in the control scheme and partially due to delays in the motor response.

The authors acknowledge their lack of a meaningful metric for assessing performance in the context of mobile machinery. A review of existing research on teleoperation, as referenced in [24], indicates that latencies below 250 ms or 300 ms are acceptable, with less than 170 ms being preferable for autonomous vehicles. Ideally, the time between input and output should be under 80 ms. While direct transfer may not be entirely suitable, the delays experienced by the EHA generally fall within an acceptable latency range; however, input-output delays occasionally exceed this threshold.
Given that operators can adjust for these delays, the successful application of this technology in an excavator appears feasible. Nonetheless, further testing with real human operators in an excavator is necessary and recommended to gather subjective feedback.

The efficiency of the developed EHA is evaluated based on the available load cycles. The energy transfers considered include electrical energy from the DC side of the power supply, hydraulic energy from the accumulator, and mechanical energy from the cylinder. Energy transfer is aggregated for input and output per system boundary by calculating power transfer at each sample point, multiplying it by the time difference between samples, and then summing all negative and positive values separately (eq. (4.3)-(4.5)). Since operation during the cycles is not quasi-stationary, the flow rate is estimated based on current quadrant operation and valve actuation, which introduces some inaccuracies due to partially open valves and volume changes resulting from compression.

As discussed in [11], there is currently no consensus on how to calculate the efficiency of systems with recuperation capability. Therefore, Table 4.1 presents three different definitions based on the experimental results from the adjusted STEAM load cycles, along with the calculated energy transfers and total energy loss. The very limited bucket movement during air grading leads to questionable efficiency results.

Table 4.1. Transferred energies (negative values exiting the system), efficiencies and dissipation ratios for the adjusted 18-t STEAM load cycles per actuator

	Dig and dump			**Air grading**			**Excavating**		
	boom	arm	bucket	boom	arm	bucket	boom	arm	bucket
$E_{cyl,out}$ [kJ]	-144.3	-24.9	-50.5	-55.0	-0.7	-0.04	-69.2	-41.1	-34.3
$E_{cyl,in}$ [kJ]	113.8	21.5	9.5	48.6	7.6	0.26	65.1	4.5	10.0
$E_{elec,in}$ [kJ]	237.2	122.5	168.0	88.9	51.2	0.66	127.0	129.5	115.0
$E_{elec,out}$ [kJ]	-53.9	-21.3	-7.7	-30.2	-7.9	-0.08	-39.3	-10.1	-6.3
$\sum E_{acc}$ [kJ]	-0.88	-2.04	-0.75	-0.06	-0.88	-0.05	-0.50	-0.38	-0.66
E_{loss} [kJ]	151.8	95.7	118.5	52.3	49.3	0.75	83.2	82.3	83.8
$\eta_1 = \frac{\lvert E_{cyl,out} \rvert}{\sum E_{elec} + \sum E_{acc}}$	79.1 %	25.1 %	31.6 %	93.7 %	1.6 %	*8.1 %*	79.3 %	34.5 %	31.7 %
$\eta_2 = 1 - \frac{E_{loss}}{E_{elec,in} + E_{acc,in} + E_{cyl,in}}$	57.1 %	33.9 %	34.2 %	62.3 %	16.6 %	*19.3 %*	57.1 %	39.3 %	33.9 %
$DR = \frac{E_{loss}}{\lvert E_{cyl,out} \rvert + \lvert E_{cyl,in} \rvert}$	0.59	2.06	1.98	0.50	5.98	*2.48*	0.62	1.81	1.89

The first definition, η_1, considers only the positive cylinder output in relation to the total energy input. The second definition, η_2, incorporates the energy input of the cylinder by

relating energy loss to the sum of positive energy inputs. Lastly, a new key performance indicator, termed ‘dissipation ratio’ (DR), is introduced as the ratio of power loss to the absolute value of transferred cylinder energy [10]. The dissipation ratio effectively addresses issues associated with the cancellation of energy transfers in other definitions, which can result in negative or misleading efficiency values. It is important to note that smaller dissipation ratio values indicate higher efficiency due to reduced energy loss, while ratios exceeding one may also occur.

The results clearly indicate that the highest efficiencies, regardless of the definition used or the load cycle analyzed, are achieved for the excavator boom. The boom also exhibits the highest energy inputs from the cylinder for all load cycles, likely due to the supported mass consisting of the boom, arm, and bucket. The substantial energy inputs correspond with high electric energy outputs. However, this very electric energy output is responsible for the previously mentioned cancellation in the denominator of efficiency definition one, which can theoretically lead to an efficiency value exceeding one.

Table 4.2 presents the efficiency η_2 and dissipation ratio (DR) results for various linear scalings of the velocity and load of the 1.8-ton dig and dump cycle. For both definitions, efficiency increases with higher loads, as smaller DR values correspond to higher efficiency. This trend aligns with the efficiency map shown in Figure 4.3, which indicates that efficiency improves with increasing loads. Conversely, a decrease in efficiency is typically expected at higher velocities; however, η_2 shows an increase instead. This phenomenon occurs because energy is stored in the drive train's inertia during acceleration, resulting in a higher electric energy input (denominator). During deceleration, this energy is converted back into electric output (numerator), resulting in a shift toward higher ratios. This highlights a misleading result that can arise from current efficiency definitions. In contrast, the dissipation ratio behaves as expected, decreasing with greater loads and increasing with higher velocities, except for a minor decrease at higher loads and lowest velocities, which might be the result of higher friction at lower speeds as well. Thereby validating its role as an appropriate key performance indicator for systems with recuperation capability.

Table 4.2. Efficiency and dissipation ratios for the scaled 1.8-t dig and dump cycle

	$\eta_2 = 1 - \frac{E_{loss}}{E_{elec,in} + E_{acc,in} + E_{cyl,in}}$				$DR = \frac{E_{loss}}{\lvert E_{cyl,out}\rvert + \lvert E_{cyl,in}\rvert}$

5. CONCLUSION & OUTLOOK

This study presents a newly developed EHA that incorporates a high-speed internal gear unit and a differential cylinder, enabling recuperation and load-holding capabilities. The EHA was experimentally tested in a hardware-in-the-loop test rig and specifically sized for use in an 1.8-ton excavator. The design focuses on a novel control approach that aims to minimize velocity deviations during quadrant switches through active throttling and active hysteresis.

Performance validation during quadrant switches was achieved using specially designed test cases. Under varying loads, the actuator demonstrated smooth cylinder velocity without oscillations when changing direction of movement. When the load direction changed during a constant velocity request, corresponding to an operational quadrant shift, only short and limited velocity deviations occurred, despite adjustments to valve positions and motor speed.

The tracking of a measured dig and dump cycle for the 1.8-ton excavator is sufficnet for use in excavators, although some deviations between the requested and actual positions were noted due to delays inherent in the control scheme. The efficiency of the EHA under tested working conditions reached 65% in three of the four quadrants, with an overall maximum efficiency of 70%. Analysis based on three downscaled load cycles (dig and dump, air grading and excavating) for an 18-ton excavator load cycles concluded that the highest efficiency, regardless of load cycle or energy efficiency definition, was achieved by the boom actuator.

Additionally, it was highlighted that current efficiency definitions often neglect energy stored in the drive train, resulting in misleading results. In contrast, a new key performance indicator introduced by the authors, termed ‘dissipation ratio’, more accurately reflects true system performance.

This contribution shows the high potential of the new EHA design and control approach. Future works include the implementation of the EHA on a real excavator to assess operator acceptance, address challenges related to force control in hardware-in-the-loop testing, and evaluate the interaction between excavator kinematics and the EHA.

6. ACKNOWLEDMENT

The IGF research project ‘22246 N / 1’ of the research association Forschungskuratorium Maschinenbau e. V. – FKM, Lyoner Straße 18, 60528 Frankfurt am Main was supported from the budget of the Federal Ministry of Economic Affairs and Climate Action through the DLR within the scope of a program to support industrial community research and development (IGF) based on a decision of the German Bundestag.

Biographies

Felix Figge received the bachelor's degree in mechanical engineering with a specialization in design methodology in 2019 and the master's degree in mechanical engineering with a specialization in product development in 2021, both from RWTH Aachen University. He is currently working as a Research Associate at the Institute for Fluid Power Drives and Systems (ifas), RWTH Aachen University. His research encompasses fluid power systems in general but focuses on the development of an electro-hydrostatic actuator for use in mobile machinery.

Prof. Katharina Schmitz studied mechanical and chemical engineering at RWTH Aachen University and Carnegie Mellon University, Pittsburgh (USA) and graduated in 2015 as Dr.-Ing. at RWTH Aachen University. Since 2018, she is full professor at RWTH Aachen University and director of the Institute for Fluid Power Drives and Systems (ifas). In addition, she is Vice Dean of the Faculty for Mechanical Engineering at RWTH Aachen, a position she holds since 2020. Prof. Schmitz’s awards and honors include several best paper awards and 2023 IMechE Joseph Bramah Medal award.

Beyond PFAS: Challenges and Opportunities in Material Innovation for replacing PTFE in Hydraulic Seals

Niklas Bauer, Gonzalo Barillas, Jürgen Hieber, Martin Goerres

Freudenberg Sealing Technologies GmbH, Corresponding Author: niklas.bauer@fst.com

Abstract.

The European Chemicals Agency (ECHA) is currently evaluating a proposal to eliminate all nonessential uses of per- and polyfluoroalkyl substances (PFAS) as many of these substances are classified as potentially carcinogenic. A partial or complete ban on PFAS could severely impact many branches of industry as PFAS are widely used in a variety of applications. Nowadays, PFAS are also used in critical components of fluid power systems. One of the most important PFAS in fluid power applications is PTFE which is used e.g. in many piston and rod seals of hydraulic cylinders. The PFAS ban which is currently being discussed could also lead to severe restrictions on using PTFE seals in fluid power applications.

As a sealing material, PTFE combines many favorable properties, especially a very high temperature resistance, low stick-slip friction, low wear and excellent media compatibility. Therefore, a ban of PTFE seals would deprive hydraulics of one sealing material with a unique combination of properties.

In this paper, we present an overview of the challenges associated with replacing PTFE with an alternative material and discuss polyurethane as an alternative material for piston and rod seals in hydraulic cylinders. An evaluation of a PU and a PTFE piston seal shows that the investigated PU seals reached superior friction, leakage and endurance behavior for the investigated operating conditions, indicating that the selected polyurethane is a viable alternative even for hydraulics with high pressures and high temperatures.

Keywords. Hydraulics, PFAS, Piston Seal, Polyurethan, PTFE, Tribology.

1. INTRODUCTION

Since 2023, the proposal by the European Union and other international authorities to regulate PFAS chemicals has been causing discussions about the impact of upcoming regulations in almost all industrial sectors. PFAS are part of many industrial and everyday products like frying pans and raincoats. For fluid power PFAS can occur among others in lubricants, hydraulic oils and seals. Seals are functionally critical and often life time determining components of all fluid power systems. Therefore, this paper focuses on

All Open Access articles are peer-reviewed, distributed under the Creative Commons Attribution-Non Commercial 4.0 International

alternatives to PFAS materials on hydraulics seals. The scope of this paper is the evaluation of an alternative material to PTFE as one highly performant sealing material.

This paper starts with a brief overview of the current status of the regulations. After that, the unique properties of PTFE are outlined and discussed with respect to the demand of hydraulic seals. After that, polyurethane (PU) is proposed and investigated as an alternative material for hydraulic applications. The performance of different PU materials regarding temperature and media resistance for hydraulic applications is compared to select one especially suitable material for experimental comparison to PTFE in terms of friction, leakage and endurance.

2. PFAS IN THE CONTEXT OF FLUID POWER SEALS

In this chapter, a brief overview of the timeline of the PFAS regulation in the EU will be given. Afterwards, the possibly affected substances in hydraulic sealing systems and their unique properties will be briefly highlighted. Focusing on PTFE, as an exemplary component and material, typical hydraulic seals within a cylinder are discussed with respect to the required material properties.

2.1. Regulatory Background

The European Chemicals (ECHA) has proposed a regulation for the substance class of per- and polyfluoroalkyl substances (PFAS). PFAS denote “any substance that contains at least one fully fluorinated methyl (CF3-) or methylene (-CF2-) carbon atom (without any H/Cl/Br/I attached to it)” [1]. Since then, an updated restriction proposal has been published [2], in which sealing applications are named as an evaluated sector. Outside the EU, different PFAS regulations are also in discussion or under effect, e.g. in Japan, China, Canada and different states of the USA – the timeline and affected substances differ from region to region. The timeline of the PFAS regulations in the EU is shown in Figure 2.1.

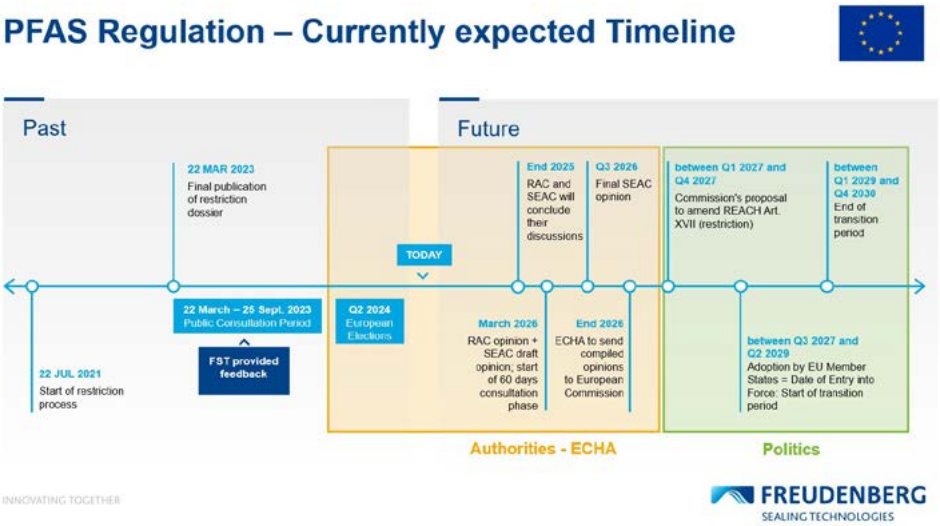

Figure 2.1. Expected Timeline for PFAS regulations [3] as of end of 2025.

As shown in the timeline above, the restriction process takes several years to go from initial proposal until it takes effect. This is partially due to the high number and huge diversity of different existing substances. The OECD discussed and propose different categories to distinguish between different groups of PFAS [4]. A discussion of different grouping strategy is discussed by Cousins et al [5]. They compare several approaches for grouping PFAS and evaluating the effects and adequate measures for restriction of these groups. The discussed grouping strategies range from a general approach covering all PFAS up to approaches differentiating between intrinsic properties such as mobility in water or approaches based on risk assessment such as toxicity.

One common differentiation that is often used in the public discussion between manufacturers and customers is the classification of PFAS based on polymeric and non-polymeric PFAS. For most sealing applications, polymeric PFAS are covering the most important materials such as plastics like PTFE, PVDF, PFA, rubbers like FKM, FFKM, FVMQ and base oils like PFPE. The category of non-polymeric PFAS covers substances with small molecules such as gases for refrigerants, foaming agents and liquids like fire fighting foams or coatings in textiles. The most important non-polymeric PFAS for sealing applications are fluorinated surfactants used as process aids in the manufacturing of polymeric PFAS like FKM. In case of a differentiation between polymeric and non-polymeric PFAS, where only non-polymeric PFAS would be affected, it is possible to adapt the manufacturing processes in order to evade the usage of these non-polymeric PFAS. This transitioning is already being made by suppliers of FKM materials.

2.2. Use of PFAS in Sealing Systems

In fluid power sealing systems, the most important substances are the fluorinated elastomers FKM and FFKM, the fluorinated silicones FVMQ as well as Polytetrafluoroethylene (PTFE). Their unique combination of high temperature stability media resistance and low friction and wear makes them an attractive material for a variety of applications ranging from transportation, food & beverage to fuel cells or batteries [6]. The material compatibility of materials and fluids is typically evaluated using insertion tests as shown for hydraulic fluids and bio-hybrid fuels e.g. in [7] and [8]. A comparison of the temperature stability and swelling behavior is given in Figure 2.2.

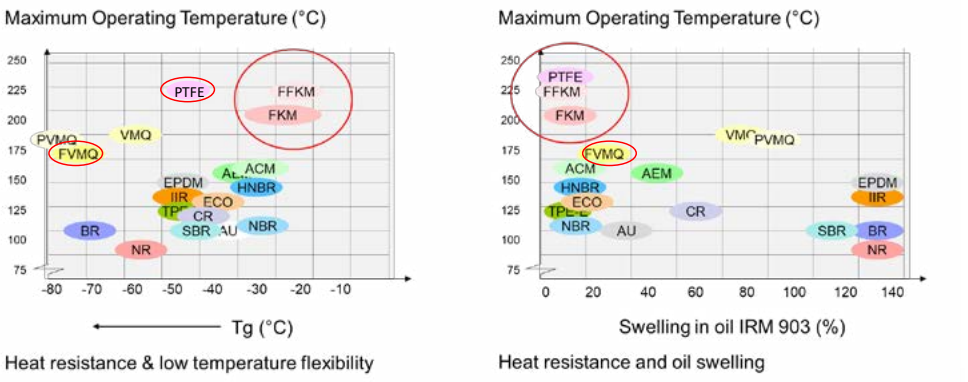

Figure 2.2. Classification of elastomer materials according to ASTM D2000 / SAE J200 PFAS substances are highlighted [6].

As seen in Figure 2.2, simply replacing all PFAS containing materials with other currently available materials would cause a loss in functionally relevant properties potentially leading to shorter maintenance intervals, premature failure of sealing systems as well as leakage of potentially hazardous fluids into the environment. Especially in the aerospace and chemical industry e.g. for processing aggressive chemicals or in the pharmaceutical and medical industry where in dosing applications the seals have to withstand both the medications and the fluids and conditions used in the cleaning and sterilization cycles. In addition, seals in medical applications have to undergo an extensive certification according to international standards such as EN ISO 10993-5:2009. [6]

The beneficial properties of PFAS containing materials for sealing applications can be summarized as follows: [6]

- High wear resistance
- Low friction coefficient
- High temperature stability
- High media resistance
- Low swelling in contact with fluids
- Permeation tightness for gases
- Compliance with industrial standards for medical safety

2.3. Typical Fluid Power Seals

In typical fluid power applications, several seals can currently contain PFAS materials. These include both rod and piston sealing package in hydraulic cylinders (wipers, rod seals, guide rings, buffer seals, piston seals), see Figure 2.3, as well as static seals and rotating seals (e.g. swivel seals and rotary shaft seals). For pneumatic applications, similarly both static and dynamic seals can be affected by possible regulations.

Figure 2.3. Typical sealing system of a hydraulic cylinder.

The main materials include FKM and FFKM, e.g. for static seals and preloading element in two-piece hydraulic seals, and PTFE mainly used in profile rings for profile rings in two-piece hydraulic seals. For illustration purposes, some typical designs[1] of hydraulic rod seals are shown in Figure 2.4. The first seal consists of just one piece which gets deformed when exposed to a pressure difference so that the contact pressure increases at higher operating pressures. The preloading of the seal results from the interference of the flexible seal with housing and rod. The second seal consists of two parts: a profile ring which has a similar function as the aforementioned one-piece seal and the back-up ring which reinforces the seal against gap extrusion. The third design shown also consists of two parts. However, here the profile ring gets reinforced by a preloading element (such as an O-Ring or a metal spring).

The first and second of the shown designs typically use polyurethane for the profile ring because of the required flexibility to preload the sealing contact. The back-up ring typically consists of a thermoplastic polymer. Thus, the first and second kind of seals do usually not contain PFAS materials. For the third option shown, PU, PTFE or thermoplastic polymers such as PA can be used for the profile ring. The preloading element typically consists of an elastomer part made from NBR or FKM or a metal spring. In conclusion, mainly the third kind of rod seals could be affected by PFAS regulations, as here both profile ring and preloading element can contain PFAS material if they are made from PTFE or FKM, respectively. Due to the lack of flexibility of PTFE, it is not used in seal designs where flexibility of the profile ring is required.

[1] These three designs are the most typical designs to occur in hydraulic applications with average diameters and operating conditions. For special applications e.g. special media, high temperatures, large diameters or special requirements, other seals like PTFE V-packings are also used but will not be covered in this paper.

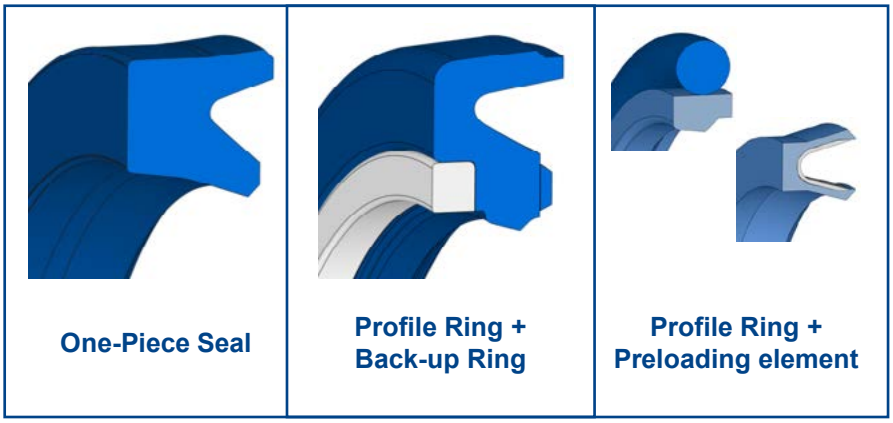

Figure 2.4. Different Seal Designs for Rod Seals.

Although slightly different in shape, similar designs to the ones shown in Figure 2.4 are also used for piston seals. For wipers, PU and elastomers like NBR and FKM are the most common material, however two-piece versions with PTFE and an elastomeric preloading element are also used. For guide rings, either PTFE or fabric-based laminate e.g. consisting of cotton-based fabric and a phenolic resin is used.

2.4. Material Requirements of Fluid Power Seals

When comparing the abovementioned strengths of PFAS containing materials with typical demands of fluid power applications (hydraulics and pneumatics) it becomes evident that not all of the properties are equally relevant for hydraulic applications. Whilst high wear resistance and low friction are still desirable properties of a seal in a hydraulic system, the importance of the other benefits is typically lower than in the previously mentioned highly demanding applications:

The temperature range in a hydraulic system is considerably lower, also because other components limit the ideal operating conditions (e.g. the degradation of mineral oils due to high temperatures as well as the temperature stability of the hoses and accumulators). Thus, the recommended maximum system temperature of a typical hydraulic system is less than 80°C [9], whereas typical stationary temperatures for mobile and industrial hydraulic applications range at around 40 to 60°C [10]. For aerospace applications, the occurring temperatures may vary.

The media resistance and low swelling has to be considered when choosing seals in fluid power applications. Similar to hydraulic systems, in pneumatic systems the seal only gets in touch with the lubricating grease[2]. For pneumatic systems, a good compatibility with the grease is important. In hydraulic systems the only media in contact with the seals is the hydraulic fluid itself (potentially containing entrained air and water). Due to the high effort

[2] Some greases in pneumatic applications contain PFAS themselves. For designing a sealing system without PFAS containing materials, the interaction of grease and sealing material has to be carefully considered. Due to the scope of this paper, only PFAS in the sealing material itself are taken into account here.

of changing the oil type of a complete hydraulic system, a hydraulic system mostly sticks to one type of oil. This means that far less media get in contact with hydraulic seals during their lifetime than seals in other applications e.g. in chemistry. However, the compatibility of sealing material and fluid is still crucial and cannot necessarily be taken for granted for all combinations of hydraulic fluids and sealing materials. Experimental results for the media compatibility of selected materials are shown in chapter 3.

The permeation tightness for gases is not important in typical fluid power applications. The compliance with medical safety is not important for most hydraulic systems. For pneumatic systems, the importance of compliance heavily depends on the application.

3. POLYURETHANE AS AN ALTERNATIVE FOR HYDRAULIC SEALS

In this chapter, the basic differences between PTFE and PU are compared from a material point of view. As a first step, the general material properties are compared and evaluated regarding their implications with respect to hydraulic applications. In the next step, the resistance to hydraulic fluids, one functionally critical property of hydraulic seals, is evaluated for six different polyurethanes.

3.1. Comparison of Material Properties for Hydraulic Seals

Besides the aforementioned favorable temperature and media resistance, PTFE also brings some unique properties that have to be paid attention to when designing hydraulic seals. First, in comparison with elastomers or PU, PTFE is not an elastic material and tends to deform plastically rather easily. The lack of elasticity means that PTFE seals typically use simpler geometries than PU seals because complex geometries are more difficult to manufacture with PTFE and also tend to get “simplified” due to plastic deformation in the application. The potential benefit of complex geometries is shown in the experimental data presented in chapter 4.

One additional consequence of the plasticity and softness of PTFE is that it is rather prone to getting damaged during assembly such as due to chamfers, threads and improper handling. Additionally, for the assembly in tight spaces, PTFE often needs to be pre-heated to around 80°C and adjusted in diameter (i.e. widened for piston seals and made smaller for rod seals). After assembly, the diameter of the seal has to be re-calibrated by plastically deforming the seal with a cone. In comparison, the assembly of elastic materials is generally easier and less prone to damaging the seals.

Disadvantages of PU in comparison to PTFE are a higher friction coefficient (especially relevant for breakaway friction) and a smaller tolerance towards the immersion in different fluids at high temperatures. In the next section, the material compatibility of different PUs with typical hydraulic fluids will be investigated.

3.2. Changes of Tensile Strength of Different Polyurethanes in Hydraulic Fluids

The material compatiblity is shown in the Figure 3.1, Figure 3.2 and Figure 3.3 for six different polyurethanes all of which are used in hydraulic sealing applications. The loss of tensile strength is chosen as one representative material property that can changes during exposure to fluids at high temperatures. As reference fluids three commercially available hydraulic oils were chosen. The first of which is a mineral oil (HVLP), the second a fire-resistant water-glycol solution (HFC) and the third a synthetic esther based (HEES). The

temperatures were chosen according to typically allowed maximum operating temperatures for polyurethanes. For assessing the material compatibility, the polyurethanes were exposed to the respective fluid and temperature for the indicated number of weeks. After the storage, the tensile strength was determined and compared to the value of a non-exposed specimen.

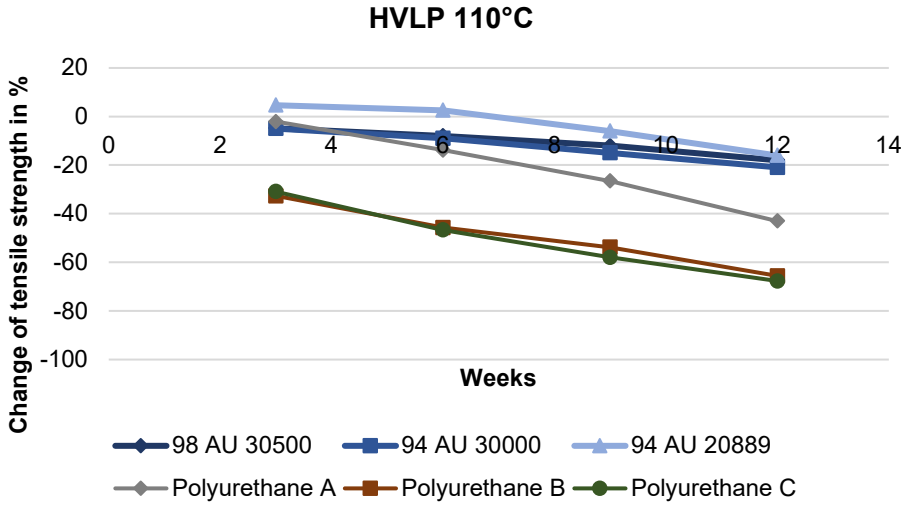

Figure 3.1. Change of tensile strengths for different polyurethanes in HLVP at 110°C.

It can be seen that the loss of tensile strength depends heavily on the chosen fluid and temperature. In other experiments (not displayed here) it could be shown that the exposure at lower temperatures generally had lower effects on the change of tensile strength. Most of the materials lose tensile strength during exposure to the fluids and temperatures. A too high loss of tensile strength can indicate that the material might perform worse in the practical application. In the worst case, the material can become so brittle that the seal specimens break by slight loads applied with bare hands.

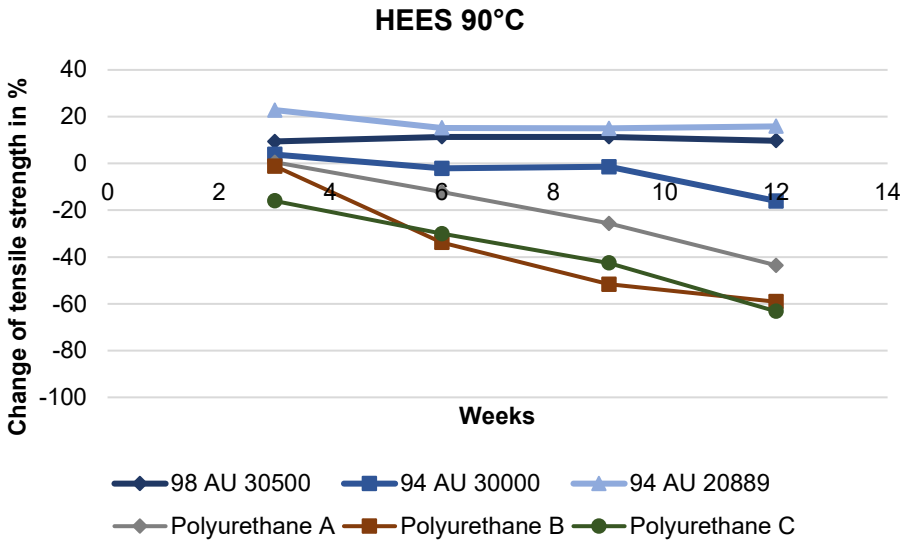

Figure 3.2. Change of tensile strengths for different polyurethanes in HEES at 90°C.

Even though the behavior when exposed to different fluids varies for each combination of fluid and material, it becomes evident that three of the investigated materials (98AU30500, 94AU30000 and 94AU20889) show particularly low changes of tensile strength for all three liquids.

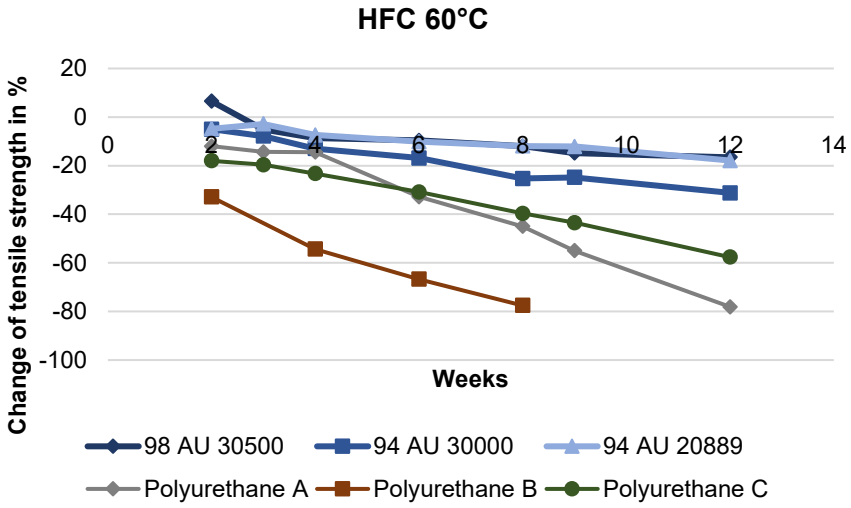

Figure 3.3. Change of tensile strengths for different polyurethanes in HFC at 60°C.

Concluding the immersion tests, it was shown that some combinations of fluids and high temperatures can cause huge changes in the material properties of polymers. However, despite the large differences between the chemical structure of the three investigated fluids,

some polyurethanes performed especially well by showing lower changes in tensile strength than the other investigated materials. This indicates that there are chemically resistant polyurethanes that can indeed be used in a variety of hydraulic applications with long-term exposure to different media at high temperatures.

4. EXPERIMENTAL RESULTS

In this chapter, the performance of PU seals is assessed in comparison to PTFE seals using experimental investigations on a hydraulic test rig. For the scope of this paper, piston seals are chosen as the reference. In the first section, the test rig is introduced briefly. In the following sections, friction, leakage and lifetime are assessed. Goal of the investigations is to show how PU seals compare with commercially available PTFE solutions.

4.1. Hydraulic Piston Seal Test Rig

For the investigations presented in this chapter, a hydraulic piston test rig was used. The test rig uses five separate modules. Each module consists of a piston, a hollow rod and a tube. Each module tests up to three seals at the same time, all of which are mounted on the piston as shown in Figure 4.1. During operation, a linear drive moves the piston back and forth within the tube. The two chambers between seals 1/2 and 2/3 are pressurized individually through channels in the hollow rod. Pressurization is chosen in accordance with the movement to imitate the operating conditions occurring in a differential cylinder for the middle seal 2.

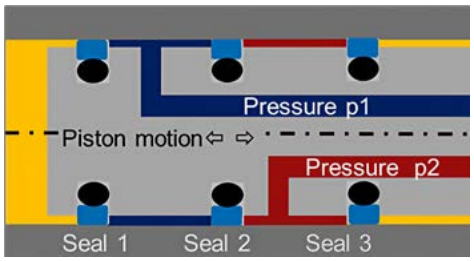

Figure 4.1. Schematic of one Module of the Piston Seal Test Rig.

A force sensor measures the friction force of the piston in parallel. The leakage of the outer seals 1 and 3 is assessed by gathering the droplets at both ends of the tube. The reciprocating motion of the piston is repeated until the chosen number of cycles is reached or when any of the seals is damaged in such a way that the chambers between the seals cannot be pressurized anymore.

4.2. Comparison of Measured Friction Forces

To compare the friction force of a PU and a PTFE piston seal, these seals were installed on the test rig described in section 4.1. Both seals are commercially available as double acting piston seals. The PU seal is a Simko 300 and is made of 98 AU 928. The geometry was optimized to gain a good combination of low leakage and low friction force. As investigated parameters, a velocity of 0.3 m/s and an oil temperature of 60 °C were chosen. The friction forces were evaluated at 50, 100, 200, 300 and 400 bar. The measured average friction forces of the two seals are shown in Figure 4.2, all normalized to the same reference force F_{Ref}. It

should be taken into consideration that the test rig measures the friction force of one module with three seals at once as shown in Figure 4.1.

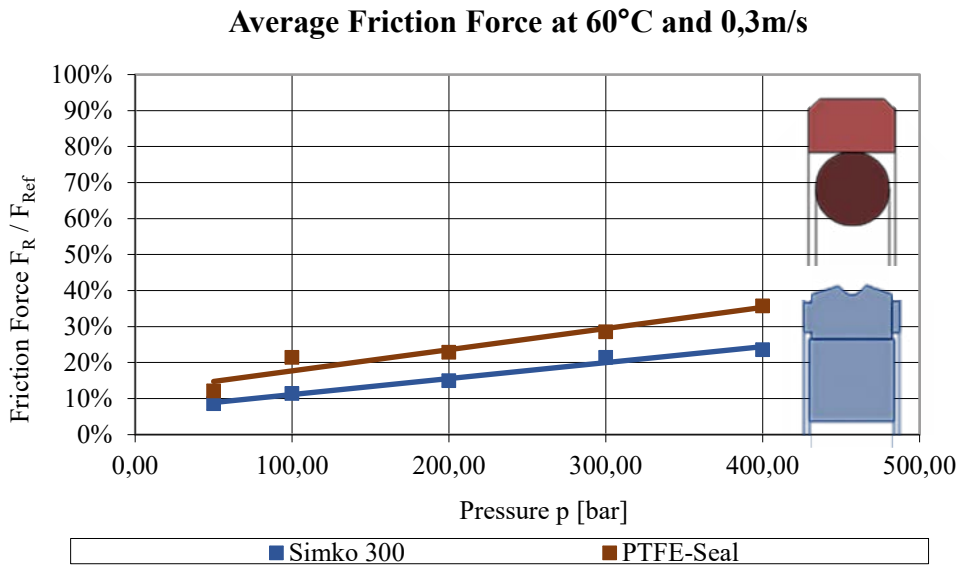

Figure 4.2. Comparison of the Friction Forces between a PTFE and a PU seal for Different Operating Pressures.

When evaluating the results, it should be noted that the friction forces during operation vary with different oils, temperatures, pressures and kinematics. However, the comparison of the two seals shows that the friction force of the PU seal at these operating conditions is lower for all investigated pressures between 50 and 400 bar. This indicates that although the friction coefficient for PTFE/steel is typically lower than for PU/steel, this does not necessarily cause higher friction forces for PU seals than for PTFE seals. The better performance of the PU seal can be attributed to the more favorable geometry of the PU seal, which has been designed to reach optimal hydrodynamic lubrication between seal and countersurface to deliver a good balance between low friction and low leakage. The geometry used for the PU seal is typically not feasible for PTFE seals due to difficulties in manufacturing and plasticity of the sealing material, which is why PTFE seals often use more simple geometries than PU seals.

4.3. Comparison of Leakage Measurements

The leakage of the two seals investigated in the previous section, the same test as shown before have been used. The seals designs are the same as in the previous section. The leakage has been determined after the test.by measuring the amount of leakage from seals 1 and 3 as shown in Figure 4.1. It should be noted that the leakage of seal 2 cannot be detected with the used test rig. The results of the leakage measurement are shown in Figure 4.3. The values for both seals were determined in the same operating conditions on the same surfaces and are given in the unit ml per 1000 doubles strokes (DS).

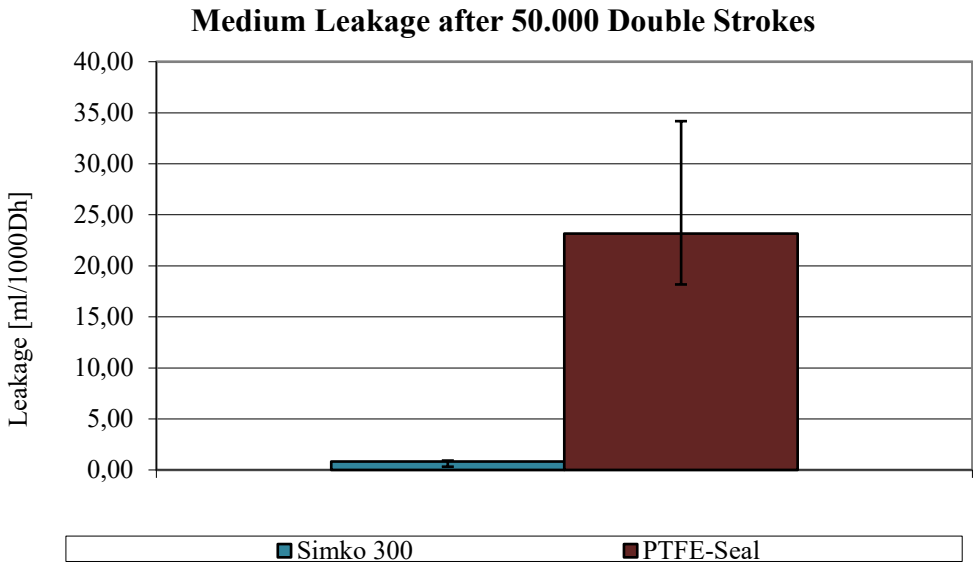

Figure 4.3. Comparison of the leakage of a PTFE and a PU seal.

The comparison of the measured leakage shows that the PTFE seal shows about 20 times higher leakage than the PU seal. This is especially remarkable considering that the friction force of the PTFE seal was higher than the friction force of the PU seal, indicating that the chosen geometry of the PU seal caused more favorable hydrodynamics than the geometry of the PTFE seal.

4.4. Endurance Test

Finally, after evaluating friction and leakage, the endurance of PU seals will be evaluated. Even more than friction and leakage, the lifetime of a seal is highly depending on the interaction of various operating conditions. The same seal design and material can reach the end of its life time in many different ways depending on the operating conditions. Some common failure modes are excessive abrasive wear, chemical deterioration of the material and gap extrusion. The latter mechanism will be the dominating failure mechanism for the operating conditions chosen for the investigation in this paper. Note that the seals and materials tested here are from the ones shown in the previous two sections.

For quickly evaluating the durability of piston seals, the formerly introduced test rig is used. As operating conditions, the combination of high pressure of 400 bar and a high temperature of 100°C are chosen, because these conditions typically cause many commonly available seal designs and materials to fail within less than 50.000 double strokes. The results of one PU seal (OMK-PU) made from the hydrolysis resistant 98 AU 30500, 4 other PU and one PTFE seal are shown in Figure 4.4.

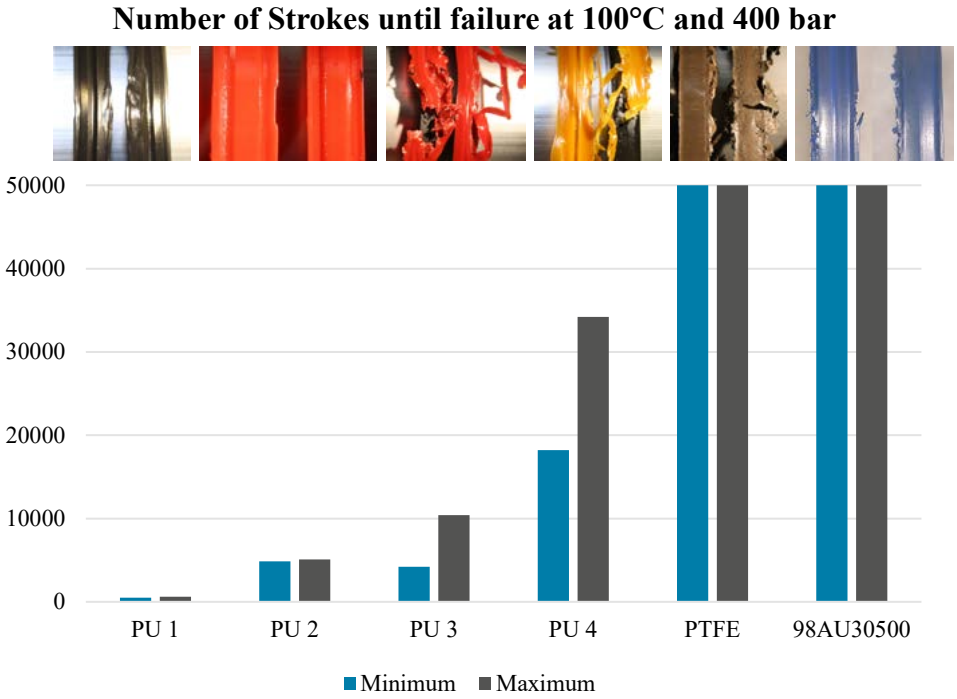

Figure 4.4. Comparison of the Life Time of one PTFE and Multiple PU Seals.

All investigated PTFE seals survived the endurance test. Out of the five PU seals, only the seal made from 98 AU 30500 managed to survive the endurance test with all five specimens. Only one of the other four PUs managed to survive with one module up to 50.000 double strokes. The reason for the premature failures can be observed in the pictures of the seals after tests. Severe extrusion occurred in all prematurely failed seals, some of which even broke apart. The results are in line with the material compatibility tests shown in section 3.2, where huge differences between the different investigated PUs occurred.

It is worth comparing the PTFE and the 98 AU 30500 seals after the endurance test. While PTFE seal already shows severe extrusion patterns, the PU seal only shows minor damage. The presence of large extrusion damage usually indicates that only limited life time remains. In addition, if parts of the extrusion damage breaks lose from the seal, they can get stuck in other hydraulic components like valves causing down time and damage.

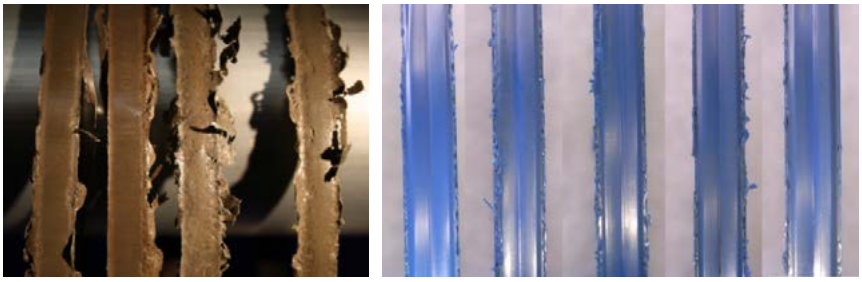

Figure 4.5. PTFE (left) and PU Seal (98 AU 30500, right) after the Endurance Test.

5. SUMMARY AND OUTLOOK

Motivated by international discussions about increasing regulations for PFAS substances, this paper investigated where PFAS containing materials are used in hydraulic sealing systems. For the scope of this paper, the focus of further investigation was on PTFE and its unique properties as a sealing material. After evaluating the beneficial material properties of PTFE, the paper discussed the potential of using polyurethane (PU) as an alternative material for hydraulic seals.

Some main advantages of PTFE over PU include lower friction and wear coefficients, better temperature and media resistance. To investigate whether PU can serve as a viable alternative, the practical consequences of these advantages in hydraulic applications were investigated using both material and seal tests.

In terms of material compatibility, it could be found that some PUs show severe degradation of material properties even after few weeks of immersion in typical hydraulic fluids at temperatures between 60 and 110°C. However, there are also hydrolysis resistant PUs like 98 AU 30500 which showed stable behavior during the immersion even after 12 weeks of severe exposure to temperature and different media. This indicates that there are PUs with sufficiently high media and temperature resistance for the majority of hydraulic applications.

For comparing the performance of these materials used in a hydraulic piston seal, a test rig was used. While some PU seals showed severe degradation even after less than 10.000 double strokes during an endurance test at 400 bar and 100°C, the material 98 AU 30500 reached the full 50.000 double strokes with less apparent damage than the PTFE seal. In terms of leakage and friction the investigated PU seal Simko 300 also showed better behavior than the PTFE seal.

Before concluding this paper, it should be noted that sealing systems are highly complex tribological systems. Therefore, especially in demanding applications, the selection of sealing design and material should be carefully adjusted to the conditions and needs. Thus, a general statement about whether “PTFE or PU is a better sealing material”, cannot be made. Especially where low break away friction forces and low stick slip probability are desired or high temperature and aggressive media is present, PTFE seals can rely on the core strengths of its material. However, the results presented here demonstrate that even at high pressures and temperatures, choosing a highly resistant PU like 98 AU 30500 as a sealing material can deliver not only comparable but superior results in terms of endurance, friction and leakage.

6. DECLARATION

For the creation of this paper, the authors used the assistance of AI tools for editing and revising parts of the text and for accelerating literature research. All AI outputs and references were reviewed, edited, and verified by the authors prior to inclusion.

BIOGRAPHIES

Niklas Bauer received the bachelor's and master’s degree in mechanical engineering from RWTH Aachen University in 2017 and 2019, respectively. From 2019 to 2025 he worked in various positions at the Institute for Fluid Power Drives and Systems (ifas) in Aachen, last as chief engineer. He graduated in 2024 with a Doctoral degree about elastohydrodynamic simulation of pneumatic sealing systems. In 2025, he joined Freudenberg Sealing Technologies as Head of Advanced Development, where he is responsible for the development of new products for new markets. He supports the University of Dresden as a lecturer on the fundamentals of sealing technology.

Gonzalo Barillas received his Diploma (Dipl.-Ing. (FH)) at the former Fachhochschule für Technik Esslingen, today's University of Applied Sciences Esslingen in 1984, his thesis thema was Tribology of Ceramic Materials. He started then in 1985 as product developer at sealing company Merkel in Hamburg, in 1990 he joined Freudenberg Sealing Technologies in Schwalmstadt, where he worked in several positions in the development and business development of seals. His last position before retiring in Dec. 2025 was Manager of advanced product development at the Lead Center Fluid Power Industry. He supports the University of Dresden as a lecturer on the fundamentals of sealing technology.

Jürgen Hieber received his Diploma in Chemistry in 1993 and his Doctorate (Dr. rer. nat.) in 1996 from the University of Tübingen, with a doctoral thesis entitled *"Electrically Conductive Polymers"*. Since 1996, he has been employed by Freudenberg Sealing Technologies, where he currently serves as Head of Material Development for the Fluid Power Industry. During his tenure, he has, among other responsibilities, led the construction of a new polyurethane granulate production facility. He has delivered several technical presentations on polyurethane materials for sealing applications.

Martin Goerres graduated in Mechanical Engineering at RWTH Aachen University in 1999. He worked as Research Associate at the Institute for Fluid Power Drives and Controls (IFAS) until 2005. He joined Freudenberg Sealing Technologies (formerly known as Merkel Freudenberg Fluidtechnic GmbH) in 2005 where he worked in various positions. As Director Engineering and Innovation he is globally responsible for the Engineering at the Lead Center Fluid Power Industry. He has been serving as a reviewer and committee member for the international fluid power and sealing community.

Percolation Analysis of Reciprocating Sealing Surfaces Based on the Statistical Evolution of HPD and PSD Induced by Wear

Abstract.

The reciprocating seal exhibits significantly different wear behaviours and surface damage patterns under various friction and operating conditions. Precisely describing the topography characteristics of the worn surface is of great significance for the analysis of oil flow and the study of the leakage mechanism. The high probability density (HPD) and the power spectral density (PSD) are commonly used for reconstructing the surface topography. It is particularly necessary to study the evolution laws of HPD and PSD during the wear process to reconstruct worn surface. This study is based on the polymer-steel reciprocating friction experiments and analyses the changes in HPD and PSD characteristics of the PTFE worn surface under different temperatures. A three-dimensional oil percolation simulation model is established to reflect the flow characteristics of the oil fluid on the sealing contact surface. Based on the actual worn surface, the evolution laws of the surface topography under different wear mechanisms are revealed. On this basis, a numerical algorithm based on HPD and PSD is proposed to realize the predictive reconstruction of the worn surface topography. The reconstructed surface can be applied to the oil percolation simulation to explore the influence of surface topography evolution on sealing performance and leakage characteristics. The research results provide a theoretical basis for understanding the wear mechanism of polymer, predicting the sealing life, and revealing the failure mechanism.

Keywords. Reciprocating seal, percolation analysis, surface reconstruction, polymer wear, oil leakage

1. INTRODUCTION

Hydraulic systems are widely used in key fields such as aerospace, shipbuilding, and high-end equipment manufacturing due to their high-power density, rapid response, and excellent reliability [1]. In hydraulic systems, the actuator is the core actuator component, and its performance and stability play a decisive role in the overall operation of the system. Among

All Open Access articles are peer-reviewed, distributed under the Creative Commons Attribution-Non Commercial 4.0 International

them, the reciprocating seal mechanism is a key functional link in the actuator. The stability, reliability, and service life of its sealing performance are directly related to the working efficiency and operational safety of the actuator [2]. The failure of the seal will not only significantly reduce the transmission efficiency of the hydraulic system but also increase maintenance costs [3].

Reciprocating seal structures exhibit distinct multiscale coupling characteristics, integrating the functions of both a sealing pair and a friction pair. Their sealing interfaces often experience a complex mixed lubrication state. Although a fluid oil film effectively separates some contact areas, the film thickness is insufficient to completely cover the microscopic topography of the sealing surface, leading to unavoidable direct contact between surface roughness peaks [4]. Mechanical contact between these submicron-scale roughness peaks not only disrupts the continuity of the oil film but can also trigger complex wear mechanisms within the contact area, including localized stress concentration, severe plastic deformation, adhesive wear, and material delamination [5].

Due to the complex and variable working conditions of sealing pairs, traditional testing methods have difficulty accurately capturing their contact state and stress evolution. Current research on the failure modes and life prediction of aerospace actuator seals is primarily based on material fatigue damage criteria. However, the microscopic topography characteristics of the contact surface are crucial for revealing the mixed lubrication behaviour, as well as the friction and wear mechanisms during service [6, 7]. As the actuator continues to operate, the contact surface topography evolves, and the lubrication state also changes accordingly. The interaction between the two ultimately drives the degradation of seal performance and wear failure. Therefore, obtaining the characteristics of surface topography evolution during service and conducting an in-depth analysis of the bidirectional coupling mechanism between lubrication and wear are key to revealing the essential mechanism of seal failure [8].

To understand the contact behaviour of rough surfaces, Persson et al. proposed a multiscale contact theory model for the elastic-plastic contact behaviour of random rough surfaces [9, 10]. This model assumes that the material exhibits an elastic response below the yield stress and undergoes plastic flow above it. On this basis, a linear relationship between the actual contact area and the normal load is derived. In the absence of plastic deformation, the actual contact area of a rough surface with self-affine fractal characteristics shows a power-law relationship with the lateral scale of the nominal contact area. This model emphasizes the surface power spectrum density (PSD) as the core parameter to characterize the multiscale characteristics of the rough surface and establish a quantitative relationship between it and macroscopic properties such as contact area, pressure distribution, and friction [11, 12].

Based on this contact theory, Persson et.al further expanded their research, introducing a coupling model of percolation theory and contact mechanics to explore the leakage behaviour and microscopic mechanism of seals under static and dynamic conditions [13]. Through multi-scale analysis of the power spectrum (PS) of rough surfaces, theoretical and numerical simulations showed that the formation and evolution of percolation channels are the key driving factors for leakage at the sealing interface. On this basis, Lorenz et al. developed a leakage prediction method based on the effective medium theory (EMT), treating the oil flow at the sealing interface as propagating in multiple independent microchannels, and combined the surface power spectrum to analyze the statistical evolution

of the seal contact area and gap height [14]. Bottiglione et al. further integrated the seal geometry, applied load, and surface roughness parameters to construct a comprehensive numerical model that can simulate contact randomness and predict leakage rate [15]. Scaraggi et al. proposed a numerical method to study the oil extrusion behaviour between soft elastic bodies and random rough rigid surfaces based on the transient mixed elastohydrodynamic lubrication theory [16].

Peng et al. analysed the differences between the multi-asperity model and the magnification-based percolation model in predicting sealing performance [17]. The study focused on the numerical prediction of gas leakage in metal sealing structures. By comparing the simulation results with the experimental data, it was found that the magnification-based percolation model performed better in leakage prediction accuracy. The model can directly characterize the microscopic topography characteristics of the sealing contact surface and analyze the spatial distribution of the contact and gap areas based on the PSD function, thereby revealing the generation mechanism of the oil percolation channel. Therefore, the model shows advantages in evaluating the influence of surface topography on local leakage behaviour.

However, the percolation model still has certain limitations:

- Current percolation calculations are mainly based on the PSD function, making it difficult to effectively couple the effects of seal load, temperature, and dynamic wear under real working conditions;
- Existing percolation theories use one-dimensional (1D) PSD functions to describe surface roughness distribution, which cannot capture the anisotropic characteristics of the worn surface.

To address the limitations of existing percolation models in coupling to actual operating conditions and characterizing surface anisotropy, this paper proposes a method for simulating oil percolation based on numerically reconstructed surface topography. This method conducts seal wear tests under typical operating conditions to obtain actual act contact surface topography data at different service stages. Based on this data, the worn surface is numerically reconstructed, and parameter extraction is performed. Furthermore, the statistical distribution and evolution of characteristic wear topography parameters are analysed, and a correlation model between wear topography and percolation characteristics is constructed, which allows for quantitative prediction and mechanistic understanding of oil percolation behaviour on worn sealing surfaces.

2. WEAR TEST

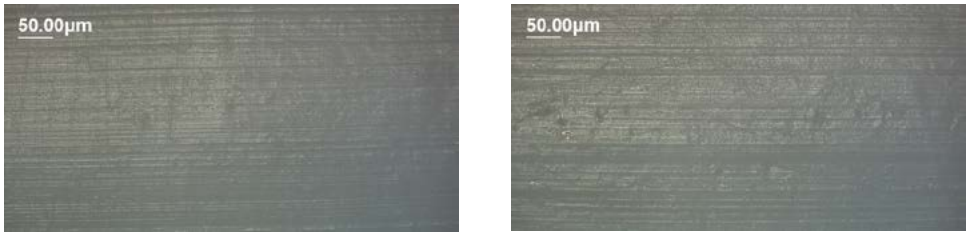
2.1. Test method

The RTEC MFT-5000 multi-functional wear testing machine was used to conduct wear tests on the commonly used material PTFE (polytetrafluoroethylene) for the wear ring. To investigate the wear characteristics of the PTFE specimens under high-temperature conditions, the specimens were heated for 15 minutes before the wear test to ensure that the material of the specimens reached thermal stability. An infrared thermal imager was used to perform real-time imaging and temperature measurement of the PTFE specimens. The specific test parameters are shown in Table 2.1.

Table 2.1 PTFE material wear test parameters

Parameters	Value
Test material	PTFE
Wear type	Ball-on-disk
Roughness of specimen	3-4μm
Grinding piece	Cr15 ball with a diameter of 4 mm
Single stroke	2mm
Frequency	3Hz
Normal load	10N
Test time	10 mins
Test temperature	20, 60℃

The worn surface can be observed and measured using two methods. A digital microscope is employed for micro-imaging of the worn surface, capturing the details of wear marks, analysing surface damage modes, and identifying different wear mechanisms. A laser confocal profilometer is used to acquire data on wear tracks and local surface topography. This data is then imported into Mountains Map software for analysis to obtain high-precision measurements of wear depth and surface topographic features. A 3D surface topography model of the worn area is reconstructed, providing data support for further analysis of the worn surface characteristics. The equipment used for wear tests is shown in Figure2.1.



(a) MFT-5000 wear testing machine (b) Laser confocal profilometer

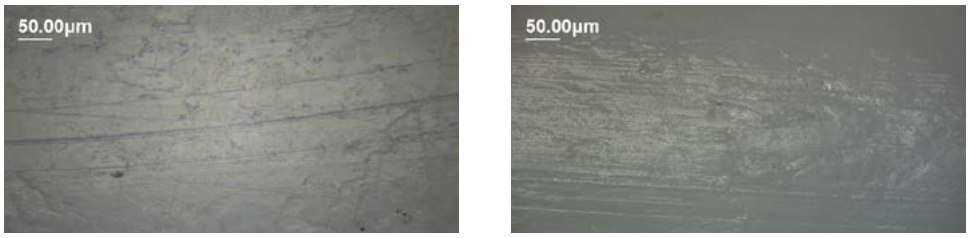


Figure 2.1. Wear test equipment

2.2. Test results

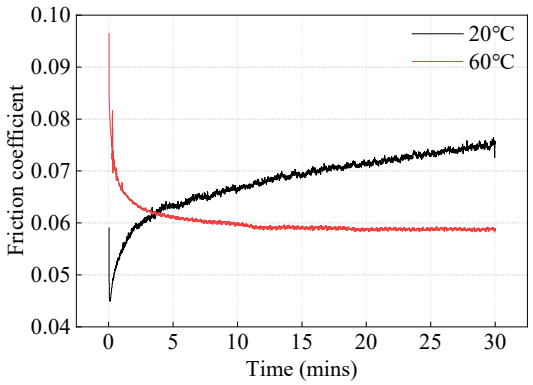
Figure2.2 shows the worn surface of PTFE at different temperatures and times. At 20°C, the PTFE surface exhibits typical scratch-like abrasive wear characteristics. The wear mechanism at this point is primarily driven by the cutting action of hard particles, resulting in a plowing effect. When the temperature rises to 60°C, the surface material starts to peel off, and localized depressions appear, predominantly exhibiting a ridge-like adhesive wear topography. The interfacial adhesion of the material is enhanced under high temperature conditions, making adhesive wear the dominant wear mechanism.

(a) 20℃, 10 mins (b) 20℃, 30 mins

(c) 60℃, 10 mins (d) 60℃, 30 mins

Figure 2.2. Worn surfaces of PTFE under different temperatures and durations

The variation of PTFE friction coefficient with wear time at different temperatures is shown in Figure2.3. From a wear mechanism perspective, abrasive wear occurs when hard abrasive particles embed themselves in the PTFE surface and scratch across it, creating a cutting or plowing effect. Adhesive wear primarily occurs when localized adhesion nodes form between the rough peaks of the two contacting surfaces, leading to material removal due to tearing caused by relative motion. At room temperature, PTFE is rigid and elastic, resulting in a small actual contact area and high local pressure, which in turn generates high interfacial shear forces. However, at high temperatures, the softening of PTFE reduces adhesion strength, reducing the adhesion between adhesion nodes.



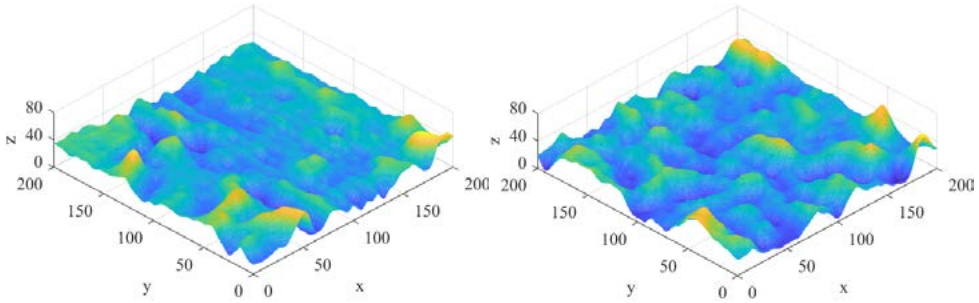


Figure 2.3. Friction coefficient variation of PTFE

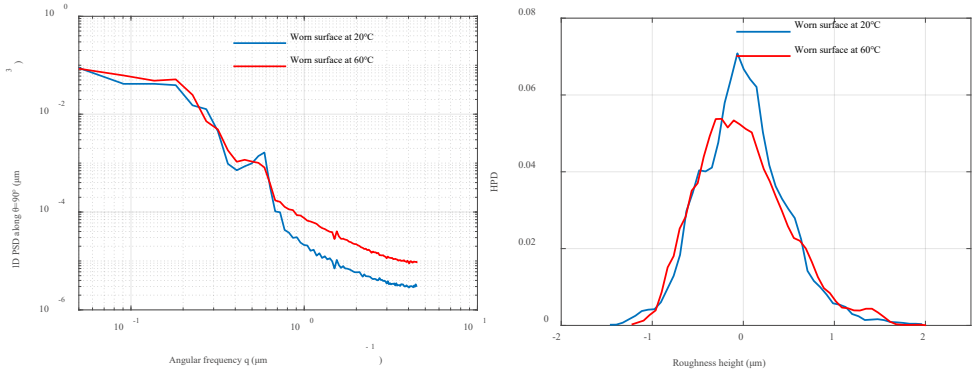
The wear rate is calculated by scanning the average wear depth on the worn surface. The wear rates at 20°C and 60°C are $5.86 \times 10^{-5} mm^3/Nm$ and $9.08 \times 10^{-5} mm^3/Nm$, respectively. Notably, the wear volume of PTFE does not show a positive correlation with the friction coefficient.

2.3. Worn surface topography

With a surface sampling accuracy of 0.7 μm, a 200×200 node area in the centre of the worn surface is selected for quantitative analysis of surface topography. Typical surface topography at 20°C and 60°C are shown in Figure2.4. At 20°C, the worn surface exhibits anisotropic characteristics, with wear scars exhibiting clear directionality. Wear primarily occurs in a specific direction. At 60°C, the worn surface exhibits isotropic characteristics, caused by the formation of uniform and discrete adhesive nodes on the surface.



(a) 20°C, 30 mins (b) 60°C, 30 mins

Figure 2.4. Localized worn surface topography

1D PSD can be used to characterize the topography characteristics of rough surfaces, reveal microscopic changes in a single direction of the worn surface. By screening all frequency points projected to the specified direction angle θ at the spatial frequency q, and performing normalization processing, the 1D average PSD function is

$$C_{1D}(q,\theta)=\frac{\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}C_{2D}(q_x,q_y)\delta_d(q-q_\theta)dq_xdq_y}{\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\delta(q-q_\theta)dq_xdq_y} \tag{2.1}$$

where δ is the Dirac function; q_θ is the specified direction projection length.

(a) 1D PSD along $\theta=90°$ (b) HPD

Figure 2.5. Worn surface statistical characteristics

Figure2.5 shows the 1D PSD along the friction direction (defined as $\theta=90°$) and the height probability distribution (HPD) of roughness at 20℃ and 60℃. The 1D PSD variation

of the worn surface reflects the transition between its anisotropic and isotropic characteristics. At 20°C, the worn surface exhibits strong anisotropy, with slight surface fluctuations along the friction direction, resulting in a low PSD of the high-frequency domain. At 60°C, the worn surface tends to be isotropic, with the energy distribution of the surface topography being relatively uniform in different directions, resulting in a higher overall PSD. The result is consistent with the observation of the worn surface topography, indicating that the wear mechanism significantly impacts the worn surface structure and its spectral characteristics.

The root mean square (RMS) roughness increases with temperature. The softening of PTFE at high temperatures intensifies wear, resulting in a rougher worn surface. The HPD of worn surfaces at both temperatures exhibits positive skewness, with numerous peaks formed by material spalling, exhibiting an asymmetric distribution. Higher temperatures exacerbate the unevenness of the worn surface height.

3. PREDICTIVE RECONSTRUCTION OF WORN SURFACE

3.1. Surface reconstruction

The surface topography reconstruction method proposed by Pérez-Ràfols is adopted, in which the PS and HPD are used as inputs to generate random surfaces that simultaneously satisfy both statistical characteristics [18]. First, two random rough surfaces with height sequences Z_h^0 and Z_s^0 are generated. The surface Z_h^0 has a height distribution consistent with the given HPD but does not meet the target PS requirement, whereas surface Z_s^0 satisfies the desired PS but deviates from the target HPD.

Both surfaces are then subjected to two-dimensional Fourier transforms, yielding their frequency-domain counterparts $\hat{Z}_h^0$ and $\hat{Z}_s^0$. Then, an iterative correction process is applied to gradually adjust the surfaces so that they meet both target distributions. This process alternates between two main steps:

- Adjusting the surface in the frequency domain to match the target PS.
- Correcting the surface in the spatial domain to match the target HPD.

Through iteration, both the PS and HPD of the reconstructed surface converge toward the specified target distributions, thereby realizing a random surface generation method that simultaneously satisfies the prescribed PS and HPD. The PS of Z_h^i is corrected and the Z_s^{i+1} that satisfies the target PS is characterized using the spectral representation method, that is

$$Z_s^{i+1} = FFT^{-1}\left[\sqrt{S} \times exp\left(i\,\phi_h^i\right)\right] \tag{3.1}$$

where, ϕ_h^i represents the phase in the frequency domain, which can be expressed in terms of the real and imaginary parts of $\hat{Z}_h^i$ obtained from the previous iteration as follows:

$$\phi_h^i = tan^{-1}\left(\frac{Im\left(\hat{z}_h^i\right)}{Re\left(\hat{z}_h^i\right)}\right) \tag{3.2}$$

At this stage, the PS of Z_s^{i+1} satisfies the target, but the HPD does not meet the requirements. By mapping the height distribution of Z_h^{I} onto Z_s^{i+1}, a new iteration of Z_h^{i+1}

that satisfies the target HPD can be obtained. Three types of errors are introduced to evaluate how well the generated surface matches the target surface in terms of PS and HPD [19].

i. Height probability distribution error err_h — quantifies the deviation between the actual height distribution of the generated surface and the target height distribution:

$$err_h = \sum_{i=1}^{N_b} |n_{ih} - n_{is}| \cdot \omega_b \tag{3.3}$$

where n_{ih} and n_{is} represent the frequency of occurrence of surface heights within a given height interval in the histograms of the target and generated surfaces, respectively; N_b is the total number of height intervals, and ω_b is the interval width.

ii. Power spectrum error (nonzero region) err_s — reflects the discrepancy between the nonzero power spectrum values of the generated surface and those of the target surface:

$$err_s = \sqrt{\frac{1}{N_s} \sum_{q_i=q_0}^{q_1} \left(\frac{|\hat{Z}_s(q_i)| - |\hat{Z}_h(q_i)|}{|\hat{Z}_s(q_i)|} \right)^2} \tag{3.4}$$

where $\hat{Z}_s(q_i)$ and $\hat{Z}_h(q_i)$ are the power spectrum values of the target surfaces at spatial frequency q_i; N_s denotes the number of nonzero spatial frequencies in the target power spectrum; q_0 and q_1 are the lower and upper cutoff spatial frequencies.

iii. Power spectrum error (zero region) err_{s0} — characterizes the performance of the generated surface in the frequency range where the target power spectrum is zero:

$$err_{s0} = \frac{\sqrt{\frac{1}{N_{s0}} \sum_{q_i<q_0 | q_i>q_1} |\hat{Z}_h(q_i)|^2}}{\frac{1}{N_s} \sum_{q_0 \le q_i \le q_1} |\hat{Z}_s(q_i)|} \tag{3.5}$$

where N_{s0} denotes the number of spatial frequencies for which the target power spectrum is zero. The iterative process continues until all three errors fall below the specified thresholds, at which point the generated surface is considered to meet the target requirements.

3.2. Topography characterization

(1) Power spectral density

The power spectral density ratio function corresponding to the 1D PSD frequency point $q_{1D}^i \in S_q$ is expressed as follows:

$$R_{1D}(q_{1D}^i) = \begin{cases} 1, & q_{1D}^i < q_s \\ \alpha_{psd}, & q_{1D}^i \ge q_s \end{cases} \tag{3.6}$$

where, α_{psd} is the power-spectrum scaling coefficient, and q_s is the adjustment frequency threshold. Using an interpolation function, the ratio function $R_{1D}(q_{1D}^i)$, which is discretely defined on the 1D PSD, is mapped into the two-dimensional (2D) frequency domain to obtain for each point $q_{2D}^{k,l}$ in the frequency coordinate system, its scaling factor [20]:

$$R_{2D}(q_{2D}^{k,l}) = R_{1D}(q_{1D}^i) + \frac{R_{1D}(q_{1D}^{i+1}) - R_{1D}(q_{1D}^i)}{q_{1D}^{i+1} - q_{1D}^i} \cdot (q_{2D}^{k,l} - q_{1D}^i) \tag{3.7}$$

where R_{2D} is the 2D PSD ratio function, and $q_{2D}^{k,l} \in \left[q_{1D}^{i}, q_{1D}^{i+1}\right]$. As worn surfaces typically exhibit pronounced anisotropy, the adjustment in the frequency domain is applied only to the frequency components along the target direction. Let $\tilde{\theta}$ denote the direction angle of an arbitrary frequency in the frequency domain, θ is the target direction, and θ_t is the directional tolerance. The directional mask matrix for the spatial frequency $q_{2D}^{k,l}$ in the 2D frequency domain is

$$Mar\left(q_x^k, q_y^l\right) = \begin{cases} 1, \left|\tilde{\theta}\left(q_x^k, q_y^l\right) - \theta\right| < \theta_t \\ 0, \left|\tilde{\theta}\left(q_x^k, q_y^l\right) - \theta\right| \geq \theta_t \end{cases} \tag{3.8}$$

The adjusted two-dimensional power spectral density function is

$$C_{2D}{}'\left(q_x^k, q_y^l\right) = \begin{cases} R_{2D}\left(q_{2D}^{k,l}\right) \cdot C_{2D}\left(q_x^k, q_y^l\right), & Mar\left(q_x^k, q_y^l\right) = 1 \\ C_{2D}\left(q_x^k, q_y^l\right), & Mar\left(q_x^k, q_y^l\right) = 0 \end{cases} \tag{3.9}$$

(2) Height probability density

Johnson transform is a distribution transformation method based on data statistical analysis, which can be used to convert between Gaussian sequences and non-Gaussian sequences [21]. The skewness and kurtosis of the input and output height sequences have the following relationship [22]:

$$Sk_0 = \frac{\left(\sum_{r=0}^{M-1}\sum_{s=0}^{N-1} f(r,s)^2\right)^{\frac{3}{2}}}{\sum_{r=0}^{M-1}\sum_{s=0}^{N-1} f(r,s)^3} Sk_\eta \tag{3.10}$$

$$Ku_0 = \frac{\left(\sum_{r=0}^{M-1}\sum_{s=0}^{N-1} f(r,s)^2\right)^2 Ku_\eta - 6\sum_{r=0}^{M-2}\sum_{p=r+1}^{M-1}\sum_{s=0}^{N-2}\sum_{q=s+1}^{N-1} f(r,s)^2 f(p,q)^2}{\sum_{r=0}^{M-1}\sum_{s=0}^{N-1} f(r,s)^4} \tag{3.11}$$

where Sk_0 and Ku_0 are the input skewness and kurtosis, and Sk_η and Ku_η are the given skewness and kurtosis. r, s, p, q is the index of the coordinate in space. The surface topography is regarded as a random process. By adjusting the power spectrum density and probability distribution characteristics, the generated surface topography has a specific skewness, kurtosis and spatial correlation. The autocorrelation function is a mathematical tool used to describe the correlation of random signals, often used in roughness modelling. The exponential form is

$$R(x,y) = S_q^2 \exp\left\{-2.3\left[(x/\beta_x)^2 + \left(y/\beta_y\right)^2\right]^{1/2}\right\} \tag{3.12}$$

where β_x and β_y are the autocorrelation lengths. By performing Fourier transform on the autocorrelation function, the output roughness height power spectral density function can be obtained:

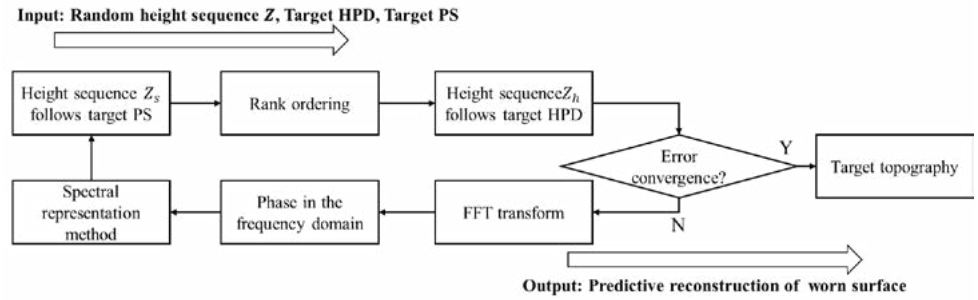
$$S(k,l) = \frac{1}{MN}\sum_{r=0}^{M-1}\sum_{s=0}^{N-1} R(r,s)\exp\left(-\frac{j2\pi kr}{M}\right)\exp\left(-\frac{j2\pi ls}{N}\right) \tag{3.13}$$

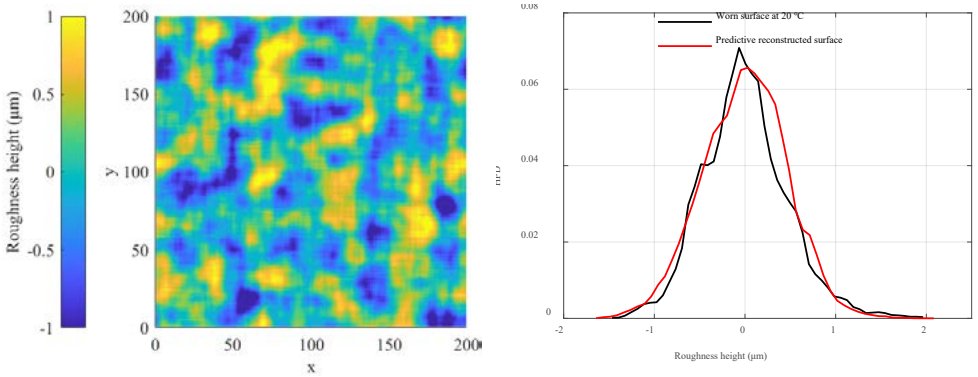
where k,l is the frequency domain index. The two-dimensional digital filter function $f(r,s)$ can be obtained through the power spectrum density function:

$$f(r,s)=\frac{1}{MN}\sum_{r=0}^{M-1}\sum_{s=0}^{N-1}\sqrt{S(k,l)}\exp\left(-\frac{j2\pi kr}{M}\right)\exp\left(-\frac{j2\pi ls}{N}\right) \tag{3.14}$$

3.3. Predictive reconstruction

Numerical reconstruction of the worn surface relies on the PSD and HPD obtained from experiments as statistical characteristic parameters. However, due to limitations in the number of test surfaces and the scope of surface topography acquisition, it is difficult for the experimental worn surfaces to cover all possible topography characteristics. By adjusting the PSD and HPD extracted from existing test data, a reconstruction process independent of the specific measured surface can be achieved. It can be used to simulate and predict the topography of worn surfaces with arbitrary characteristics. Furthermore, the worn surface topography can be predictive based on operating conditions to simulate oil percolation. The predictive reconstruction process of the worn surface topography is shown in Figure3.1.





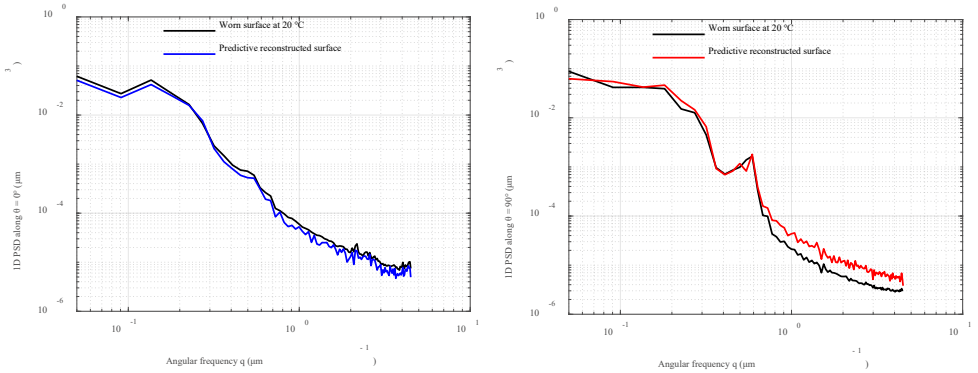


Figure 3.1. Flowchart for predictive reconstructed worn surface topography

To verify the effectiveness of the predictive reconstruction method, the worn surface at 20°C shown in Figure2.4 (a) is chosen as the research object. $\alpha_{psd}=1.8$, $q_s=0.6$ and $\theta_t=\pm5°$ are selected to adjust its PSD. The results are shown in Figure3.2.

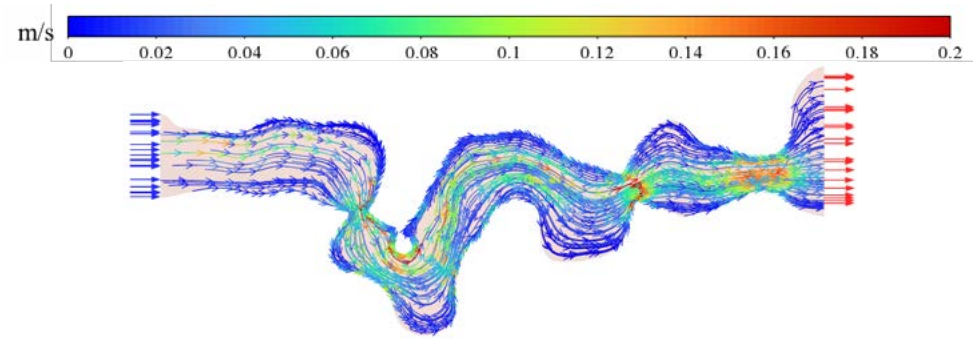
(a) Reconstructed surface (b) HPD

(c) 1D PSD along $\theta = 0°$ (d) 1D PSD along $\theta = 90°$

Figure 3.2. Predictive reconstructed surface and its characteristics

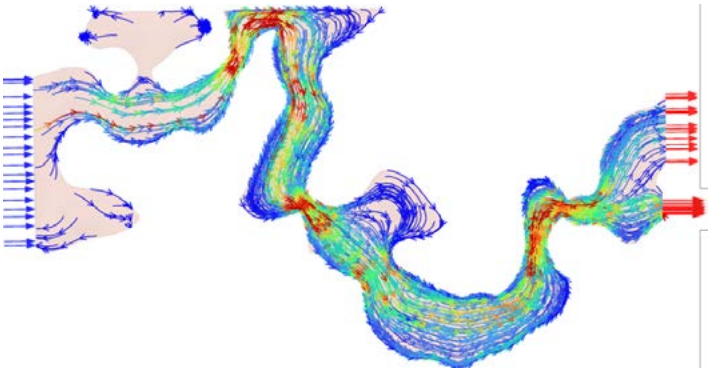
Define $\theta = 90°$ as the seal's axial direction, i.e., the direction of reciprocating friction, and $\theta = 0°$ as the seal's circumferential direction, perpendicular to the reciprocating motion. By comparing the 1D PSD in these two directions, the anisotropic characteristics variation of the surface topography can be reflected.

The 1D PSD of the original worn surface in the high-frequency region of the friction direction is significantly lower than that in other directions, indicating that the surface exhibits significant anisotropy. During the prediction and reconstruction process, the 1D PSD in the high-frequency region is appropriately amplified to compensate for the surface anisotropy. The anisotropy of the predictive and reconstructed surface is weakened, tending towards an isotropic state, while the HPD of the roughness remains unchanged. The 1D PSD in the $\theta = 0°$ direction remains essentially the same before and after reconstruction. The surface energy increases in the $\theta = 90°$ direction and when $q > 0.6$, demonstrating that this method effectively adjusts the high-frequency characteristics in the target direction without affecting the roughness characteristics in other directions.



4. OIL PERCOLATION ANALYSIS

4.1. Actual worn surface

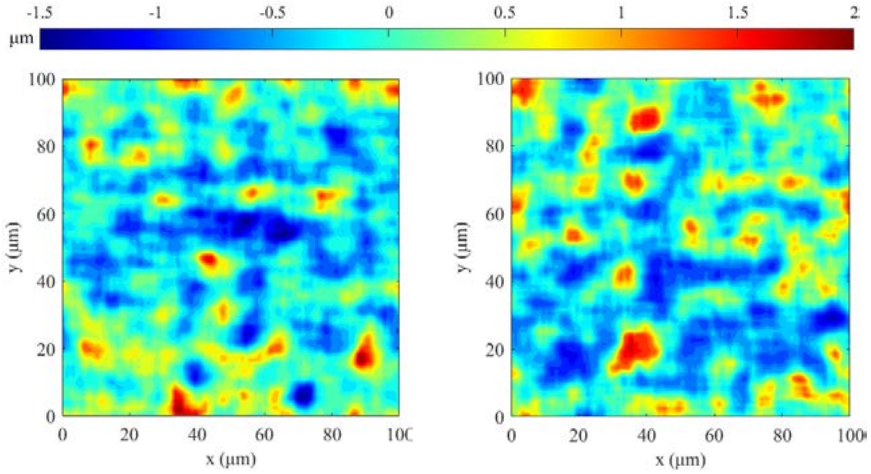


The paper adopts the oil percolation simulation method proposed in Ref [23] to conduct three-dimensional simulations of the percolation behaviour of worn surfaces obtained from tests at 20°C and 60°C. By extracting oil film thickness distribution data from the seal contact surface, an oil channel structure model of the oil percolation can be constructed, enabling the analysis of oil flow behaviour within the percolation channel. Figure4.1 shows the flow velocity distribution within the oil percolation channel on the sealing surface at different temperatures.

The oil leakage rates on the worn surface at 20°C and 60°C are $2.81 \times 10^{-5} cm^3/s$ and $3.62 \times 10^{-5} cm^3/s$. PTFE produces significant shear deformation and stress dispersion due to its excellent energy dissipation capabilities. This process suppresses the ability of abrasive particles to create deep scratches on the surface during ploughing effect. In contrast, adhesive wear primarily results from localized adhesion between the materials at the contacting surfaces. Under reciprocating shear loads, adhesive nodes fracture and material

delamination occur, and their formation is closely related to the adhesive strength of the contact interface. At high temperatures (e.g., 60°C), thermal softening of the material enhances adhesive strength, making it more likely to form deeper wear scars.

(a) Actual worn surfaces at 20°C

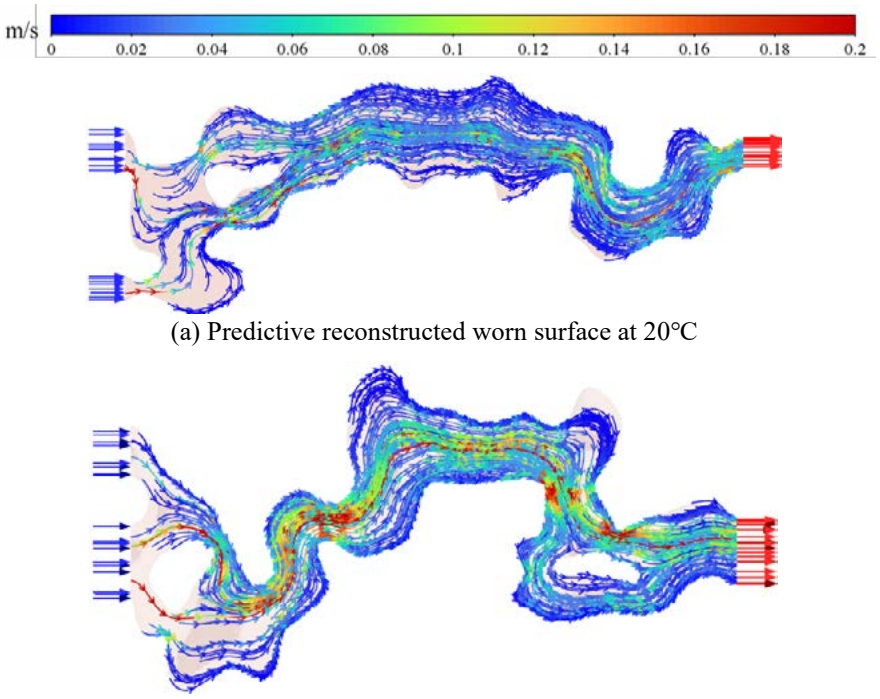


(b) Actual worn surfaces at 60°C

Figure 4.1. Oil percolation characteristics of actual worn surfaces

Therefore, the worn surface at 60°C is more susceptible to enhanced adhesive wear than that at 20°C. The oil flow channels exhibit variation in cross-sectional geometry, particularly in the critical constriction, where a larger channel area and higher oil flow rate are observed. This phenomenon indicates that high-temperature operating conditions not only alter the dominant wear mechanism but also significantly affect the lubrication and flow properties of the sealing surface, impacting the stability of sealing performance.

4.2. Predictive reconstructed worn surface



To investigate the influence of the reconstructed worn surfaces on the analysis results of percolation characteristics, analyses are conducted on these surfaces at 20°C and 60°C. The results are then compared with those from the test worn surfaces. The reconstructed worn surfaces for percolation analysis are shown in Figure4.2. The RMS roughness of the reconstructed surfaces is consistent with that of the actual worn surfaces. This consistency eliminates the interference of roughness differences on the percolation behaviour, thereby more accurately evaluating the influence of surface reconstruction on the percolation channel structure, velocity distribution, and other related factors.

(a) Reconstructed surface at 20℃ (b) Reconstructed surface at 60℃

Figure 4.2. Predictive reconstructed worn surfaces for percolation analysis

Figure4.3 shows the oil percolation characteristics on the predictive reconstructed worn surfaces at different temperatures.

(a) Predictive reconstructed worn surface at 20℃

(b) Predictive reconstructed worn surface at 60℃

Figure 4.3. Oil percolation characteristics of predictive reconstructed worn surfaces

At 20°C, a wide but shallow percolation channel is formed along the reciprocating motion direction on the reconstructed worn surface, and the oil flow velocity is relatively low. At

60°C, the width of the percolation channel at the critical constriction is narrower, but due to the increase in the wear depth of the sealing surface, a larger effective flow area is formed, and the local maximum flow velocity reached 0.181 m/s. Compared to the width, the height of the percolation channel directly determines the oil film thickness and has a greater impact on the overall flow capacity of the channel.

The numerical calculation of the net leakage rate of oil on the reconstructed worn surface is conducted, and it is compared with the analysis results of the leakage rate on the corresponding actual worn surface, as shown in Figure4.4.

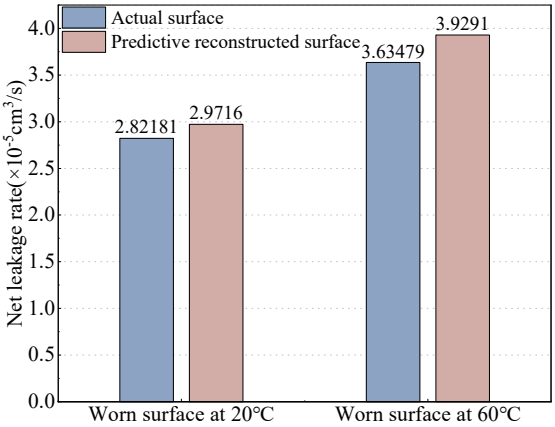


Figure 4.4. Comparison of net leakage rate results

Since the reconstructed surface maintains the same topography characteristic parameters as the actual surface, such as PSD, HPD, RMS roughness, etc., both show similar leakage characteristics. The leakage rate of the reconstructed surface is slightly higher than that of the actual surface. The error arises from the differences in the topography structure arrangement and topological form of the reconstructed surface compared to the actual surface. The topography affects the contact state and percolation channels, resulting in different leakage rates. However, the error is relatively small, and the reconstructed surface can more accurately reflect the change trend of the leakage rate under different temperatures. It still has good reliability in predicting oil leakage.

5. CONCLUSION

As the wear temperature increases, the surface damage pattern changes from continuous scratches along the reciprocating direction to discrete, localized adhesive failure nodes, indicating a shift from abrasive to adhesive wear. Material exfoliation depressions, resulting from shear-adhesive nodes, begin to appear on the worn surface. During the abrasive wear-dominated phase, the friction coefficient is high. In contrast, during the adhesive wear-dominated phase, the softening of the PTFE surface reduces shear strength and the friction coefficient. A method for predicting and reconstructing worn surface topography is developed. This method reconstructs a surface with identical PSD and HPD statistical characteristics from experimentally derived worn surface topography.

Furthermore, the anisotropic characteristics of the original surface are modified by adjusting its 1D PSD along a single direction. The HPD of the surface roughness can be modified using a Johnson transform. Comparison of oil percolation analysis results between the original and predictive reconstructed surfaces reveals that, due to differences in morphological arrangement and topology, the leakage rate calculations exhibit minimal error, accurately reflecting the leakage rate trends of the worn surfaces at different temperatures. At room temperature, grooves created by abrasive wear easily form percolation channels that penetrate the sealing surface. However, due to the shallow wear depth, leakage is low. At high temperatures, adhesive failure nodes cause significant material removal, forming large cross-sectional percolation channels that increase overall flow capacity and leakage.

Abstract.

Fluid power systems are widely used in demanding and harsh environments such as marine and offshore installations, where service, maintenance, and repair costs are extremely high. This includes usage in offshore wind turbines, which impose stringent and rigorous requirements on system lifetime, reliability, and availability. As a result, accurately predicting these complex systems' lifetime, degradation patterns, and optimal service intervals is becoming increasingly important for ensuring operational efficiency and minimizing levelized cost of energy. However, the persistent absence of reliable and validated methods to accurately predict component lifetimes under realistic and variable operating conditions means that such systems are typically designed, operated, and maintained based on historical failure data, empirical observations, and conservative safety assumptions.

Among the most critical and failure-prone components in these systems are hydraulic cylinders, particularly the hydraulic seals, which are highly prone to wear and degradation over time. Previous studies have effectively combined Finite Element Analysis (FEA) with advanced numerical simulation techniques to model and predict seal wear performance under a wide variety of operating conditions. Extending on these established approaches, this study develops and applies a comprehensive sensitivity analysis examining the correlation and interaction between key influencing factors such as ambient temperature, pressure, and duty cycle, to predict seal wear.

This research incorporates wear simulation modeling in which Ansys is used to model the contact and deformation behavior, and a numerical framework is developed in MATLAB to predict fluid and asperity contact pressures, lubricant film thickness, and wear. This approach integrates detailed surface contact modeling, material properties, and realistic boundary conditions. Through a series of carefully designed simulations, this study attempts to predict the wear behavior of hydraulic seals over time, offering valuable insights that can be used for improving component performance and enhancing the overall reliability and longevity of fluid power systems in demanding operational environments.

1. INTRODUCTION

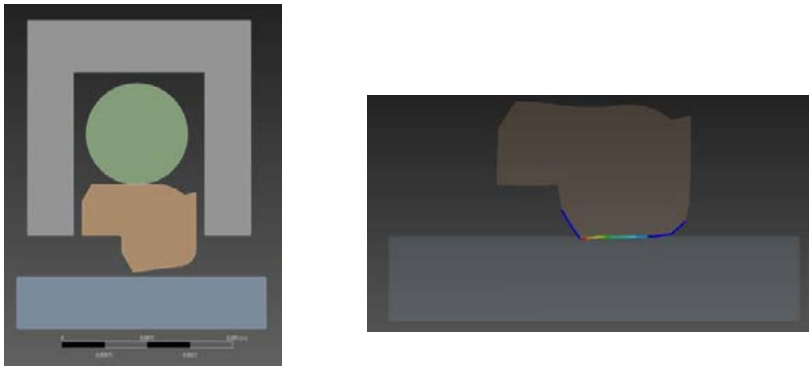
Reciprocating hydraulic seals serve as auxiliary components in hydraulic systems, yet they are also among the most critical parts because they prevent sealed fluid from leaking. If the seal operating mechanism is not well understood, it may be used incorrectly, potentially leading to seal failure and unpredictable consequences. White and Denny were the pioneers in analyzing the behavior and sealing efficiency of reciprocating seals between 1944 and 1947 [1] [2]. A further wave of experimental and theoretical analysis has been carried out since then.

According to experimental findings, reciprocating movement of the piston rod induces hydrodynamic forces. Two analytical methods are commonly used to study fluid film inverse hydrodynamic lubrication. The inverse hydrodynamic lubrication (IHL) approach simplifies the model by assuming full-film lubrication and exceeding the impact of fluid dynamic pressure on seal deformation, thereby limiting its effectiveness [3]. The elasto-hydrodynamic lubrication (EHL) method, however, incorporates a balance between static contact pressure and fluid pressure, which leads to a more realistic depiction of lubrication film behavior in a sealing context [4].

Among the type of seals that have been employed to analyse the lubrication characteristics, we can find O-ring seal, V- cup seals, and step seals. Previous studies on these kinds of seals have revealed that the lubrication in this interface is in the mixed lubrication state [5].

As a result of the interference fit between the seal and the inner wall of the cylinder, both surfaces initially possess fine asperities formed during the shaping and machining process. The reciprocating motion of the piston rod introduces frictional forces that not only smooth the cylinder wall but also cause migration and wear of the seal's surface profile. This wear leads to changes in the geometry of the sealing lip, which in turn, can significantly influence the integrity and performance of the sealing system [6] [7].

The most common kind of seal failure is wear, so it is crucial to accurately predict seal wear characteristics. For the prediction of wear in hydraulic seals, both experimental and simulation methods have been employed. Among the empirical work that has been analysed, we can find the studies of Ridgway et al. [8], which analysed the wear behaviour of the seal ring in slurry-free environment and reached the conclusion that non-uniform packing compression is not the sole factor influencing the lifetime and reliability of the gland seal. Yang et al. [9] analysed the friction behaviour of seals containing different PolyTetraFluoroEthylene (PTFE) content. Moreover, Lee et al. [10] suggested an experimental method for the accelerated wear of fluororubber (FKM) seals by introducing 0 – to 1 microns alumina particles mixed with the lubricant; nonetheless the outcome of this experiment indicated that the wear performance was similar to normal working conditions. Pan Deng et al. [11] evaluated the impact of different pressures to analyse their effect on the wear rate of PTFE piston seals. The outcome of this experiment indicated that the wear performance was similar to normal working conditions. Liu et al. [12] investigated how varying pressure levels influence the wear rate of PTFE piston seals. The outcome of these experiments indicate that wear was more pronounced at higher pressures. In addition to this, Gao et al. [13] analysed the wear behaviour of different coating seals. They found that the



highest possible temperature and the increment of temperature related to the friction surface affect the wear resistance and coating durability. Furthermore, the relationship between leakage rate and skewness surface topography was explored by Ruhmani et al. [14]. Even though the tribological characteristics of a seal can be explored through experimental means, this entails manpower and resources. As a result, it has been explored to use numerical simulations to predict the wear behaviour. One of the first analytical models to predict wear on seals was implemented by Yang et al. [15]. In addition to this, Beksi et al. [16] implemented a birth-death technique on an FEM model to better study the seal wear in reciprocating seals. Moreover, other studies like the ones presented by Frolich et al. and Li et al. [17] [18] proposed methods to assess the effects of factors like friction and heat generation on wear. Nonetheless, these methods primarily examine the friction behaviour associated with the seals large–scale deformation under external compression, while neglecting the impact of microscopic factors at the lubrication interface on seal wear. The macro deformation of the seal generates heat, which in turn reduces the fluid's viscosity. Thus, the macro deformation mechanics are closely linked with the micro-hydrodynamics of the fluid film. Moreover, studies performed by Liu et al. [19] and Zhang et al. [20] employed A multiscale wear simulation approach for rotary lip seals operating under mixed lubrication conditions, considering the microscopic characteristics of the interacting surfaces. The results of these studies showed that decreasing the axial asperity density and increasing the circumferential asperity density can effectively reduce seal wear.

Even though other studies have modelled wear in hydraulic seals using various approaches, including the modelling of micro-elastohydrodynamic effects under different working conditions, no sensitivity analysis based on this approach has been conducted for hydraulic seals to examine how ambient temperature, sealing pressure, and speed during outstroke affect the wear. The purpose of this study is to describe wear using a micro-elasto hydrodynamic model that incorporates the effects of lubrication in a reciprocating seal. This is achieved by calculating the parameters present at the contact interface to account for lubrication effects and to improve the wear prediction using Archard’s wear equation.

2. SEAL DESCRIPTION

This study aims to analyse the contact between a step-seal made of an O-ring and a Turcon Ring as shown in Figure 1, Typically, the O-ring is manufactured from nitrile rubber, while the Turcon ring is made from a composite material based on polytetrafluoroethylene (PTFE). When the step seal is mounted on the rod, the sealing edge forms a steep contact pressure gradient on the high-pressure side and a gentler gradient on the low-pressure side. This distribution of pressure reduces fluid adhesion to the rod during the outstroke and helps return any remaining fluid film on the rod into the system.

The reciprocating rod step seal consists of an elastomeric O-ring, commonly manufactured from nitrile rubber (NBR), and a sealing ring made of a PTFE-based composite that is in direct contact with the rod surface. The O-ring provides elastic preload and accommodates installation and pressure-induced deformations, while the PTFE sealing ring is responsible for sealing performance due to its low friction coefficient and good wear resistance. This combination of materials enables the seal to operate reliably under mixed lubrication conditions, where both fluid film lubrication and asperity contact occur during reciprocating motion.

3. MODEL OF MIXED LUBRICATION

3.1. Numerical Simulation

This study aims to characterize wear through a micro-elastohydrodynamic model that accounts for the influence of lubrication in reciprocating seals. The model calculates key parameters related to the lubricated contact, intending to determine the asperity contact pressure for use in the Archard's wear equation. On a microscale level, the lubrication model displays robust coupling among fluid mechanics, asperity contact mechanics, deformation mechanics, and thermo-mechanics effects. Therefore, an iterative computational procedure has been built and employed to manage the coupling relationship. These relationships are described by a set of governing equations (including the Reynolds equation), which are solved using the finite element method.

The employed multiscale wear simulation model integrates a microscale mixed Thermo-Elasto-Hydrodynamic (TEHD) lubrication model with a macroscale wear model to simulate the wear behaviour of reciprocating lip seals under mixed lubrication conditions. The microscale model is designed to resolve critical tribological parameters such as lubrication film thickness, hydrodynamic pressure, and asperity contact pressure. The governing equations form a coupled multiscale framework in which each equation represents a dominant physical mechanism governing reciprocating seal wear under mixed lubrication. The Reynolds equation describes the hydrodynamic behavior of the lubricant film, while asperity contact is modeled using the Greenwood–Williamson formulation, which represents solid–solid interactions through a statistical description of surface asperities. The model links microscale contact, hydrodynamic pressures, and thermal relations account for frictional heating and its influence on lubricant viscosity. The equations are implemented through an iterative numerical scheme in which hydrodynamic and asperity contact pressures are solved simultaneously and jointly determine the film thickness. Frictional heat

generation updates the lubricant viscosity and feeds back into the pressure solution until convergence is achieved at each time step. After convergence, the asperity contact pressure is incorporated into a modified Archard wear model to compute material loss. As a result, the model behavior emerges from the coupled evolution of lubrication, contact, thermal, and wear mechanisms rather than from any single equation in isolation.

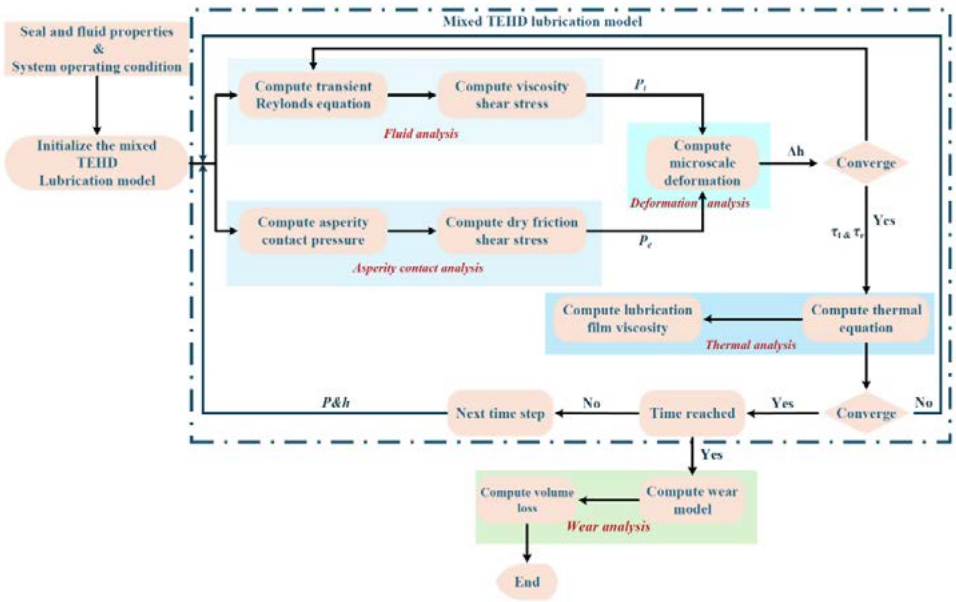

Figure 2. Schematic of the computational procedure TEHD: Thermo-elasto-hydrodynamic.

The thermal mechanics, fluid mechanics, and asperity contact mechanics, and deformation mechanics are recalculated until the lubrication film thickness, and the average temperature achieve convergence which has been explained in the following sections. Afterwards, the asperity contact pressure is used in the Archard's modified equation to calculate wear.

3.2. Mixed TEHD Lubrication Model

The multiscale wear simulation model used here incorporates a microscale mixed Thermo-Elasto-Hydrodynamic (TEHD) approach with a macroscale wear model to simulate the wear behavior of reciprocating lip seals under mixed lubrication conditions. The microscale model is designed to resolve critical tribological parameters such as lubrication film thickness, hydrodynamic pressure, and asperity contact pressure, employing the version of the Reynolds equation that considers cavitation given by Payvar et al. [21]:

$$\frac{\partial}{\partial x}\left(\phi_{xx}\frac{h^3}{\mu}\frac{\partial(F\Phi)}{\partial x}\right) 6u\frac{\partial}{\partial x}\{[1+(1-F)\Phi](h_T+\sigma\phi_{s.c.x})\} + 12\frac{\partial}{\partial t}\{[1+(1-F)\Phi](h_T+\sigma\phi_{s.c.x})\} \quad (1)$$

Where, h is the film thickness, μ is the fluid viscosity, σ is the root mean square roughness of the seal, and u is the rod speed. ϕ_{xx} is the pressure flow factor, related to the fluid

obstruction due to surface roughness, and $\phi_{s.c.x}$ is the shear flow factor. This represents the extra flow transport resulting from surface sliding. F is the cavitation index and Φ is the fluid pressure or the density of the cavitation region.

In the full film region: $\Phi > 0$, $F = 1$, $p_f = F\Phi,\ \rho = \rho_f$ (2)

In the cavitation region: $\Phi < 0$, $F = 0$, $p_f = 0,\ \rho = \rho_f(1 + \Phi)$ (3)

When solving the Reynolds equation, it is essential to define both the inlet and outlet boundary conditions. During the outstroke and instroke phases, the fluid pressure corresponds to the sealed pressure on the fluid side and the ambient pressure on the air side, respectively.

At fluid side: $\phi\ (x = 0) = p_s$ (4)

At air side: $\phi\ (x = L_x) = p_e$ (5)

where L_x is defined as the sealing region, p_s corresponds to the pressure within the sealed area, and p_e refers to the surrounding ambient pressure.

As described by Ran et al. [22] the film thickness can be expressed as:

$$h = h_{st} + \Delta h \quad (6)$$

where h_{st} denotes the static film thickness, and Δh represents the elastic deformation of the sealing lip in the normal direction, which can be determined using the influence coefficient method. Ran et al. [22] mentioned that the mean truncated film thickness is expressed as follows:

$$h_T = \int_{-h}^{\infty}(h + \delta)f(\delta)d\delta \quad (7)$$

Where δ represents the roughness amplitude of the seal surface measured relative to the mean level. $f(\delta)$ denotes the probability density function of δ. When the asperity heights of the seal surface follow a Gaussian distribution, the mean truncated film thickness can be expressed as follows:

$$h_T = \frac{h}{2} + \frac{h}{2}erf\left(\frac{h}{\sqrt{2}}\right) + \frac{1}{\sqrt{2\pi}}\, e^{-\frac{h^2}{2}} \quad (8)$$

Where erf represent the error function

The shear stress resulting from the fluid viscosity can then be determined by the following relationship, as described by [23]:

$$\tau_f = \frac{-\mu u}{h}(\phi_f - \phi_{fss}) - \phi_{fpp}\frac{h}{2}\frac{dp_f}{dx} \quad (9)$$

where ϕ_f, ϕ_{fss} and ϕ_{fpp} are shear stress flow factors.

Asperity contact analysis

When the elastic seal is compressed against the rod, contact occurs at multiple microscopic asperities within the nominal contact area. The distance or separation between the seal and rod surfaces greatly affects key sealing characteristics, including leakage and friction.

The asperity contacts P_c between the seal surface and the cylinder wall can be described by the Greenwood Williamson (G–W) surface contact model [24].

$$P_c = \frac{4}{3}\frac{1}{(1-\nu_s^2)}\sigma^{3/2}R^{1/2}\eta\frac{1}{\sqrt{2\pi}}\int_H^\infty (z-H)^{3/2}e^{-z^2/2}\,dz \quad (10)$$

$$P_a = \int_d^\infty (z-d)\;\phi(z)\,dz \quad (11)$$

Where η is the seal asperity density, R is the asperity radius, and σ is the RMS roughness of the seal surface

E represents the equivalent Young's modulus, which can be expressed as

$$E = \frac{E_{seal}}{1-\upsilon_{seal}^2} \quad (12)$$

Where E_{seal} and υ_{seal} are the Young's elastic modulus and Poisson's ratio of the seal, respectively.

The dry friction shear stress τ_c is also described by the following formula found in [22]

$$\tau_c = -\frac{u}{|u|}fp_c \quad (13)$$

For this case, f is the dry friction coefficient.

Thermal analysis

Since viscosity, the key parameter in the Reynolds equation, depends on temperature, its effect on sealing performance must be considered. Friction in the sealing area raises the surface temperature, and the resulting heat is mainly dissipated through conduction and convection. Part of the heat is conducted through the seal and rod, while a smaller portion is carried away by the lubricant. Wang et al. [25] introduced a modified quasi-3D energy equation that accounts for surface roughness to analyse temperature distribution T in the fluid film. Because the lubricating layer is only a few microns thick, the heat removed by the lubricant is negligible. Salant et al. [26] proposed a simplified model assuming all heat transfers to the rod, given its higher thermal conductivity compared to the seal. Where T_e is the ambient temperature L_x is the length of the surface contact, ρ_r is the density of the rod, c_r is the specific heat capacity of the rod, k_r is the thermal conductivity of the rod.

$$T - T_e = 1.07\frac{QL_x}{2k_r}\left[\frac{\rho_r c_r|u|L_x}{2k_r}\right]^{-1/2} \quad (14)$$

$$Q = (\tau_f + \tau_c)u \quad (15)$$

Because the viscosity of the lubricating film changes with both pressure and temperature, a viscosity–pressure–temperature relationship is used to calculate the film viscosity in the sealing region, which is expressed as [25]:

$$\mu = \mu_0 exp\left\{(ln\mu_0 + 9.67) \times \left[(1 + 5.1 \times 10^{-9} p_f)^{\zeta} \times \left(\frac{T - 138}{T_e - 138}\right)^{-\psi} - 1\right]\right\} \quad (16)$$

where μ_0 represents the viscosity under the atmospheric pressure p_e and ambient Temperature T_e. The dimensionless constants ζ and ψ can be defined as:

$$\zeta = a/[5.1 \times 10^{-9}(ln\,\mu_0 + 9.67)\,] \quad (17)$$

$$\psi = b(T_e - 138)/(ln\,\mu_0 + 9.67) \quad (18)$$

where a denotes the Barus viscosity–pressure coefficient (Pa^{-1}) and b represents the Reynolds viscosity–temperature coefficient (K^{-1}).

Deformation analysis

For this approach, an offline FEA model is first adopted for analysing deformation mechanics. The first is the macroscopic deformation used to calculate sealed pressure distribution and contact length; the other is the microscopic parameters such as the asperity contact pressure and the fluid pressure employed for the wear calculation.

The static contact pressure, P_{st}, is assumed to be the combined effect of the hydrodynamic pressure and the asperity contact pressure, expressed as $P_{st} = P_f + P_c$ (19).

Because the lubricating film is relatively thin, the microscale deformation of the sealing lip is assumed to exhibit linear elastic behaviour. By dividing the contact length into N axial nodes, the normal deformation of the seal lip at the *i*-th node caused by the film, (the change in film thickness described in eq. (2) Δh) can be calculated by the following expression as described by [22]:

$$\Delta h_i = \sum_{j=1}^{N} C_{ij}\,(p_f + p_c - p_{st})_j \quad (20)$$

Where C_{ij} is the deformation coefficient matrix obtained from FEA.

Wear analysis

Multiple theoretical and experimental models in previous work have been done regarding material wear, such as abrasive wear and adhesive wear.

Archard's wear model is one of the most commonly employed, and widely used for the calculation of wear on seals.

For this case, the wear volume loss is considered to be linear to the sliding distance, load, and the inverse of hardness of the softer material. The original equation is expressed as:

$$V = \frac{K}{H} WS \quad (21)$$

In this scenario V is the volume loss, K is the dimensionless Archard coefficient, W is the contact force, H is the surface hardness of the softer material, and S is the sliding distance.

The wear modulus then is

$$k = K/H \quad (22)$$

Then, the Archard's wear model may be written as.

$$V = kWS \quad (23)$$

When this is divided by the contact area A, the wear film thickness can be obtained by

$$h_W = kp_nS \quad (24)$$

in which case p_n is the normal contact pressure.

The lubricating conditions present in the rod seal are of mixed lubrication. For this micro hydrodynamic lubrication model a competition between the fluid and asperity contact is considered. If lubrication is not present in sealing zone, the normal contact pressure would be equal to the static pressure. Under mixed lubricating conditions, the sealing lip is supported by both the fluid dynamic pressure and asperity contact pressure. Wear in this case is generated through asperity contact; as a result, the wear model is redefined as

$$h_w = kp_cS \quad (25)$$

Where p_c is the asperity contact pressure obtained through the mixed lubrication model.

Table 1. Main simulation parameters

Parameter	Value	Parameter	Value
Ambient Temperature (T_e)	40°C	Compression rate of seal (ε)	8 %
Sealed Pressure (p_s)	0-20 MPa	Rod diameter (d)	25.4 mm
Ambient Pressure (p_e)	0.1 MPa	Initial sectional height of seal (l)	3.18 mm
Reference Viscosity (η_0)	0.04 Pa.s	Thermal conductivity rod (k_r)	25 W·m^{-1}·K^{-1}
Density of rod (ρ_r)	7700 kg·m^{-3}	Viscosity–temperature coefficient (β)	3.18 × 10^{-2} K^{-1}
Stroke length (S)	200 mm	Root mean square roughness of seal (σ)	0.6 μm
Speed of rod (u)	20–200 mm/s	Specific heat capacity of rod (c_r)	460 J·kg^{-1}·K^{-1}
Dry friction coefficient (f)	0.25	Viscosity–pressure coefficient (α)	2 × 10^{-8} Pa^{-1}
Young's modulus of seal (E_{seal})	380 MPa	Poisson's ratio of seal (ν seal)	0.4

Wear coefficient (k)	1.2×10^{-5} mm³/Nm		

Simulation values reported in Table 1 are based upon [19] and [22].

4 RESULTS AND DISCUSSIONS

The following results are presented showing how the asperity contact pressure varies as function of the sealed pressure at different temperatures. Figure 3 displays the curves of asperity contact pressure at different sealed pressures and temperatures.

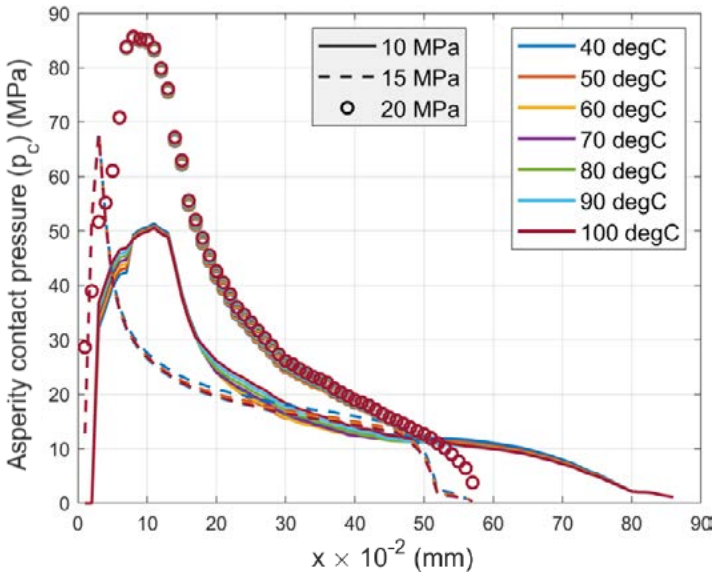

Figure 3. Curves of asperity contact pressures at various sealed pressures under varying ambient temperatures obtained from the computational procedure TEHD (thermal elasto-hydrodynamic).

Figure 3 displays the evolution of the asperity contact pressure along the sliding direction x for sealed pressures of 10, 15, and 20 MPa at ambient temperatures ranging from 40 °C to 100 °C. Generally, the asperity pressure displays a sharp initial peak near the contact entry, followed by a gradual decay towards the outlet region. This behaviour would reflect the localized concentration of contact stress at the starting edge, where the load is supported by asperities.

The decay of the asperity contact pressure follows a similar trend for all sealed pressures and temperatures, indicating that the contact mechanics remains dominated by surface topography rather than temperature-induced geometric changes. Compared with the lower sealed pressures, the overall asperity contact pressure magnitudes are higher as the sealed pressure increases, with maximum values of the asperity contact pressure approaching 65–75 MPa at a sealed pressure of 15 MPa and the asperity contact pressure would reach a maximum at 80–90 MPa at a sealed pressure of 20 MPa near the contact entrance.

Similar to the behaviour observed for each sealed pressure individually, all profiles nearly overlap through the entire contact domain, indicating that within this load range, the asperity deformation shows minor variation to ambient temperature variations. Nonetheless, when the ambient temperature rises, a slight increase in asperity contact pressure distribution can be seen.

Finally, the results indicate that the overall asperity contact pressure distributions augment when the sealed pressure increases. As the external load grows, the contact asperities experience augmented deformation, resulting in increased localized contact stresses at the edge of the contact zone.

4.1 Combined effect of sealed pressure, rod speed and ambient temperature.

The wear behaviour of the reciprocating hydraulic step rod seal and its lubrication performance are greatly influenced by the rod's operating outstroke speed. Therefore, the proposed method is used to analyse the seal wear and lubrication characteristics under various rod outstroke speeds, sealing pressures, and ambient temperatures. The results of this analysis may be seen in Figure 4. Showing the resulting wear as a function of sliding outstroke speed, temperature, and sealed pressure.

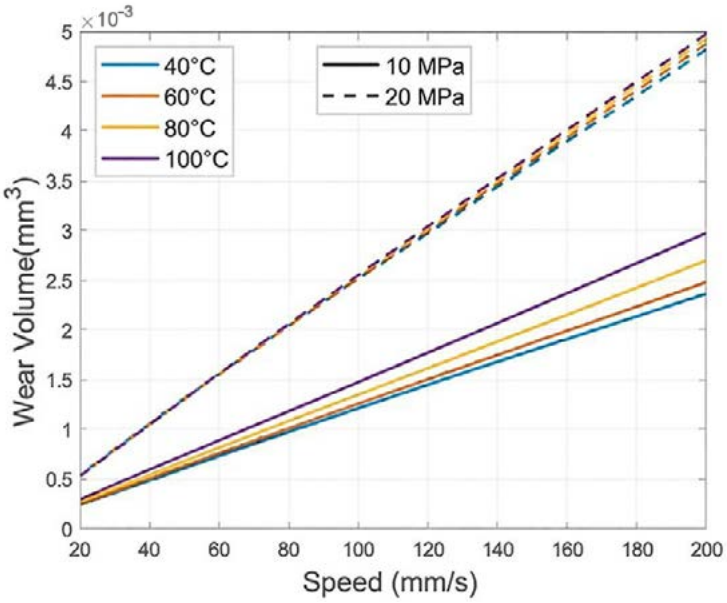

Figure 4. Wear volume per stroke of the rotary lip seal versus speed under different sealed pressures and ambient temperatures.

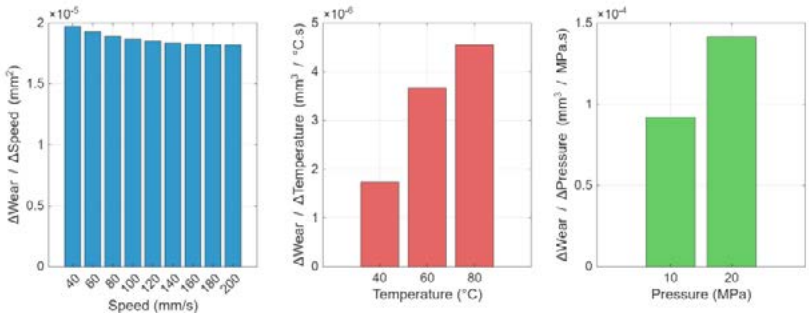

Figure 5. Sensitivity Analysis of Wear with each parameter.

The set of line plots shown in Figure 4 displays a dependence of wear volume on both parameters with different behaviour observed for each pressure condition. At both pressures, the wear volume increases with rising outstroke speed and temperature. This effect is more pronounced at 20 MPa, where wear volumes are higher all over the full range of test conditions. This suggests that the increased contact pressure would intensify the wear process, mainly due to augmented asperity deformation, and slightly worsened lubrication conditions at higher ambient temperature. However, the change in wear for both the 10 MPa and 20 MPa sealed pressures is more strongly influenced by outstroke speed than by the increase in ambient temperature. For the different speed cases analysed in this study we can observe that wear increases with rod outstroke speed. Having a maximum value of wear at a rod speed of 200 mm/s, and for the distinct sealed pressures the asperity contact profile has a low variation when the ambient temperature is changed for all the analysed sealed pressure cases. It is observed that wear is slightly higher at an increased ambient temperature of 100 degrees Celsius for both sealed pressures, with a lower variation between temperatures for the 20 MPa sealed pressure case. In Figure 5 it is observed that both speed and pressure have more or less the same influence, this confirms that controlling pressure and speed is key to reducing wear in hydraulic seals.

5 CONCLUSIONS

In this paper, a sensitivity analysis regarding accelerating wear factors, including sealed pressure, rod outstroke speed, and ambient temperature, is presented based on a wear simulation model which is developed for a reciprocating hydraulic step-rod seal under mixed lubricating conditions. From the model, it is observed that with increased sealed pressure the resulting calculated asperity contact pressure increases. In addition, ambient temperature rising from 40°C to 100°C causes a modest increase in the peak asperity contact pressure, despite the low overall variation. It is observed that with an increase in sealed pressure, the value of wear also increases, as a higher sealed pressure results in higher asperity contact pressure and increased contact between asperities. Moreover, it is observed for all sealed pressure scenarios that the calculated wear increases in an arguably mostly linear manner with the outstroke speed. The increased effect that the augmentation of both sealed pressure and operating outstroke speed had on the calculated wear could be explained by the elevated contact between asperities and the worsening lubricating conditions. It is observed that the highest accelerating factor out of the ones analysed in this study is the sealed pressure,

followed by operating outstroke rod speed, whereas the ambient temperature effect has a lower effect across all operating conditions.

In conclusion, this study presents a comprehensive investigation into the wear behavior of reciprocating hydraulic step-rod seals operating under mixed lubrication conditions, with a particular focus on the sensitivity of wear to key accelerating factors: sealed pressure, rod outstroke speed, and ambient temperature. Using a simulation model grounded in Archard's wear equation, the analysis reveals that sealed pressure is the most dominant contributor to wear progression. As sealed pressure increases, the asperity contact pressure rises significantly, leading to intensified surface interactions and greater material loss. Rod outstroke speed also plays a critical role, as higher speeds exacerbate dynamic contact conditions and reduce the effectiveness of lubrication, further accelerating wear. In addition, ambient temperature directly influences wear. This impact is attributed to the thermal exchange between the environment and the lubricated contact zone, with a direct effect on viscosity, confirming ambient temperature as a contributing factor in wear.

To complement the simulation-based insights, the study also emphasizes the importance of accelerated testing protocols for evaluating seal wear characteristics under controlled yet extreme operating conditions. These tests would simulate high-pressure, high-speed, and variable-temperature environments to induce wear over shortened timeframes, allowing for rapid assessment of seal durability and performance. Accelerated testing not only validates the simulation results but also provides empirical data that can be used to refine predictive models and improve material selection and seal design. Employing simulation approaches, this study offers a robust framework for understanding and managing wear in hydraulic sealing systems. The overarching vision is to enable predictive maintenance, reduce downtime, and enhance the reliability and operational lifespan of hydraulic components. Ultimately, controlling sealed pressure and rod speed emerges as the most effective strategy for minimizing wear. This dual approach simulation-driven analysis and accelerated testing would lay the foundation for smarter, more resilient hydraulic systems in demanding industrial applications.

Novel ultrasonic position sensor for hydraulic clamping cylinders

Authors: Markus Fritton, Julia Wick, Albert Dorneich

Balluff GmbH, Zabergäustraße 8, 73765 Neuhausen a.d.F., Germany,
albert.dorneich@balluff.de

Abstract.

Piston position detection for hydraulic actuators is a common task in hydraulic systems. Sensors based on several sensing principles can be found on the market. Nevertheless, a robust and compact solution for short stroke cylinders was missing. To fill this gap, a novel ultrasonic position sensor was designed, built and tested for applications in hydraulic actuators.

Keywords. Clamping position sensing, condition monitoring, clamping cylinder, block cylinder, digitalization in hydraulics, ultrasonic sensing

1. INTRODUCTION

Modern industrial production is characterized by a high degree of automation and digitalization. Hydraulic clamping cylinders for automated clamping in machining centers make a significant contribution to efficient and high-quality manufacturing of metal parts such as gearboxes and engine blocks [1].
Until recently, there were no sensors available that could detect and monitor both the clamping status, and the clamping travel of the hydraulic actuators used. In this paper we describe the development of a novel position sensor based on ultrasonic sensing.
The presented sensor enables direct, quick and continuous position measurement in short-stroke hydraulic cylinders up to 80 mm. Additional data for condition monitoring of hydraulic components with quality control for workpieces can be provided. This generates reliable information on the clamping status or piston position and lets the machine operator detect critical deviations or changes in the clamping process or hydraulic system early on. Therefore, the sensor is ideally suited for applications such as swing, lever and vertical clamping cylinders, block cylinders, hydraulic directional control valves, hydraulic chucks and small hydraulic cylinders for precise positioning.

2. SENSING PRINCIPLE: OPPORTUNITIES AND LIMITATIONS

2.1. Comparison of sensing principles

The goal of this work was the development of a piston position sensor for applications with limited available space. Solutions which need additional space around the hydraulic cylinder

All Open Access articles are peer-reviewed, distributed under the Creative Commons Attribution-Non Commercial 4.0 International

were therefore not preferred. Besides, a very compact design is required to avoid damage to the sensor in rugged environments. Since it is not desirable to use add-on parts to transfer the internal piston movement to an add-on sensor outside the cylinder, the measurement should be executed directly inside the cylinder.

Many sensing principles are available for position measurement such as [2]:

- Optoelectronic sensors (triangulation and time-of-flight) using optical lenses are contactless, precise and widely applied in open space but will fail in operation inside the cylinder because of the high-pressure and the opaque hydraulic oil.
- Magnetostrictive contactless sensors [3] provide a robust position detection inside the cylinder up to pressures of several 100 bars but have a poor ratio of the length of the sensor housing to the detection range for strokes < 100 mm.
- Draw wire sensors are prone to wear because of the mechanical movement of the wire.
- Oil flow sensors can provide an indirect indication of the piston position by tracking the oil volume. These sensors are often inserted into the supply line of more than one cylinder and can therefore enable overall monitoring of the status of the hydraulic system only.
- Microwave sensors may be suitable but are not yet available on the market [4].
- Alternately, clamping force sensors may be used for clamping monitoring [5].

As a result, ultrasonic time-of-flight-sensing was chosen as the favourite principle (Figure 1.1).

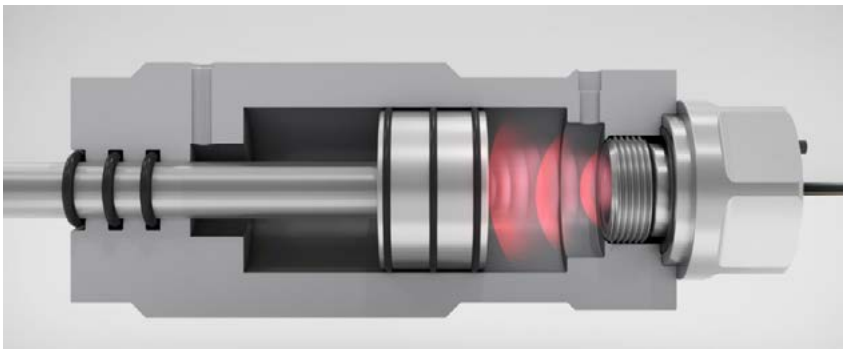

Figure 1.1: Hydraulic cylinder in cross section: rod, cylinder housing with two inlets for hydraulic oil, piston and sensor with cable are shown from left to right. The ultrasonic wave is displayed schematically in red.

2.2. Fundamentals of Ultrasound

Ultrasound is defined as sound in the frequency range of 20 kHz to 1 GHz which is not detectable by human hearing [6]. It can occur in solids, liquids and gases. If particles of a liquid are displaced from their initial position an acoustic wave will propagate through space and time due to the inertia and repulsive forces between the particles. Propagation of sound in matter is one of the fundamental phenomena in physics and may be exploited for technical applications such as sensing. It can be described by the pressure $p(\boldsymbol{x},t)$ and the sound particle velocity $v(\boldsymbol{x},t)$ and leads to a set of coupled second-order differential equations. In acoustics

as in other physical domains, phenomena such as superposition, interference, attenuation, reflection, refraction and diffraction must be considered.

In liquids, there are only longitudinal waves having a speed of propagation c given by (2.1) where E is the elasticity and ρ is the density:

$$c = \sqrt{\frac{E}{\rho}} \qquad (2.1)$$

Another important quantity in acoustic systems is the acoustic impedance Z given by (2.2).

$$Z = \rho \cdot c \qquad (2.2)$$

If an acoustic wave meets a boundary between two different materials having the impedance Z_1 and Z_2, the wave will be partly reflected and partly transmitted. If p_+ and v_+ are the pressure and the velocity of the incident wave and p_- and v_- of the reflected wave, respectively, the reflection factor r is defined by (2.3).

$$r = \frac{p_-}{p_+} = \frac{v_-}{v_+} \qquad (2.3)$$

To fulfil the continuity of pressure and velocity at the boundary, the reflection factor must follow (2.4).

$$r = \frac{Z_1 - Z_2}{Z_1 + Z_2} \qquad (2.4)$$

Table 1 shows the material parameters and impedance of relevant materials. The properties of ceramic are applied for the piezo element.

Property	Hydraulic oil	Steel	Ceramic
Speed of sound c [m/s]	1462	5920	10050
Density ρ [g/cm^3]	0.88	7.90	3
Impedance Z [Ns/m^3]	$1.29 \cdot 10^6$	$46.77 \cdot 10^6$	$30 \cdot 10^6$

Table 1: Material parameters and impedance of relevant materials

2.3. Ultrasonic Position Sensing

For ultrasonic position sensing, an ultrasonic wave is generated by a wave source such as a piezo element [2]. The emitted wave propagates through the hydraulic fluid inside the cylinder in the axial direction, is reflected by the piston, travels back to the sensor and is finally detected by the piezo element. It results from equation (2.4) and table 1 that approx. 95% of the amplitudes of the incident wave are reflected at the boundary between the oil and piston. The two-way time-of-flight τ_p is acquired by a time-to-digital converter (TDC, chapter 2.5). The piston position s_p is determined from τ_p using equation (2.5).

$$s_p = \frac{c(T,p) \cdot \tau_p}{2} \qquad (2.5)$$

The speed of sound $c(T,p)$ of the hydraulic fluid is dependent on the type, temperature T and the pressure p of the hydraulic fluid.

2.4. Temperature and pressure compensation

To compensate for the temperature and pressure, a second target – the reference target – is designed into the ultrasonic position sensor at a fixed position s_r. The reference target is designed in the shape of a three-armed star and has a fixed distance to the piezo element (Figure 2.1 at the left end of the sensor). The metal structure reflects only a fraction of the ultrasonic wave and allows most of the wave to propagate in the direction of the piston. The speed of sound can be calculated by the central processing unit (CPU, chapter 2.5) by using equation (2.6). The time-of-flight τ_r is obtained from the first echo by the TDC.

$$c(T,p) = \frac{2 \cdot s_r}{\tau_r} \quad (2.6)$$

Therefore, the desired quantity s_p can be continuously determined during the sensor operation by inserting *c(T, p)* into equation (2.5) without any a priori knowledge of the type, temperature and pressure of the hydraulic fluid.

Figure 2.1: Picture of the ultrasonic position sensor

2.5. Sensor design

Figure 2.2 shows the block diagram of the electronic circuitry of the ultrasonic position sensor. The position measurement is controlled by the CPU. An ultrasonic wave is generated by the piezo element which is electrically excited by the transmitter-electronics TX. The TDC starts its timer at the point in time of the wave transmission. After reflection of the wave by the reference target and the piston respectively, the wave is inversely transferred into an electrical signal by the piezo element. The received signal is amplified by the low noise amplifier LNA and the variable gain amplifier VGA. Finally, the signal is compared to a level by the comparator COMP. The VGA compensates for the attenuation of the ultrasonic wave which is dependent on the stroke of the cylinder, the hydraulic oil and the temperature. The output signal of COMP is used as a stop signal for the timer of the TDC. The TDC provides the time-of-flight resulting from the difference between the start and the stop time. After temperature compensation the piston position is calculated by the CPU. Finally, the output stage generates a standardized voltage or current signal proportional to the piston position. Alternatively, the piston position can be digitally transmitted to an IO-Link master [7], [8]. The power block converts the standardized supply voltage of 24 V into 3.3 V to feed the electronic circuitry and ensures electromagnetic compatibility (EMC).

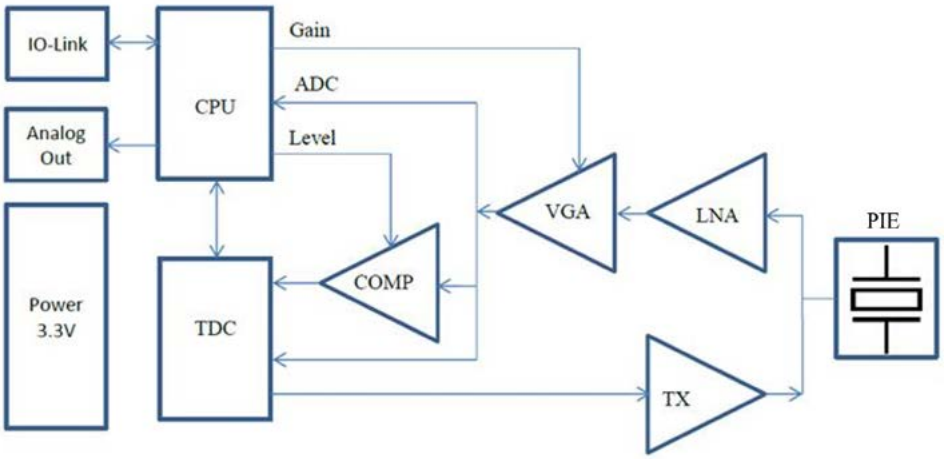

Figure 2.2: Block diagram of the electronic circuitry: CPU central processing unit, TDC Time -to-digital-Converter, COMP Comparator, VGA variable gain amplifier, LNA low noise amplifier, TX transmitter, PIE piezo element

Figure 2.3 illustrates the sensing principle for one measuring cycle. The emitted wave is visible between 0 and 5 µs. A first echo appears at approximately 12 µs resulting from the reference target (Figure 2.1). A second larger echo appears at about 67 µs which corresponds to the piston.

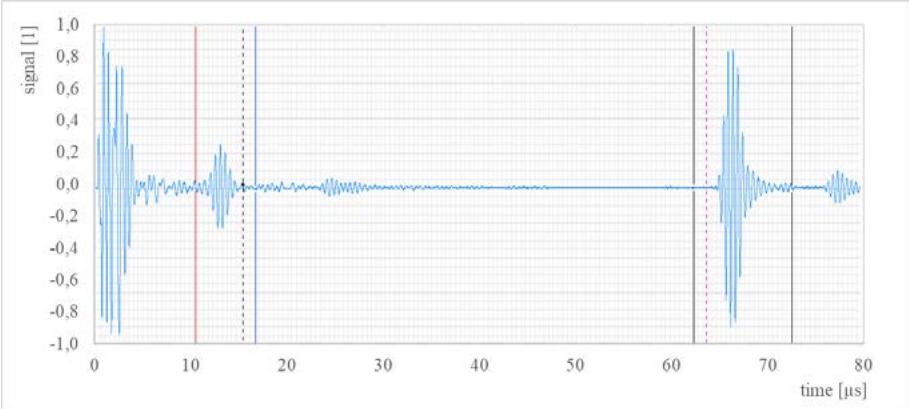

Figure 2.3: Sensor signal of one measuring cycle: x-axis time [s], y-axis normalized signal at the piezo element

Figure 2.4 demonstrates the sensor operation independently of the pressure. The plateaus at 27 mm and 6 mm correspond to the clamped and released state (“open position”) of the clamping device, respectively (blue curve). The transient phases of the piston in between these two states can be reliably monitored. The strong increase of the pressure (green curve) in the clamped position to 60 bars does not reduce the accuracy of the sensor output.

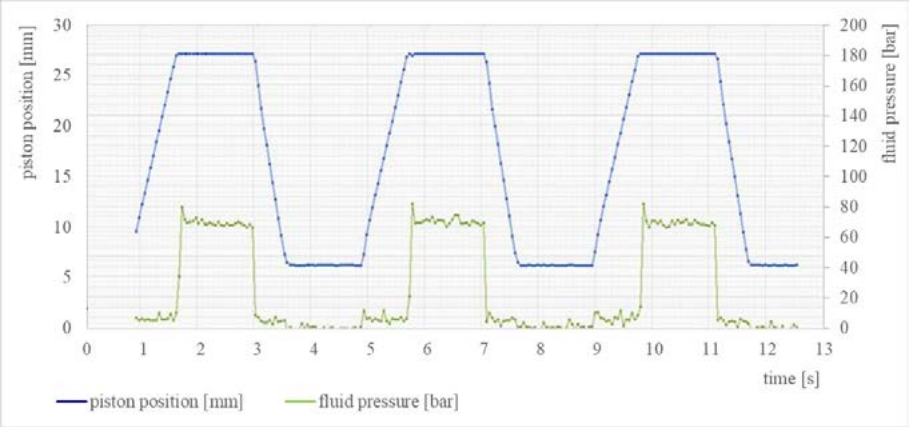

Figure 2.4: Sensor output: Piston position [mm] (blue curve) and fluid pressure [bar] (green curve) plotted during three clamping cycles as a function of time [s]

During the development of the sensor, a non-immersive solution was investigated. The sensor would not be wetted by oil. Instead, the sensor would be assembled behind the cylinder end wall (right side in Figure 1.1) outside the cylinder. This setup has some advantages for the cylinder manufacturer. Unfortunately, in this case about 95% of the wave amplitude is reflected at the boundary between the steel end wall and oil inside the cylinder (chapter 2.2). Consequently, the wave will travel back and forth inside the end wall and will superimpose on the piston echo. This will lead to a degradation in the quality of the measurement. Therefore, an immersive setup was finally chosen (Figure 1.1).

Additional measures have been taken to reduce the reflections at the boundary between the piezo element and the oil. However, a detailed description is beyond the scope of this publication.

2.6. Performance and limitation of the ultrasonic position sensor

The ultrasonic position sensor provides a selectable analogue voltage or current output (0…10V or 4…20 mA) and an IO-Link interface [7]. IO-Link is predestined as a digital, bidirectional, peer-to-peer communication system to support the configuration of the sensor and the transmission of sensor data [8] [9]. Table 2 lists the performance characteristics of the ultrasonic position sensor.

The limitation of the measurement range to currently < 100 mm is caused by attenuation of the ultrasonic wave, which leads to decreasing signals for long strokes. The maximum measuring rate is limited by the time-of-flight inside the cylinder. A new measurement cycle can be started after the arrival of the previous echo only considering the maximal measuring range. Noise will also limit the effect of the temperature and pressure compensation because short pressure peaks which appear in the hydraulic system must be acquired without filtering or averaging.

Performance characteristic	Value
Measuring range	0…80 mm
Pressure rating max.	350 bar
Burst pressure	455 bar
Dimension	∅ 30 x 30.9 mm
Sensor housing material	1.4104
Measuring rate max.	500 Hz (digital) 1000 Hz (analog)
Non-linearity max.	± 250 µm
Repeat accuracy	± 50 µm
Temperature drift max.	5 % full scale

Table 2: Performance characteristics of the ultrasonic position sensor [7]

The typical output characteristic at room temperature is shown in figure 2.5.

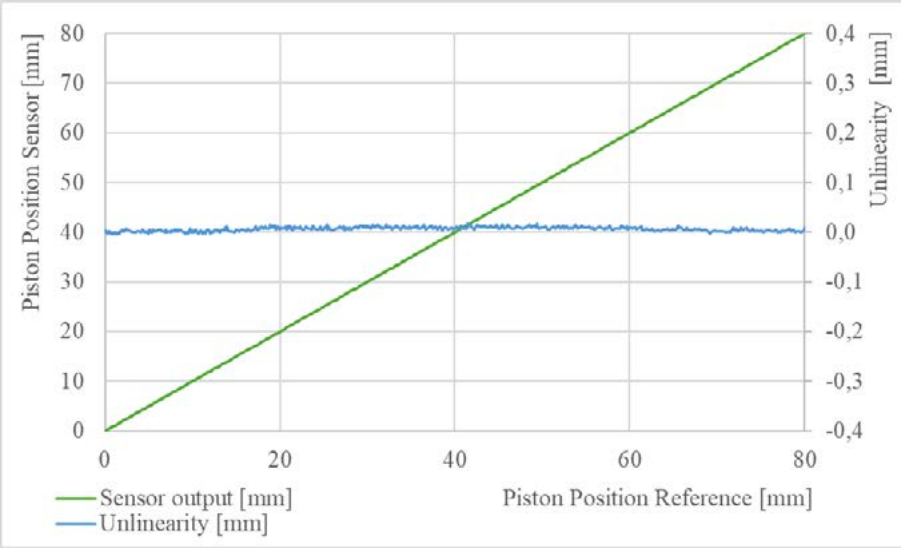

Figure 2.5: Output characteristic during travel over the full piston stroke of 80 mm. Piston position sensor [mm] (green curve) and unlinearity [mm] (blue curve)

3. APPLICATIONS FOR SWING CLAMPING CYLINDERS

Figure 3.1 represents a typical swing clamping cylinder. The hammer at the upper end of the piston rotates by 90° during its vertical movement to allow the workpiece to be placed in the “open position”. The ultrasonic position sensor provides information of the clamping status for high-efficiency PLC-controlled manufacturing in machining centers (figure 3.2).

Figure 3.1: Swing clamping cylinders: The ultrasonic position sensor is attached to the end face. The piston is equipped with a hammer to clamp the workpiece.

The automated manufacturing process consists of the main following steps:

1. Picking of the raw workpiece by the worker, a robot or an automated device from a tray or another container
2. Transport of the workpiece into the workspace and placement on the workbench of the machining center
3. Clamping of the workpiece by the clamping cylinder. The clamping cylinder should travel from its “open position” until “clamped with workpiece” which causes a mechanical stop.
4. Machining process such as milling, grinding or drilling. High forces and torques are applied to the workpiece during this step.
5. Releasing of the workpiece by the movement of the clamping cylinder to the “open position”
6. Picking of the processed workpiece by the worker, a robot or an automated device from the workbench
7. Transport of the workpiece out of the workspace and placement into a container of the processed workpieces

Several possible situations may occur after the clamping in step 3:

a. The workpiece is correctly inserted and clamped. The clamping position of the clamping cylinder (“clamped with workpiece”) is in the predefined range. Step 4 may be executed.
b. The workpiece is not placed at all due to faulty execution of the preceding steps. The clamping cylinder travelled too far to a position “clamped without workpiece”. The preceding steps 1 and 2 must be repeated.
c. The workpiece was placed at the wrong position and is consequently not clamped correctly
d. An incorrect workpiece was placed and is consequently not clamped correctly.
e. The workpiece is placed at the correct position but was not clamped.

Cases c, d and e may cause severe damage of the workpiece and the machining center in step 4 and leads to production downtime and high reject rates. By monitoring the entire clamping process, it is also possible to detect pressure fluctuations in the hydraulic unit, defects in the swivel mechanism and defective seals. Thus, the integration of the ultrasonic position sensor can help to prevent damage and downtime in the daily production process.

Figure 3.2: Machining center: Two swing clamp cylinders integrated in the workbench are visible. The cylinders are in the position “clamped with workpiece”

Polymer injection molding machines are another application for ultrasonic position sensors. Block cylinders are used in these machines to eject the molded part or to move inserts during the molding process. Ultrasonic position sensors can monitor this movement for process quality improvements and condition monitoring.

4. CONCLUSION

Ultrasonic sensing is a suitable principle for continuous, accurate and quick detection of piston position for short stroke cylinders. Modern electronic components, materials and compensation algorithms enable a compact and cost-efficient design for applications in machining centers and other automated machines. IO-Link makes it possible to achieve an excellent user experience during commissioning and configuration of the ultrasonic position sensor. The performance characteristics that are achieved have the potential to make this new type of sensor a game changer in position detection of short-stroke hydraulic cylinders and condition monitoring of the clamping process in factory automation.

From Pressure Pulses to Noise Sources – NVH-Oriented Design of Hydraulic Systems

Benedikt Müller[1], Heiko Baum[1]

[1] *FLUIDON GmbH, benedikt.mueller@fluidon.com, heiko.baum@fluidon.com*

Abstract.

This paper shows how fluid sound propagation in complex fluidic systems can be described accurately and in a numerically efficient manner using 1D CFD. Key modeling components are presented, and examples illustrate how these can be used to create a complete model for analyzing the vibration and resonance behavior of the fluid.

Based on this 1D CFD, a simplified, one-sided fluid-structure coupling is presented. Mechanical alternating forces on pipes and components are derived from transient pressure and velocity profiles, whereby the influence of the structural response on the fluid is neglected. This assumption significantly reduces the complexity of the model and enables highly efficient, fast-computing simulations.

The approach allows early identification of NVH-relevant loads and specifically supports the design of robust and structure-friendly piping systems.

Keywords: 1D CFD, unilateral fluid-structure interaction, simulation, vibration fingerprint, resonance behavior, NVH-relevant loads, NVH optimization

1. INTRODUCTION

Despite technical advances in automation, the machine operator remains a central figure in agricultural and construction machinery. Complex operating environments, legal frameworks, and the need for situational decisions make complete autonomy unrealistic at this point. In many cases, semi-automated systems take over the execution, while humans retain overall control and responsibility. This is precisely why acoustic comfort in the workplace cabin is becoming increasingly important: noise and vibrations have a direct impact on concentration, fatigue, and long-term health – and are becoming a decisive quality factor in machine development. NVH optimization is thus not only a technical necessity, but also an ergonomic and economic one. At the same time, reducing noise emissions into the environment is becoming increasingly important. This is particularly relevant when construction machinery is used in sensitive areas such as inner-city areas or during night work, where low noise pollution is essential.

Improvements in noise reduction on the drive side – for example, through quieter engines or electrification – means that hydraulic noises, such as those caused by pressure ripple from piston pumps, are no longer masked as they used to be. These noises are now clearly audible. This development is exacerbated by ever-higher power densities and increasing system dynamics, which make resonances in the branched piping system more likely. The result is structural excitation and airborne noise emissions, which significantly influence the overall NVH impression of the vehicles.

2. HYDRAULIC PRESSURE RIPPLE AS A SOURCE OF NVH

Hydraulic pressure pulsations are primarily caused by time-varying volume flows. Typical excitation sources are displacement pumps with kinematically induced flow ripple, dynamic valve operations, and abrupt changes in flow boundary conditions, for example as a result of load changes or emergency shutdowns.

These excitations lead to the formation of pressure waves that propagate at the speed of sound in the fluid along the pipe system and are partially reflected at cross-sectional changes, branches, and open or closed boundary conditions. The physical principles of this wave propagation and the associated acoustic effects are described in detail in *technical acoustics* (see [1]).

Within this context, this article deliberately focuses on fluid acoustics rather than on the classic, component-oriented, concentrated parametric system simulation of fluid power systems. **Figure 2.1** illustrates the propagation and decay characteristics of pressure waves in a fluid power system with sufficient damping.

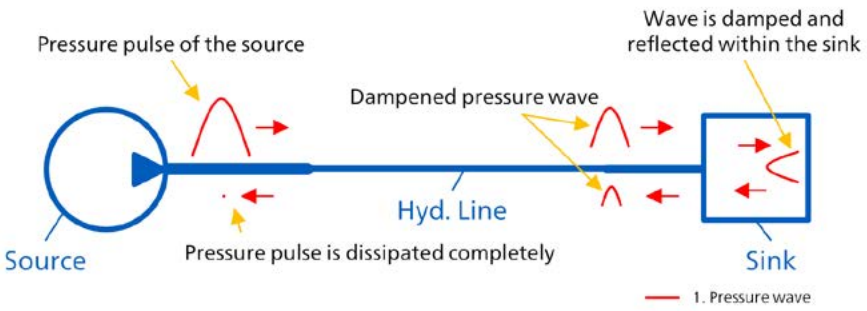

Figure 2.1: Pressure wave propagation in a system with high damping

In practice, the pressure ripple of the source – especially the pump – is often so pronounced that the introduced pressure wave is not completely dissipated. In addition, the effective system damping can be reduced, for example as a result high operating temperatures. Consequently, a relevant portion of the pressure wave remains in the pipe system and, after multiple reflections, reaches the excitation source again.

In the event of a resonance, this backward-travelling pressure wave hits a newly generated wave in-phase, causing the pressure pulsations to superimpose and reinforce each other (**Figure 2.2**).

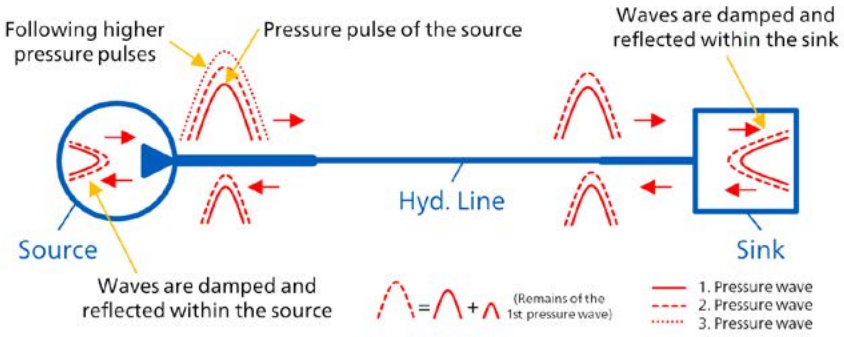

Figure 2.2: Pressure wave propagation in a system with insufficient damping

When excitation frequencies encounter the natural frequencies of the line system, resonant states arise with locally highly increased pressure amplitudes. From an NVH perspective, it is not only individual pressure peaks that are critical, but in particular, permanently acting, pulsation-induced alternating forces.

Two mechanisms of action are particularly important here:

- **Structural excitation** due to time-varying forces on pipe bends, elbows, branches, and fastening points
- **Sound emission**, either directly from vibrating pipes or indirectly via excited machine parts

While short-term pressure surges are often evaluated in terms of their maximum mechanical stress, pulsation-induced alternating forces lead to cyclic loads. These can cause material fatigue, loosening of connectors, or leaks in the long term, and have a significant impact on the overall NVH impression of modern machines. However, these effects are often underestimated in early development phases.

3. WHY 1D CFD?

A transient, one-dimensional simulation approach is used to analyze the fluid-acoustic effects described above. This approach enables a time-resolved simulation of the pressure and volume flow profiles along complex, branched pipe systems. A prerequisite for the validity of the one-dimensional analysis is that the pressure waves propagate as plane waves at the speed of sound in the relevant frequency range – an assumption that is well fulfilled for typical hydraulic pipe systems in mobile machines.

Compared to three-dimensional CFD approaches, 1D CFD offers significant advantages:

- Significantly reduced modeling effort
- Very short computing times
- High numerical stability for highly dynamic processes
- Possibility of extensive parameter and variant studies

Compared to concentrated parametric (0D) methods, 1D CFD enables a more realistic representation of wave propagation and resonance effects, while offering high numerical robustness and often lower computing costs.

Another significant advantage of the time domain approach is that it takes into account nonlinear effects such as those caused by real valve characteristics, pressure-dependent material properties, or transient boundary conditions.

4. COMPONENTS IN 1D CFD

With the *Piping Systems Library* [2], Fluidon has developed a model library that enables consistent mapping of hydraulic systems for fluidoacoustic analysis and NVH-oriented optimization. In addition to detailed pipe models, the library includes components for describing displacement units, valves, cylinders, and accumulators, thus enabling the consistent setup of acoustically relevant system models.

4.1. Pipes and Hoses

A central element in the acoustic simulation of hydraulic piping systems are pipes and hoses, whose behavior is decisive for the propagation of fluid sound in the system. The continuity equation and the Navier-Stokes equation are the basic fluid mechanics equations on which the calculation is based. A proven method for solving this partial differential equation system is the method of characteristics (MoC), which is characterized by high accuracy and low computational effort.

In the simulation of acoustic processes in pipes, it is necessary to take into account not only stationary friction but also dynamic friction, often referred to as frequency-dependent friction. The method developed by *Trikha* [3] implements this efficiently. *Theissen* [4] uses the method of characteristics with frequency-dependent friction to calculate oil hydraulic systems.

Figure 4.1 shows in the upper part that, in the case of slow oscillation, the flow profile is similar to that in the stationary case. However, if the frequency increases (lower part), history plays a major role in the shape of the flow profile, with higher shear velocities and thus increased friction occurring in the boundary layer.

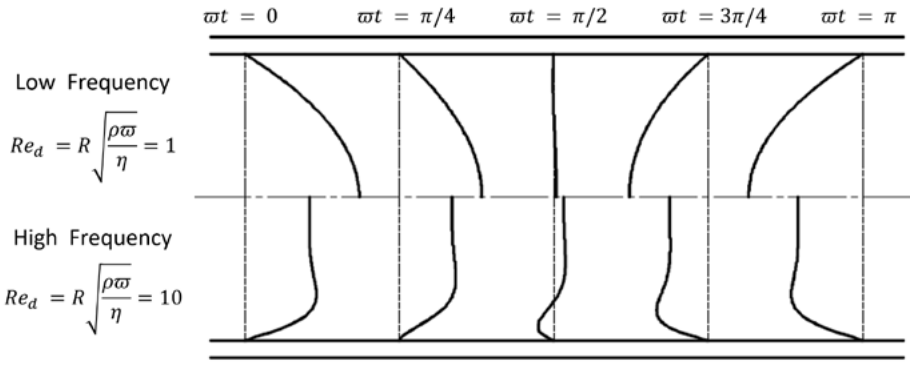

Figure 4.1: Flow profiles of oscillating pipe flows [5]

An important extension is the consideration of the viscoelastic behavior of hoses [6], [5], which is parameterized as a complex modulus of elasticity in the current implementation in DSHplus [7]. The viscoelastic component of the material behavior of hose material is represented by a Kelvin-Voigt model, which, connected in series with the linear elastic component, represents a so-called Zener body (**Figure 4.2**).

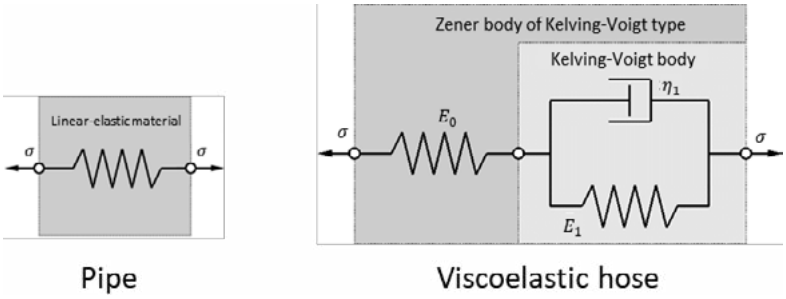

Figure 4.2: The viscoelastic component of the material behavior of hose material is represented by a Kelvin-Voigt model.

While the parameterization of a linear elastic steel pipe can be easily traced back to material and geometry values, measurements are still required for the exact parameterization of viscoelastic hose lines. The method for metrologically determining the four-pole transfer matrices in the frequency domain according to ISO 15086-3, which goes back to [8], has been used and further developed by Fluidon in numerous projects. Automated curve fitting methods then allow the models to be compared with the measurement data as a function of the operating parameters. **Figure 4.3** shows an example test setup for four-pole measurement. A comprehensive description of the measurement method, which originally comes from acoustics of exhaust systems for combustion engines, and the possible measurement setups, including a discussion of their specific advantages and disadvantages, can be found in *Tao et al.* [9].

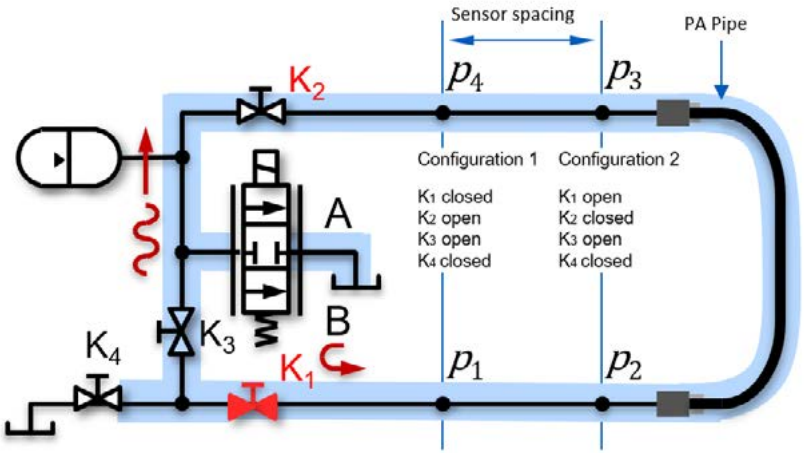

Figure 4.3: Test setup for four-pole measurement according to the secondary source method [10, p. 467]

Variable material data, thermohydraulic effects, cavitation, and gas transport are explicitly taken into account in the 1D CFD calculation and included in the solution of the conservation equations as time-dependent variables.

The time interpolation method proposed by *Savar et al.* [11] achieves greater flexibility in discretization with lower numerical damping, which is particularly advantageous when modeling complex systems. Further efficiency gains in the calculation of large models are achieved through parallel calculation of pipe sections.

4.2. Open / Closed End

In addition to the pipes, other components are required to model complete systems. The simplest boundary conditions are open and closed ends, at which either a pressure or a volume or mass flow is applied.

A pressure boundary condition can be used, for example, to represent a pressure source or a tank ($p \approx 0$). An applied volume flow can already represent a simple pump and forms the basis for more advanced models of displacement units.

If 1D CFD is coupled with concentrated parametric (0D) models, open or closed ends serve as defined interfaces to the 0D components.

4.3. Connectors

The algorithms of the method of characteristic and the resulting model structure do not allow two line elements to be connected directly. Instead, two or more lines are interconnected via connecting elements. With the help of the 2- to n-way connectors shown in **Figure 4.4**, up to 8 lines can be interconnected.

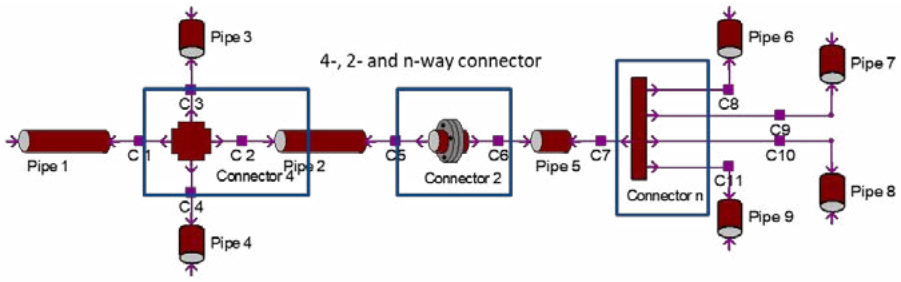

Figure 4.4: Connector types

4.4. Pumps and Motors

With the closed end, a volume flow can already be imposed on a system model, which can also be defined as variable over time, for example, according to a measured flow ripple or a pump start-up. In the case of a straight pipe closed at both ends, the pressure oscillation situation shown in **Figure 4.5** is obtained.

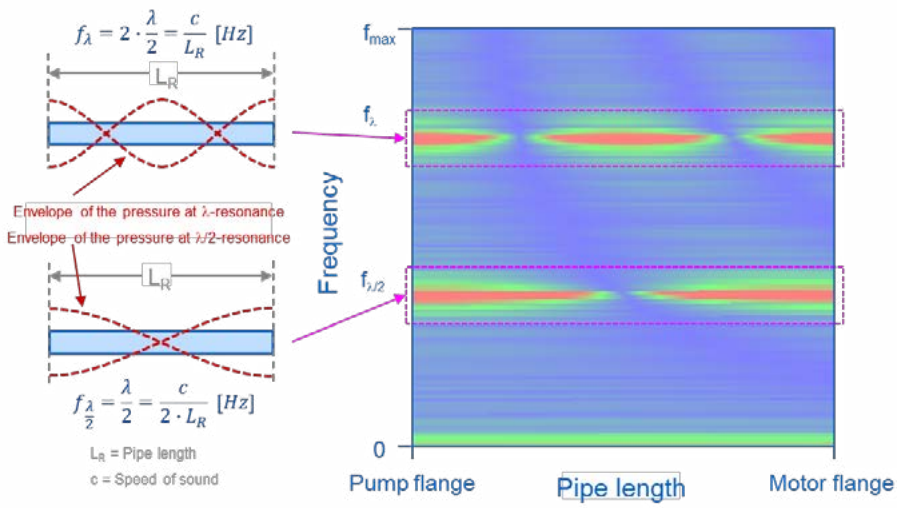

Figure 4.5: Resonances of a pipe with closed ends

A color-coded top view of the stored pressure values of the data matrix is displayed as a *pressure vector plot* [12]. The pipeline (abscissa) starts at the pump and ends at the consumer. The ordinate does not show the simulation time, but rather the excitation frequency. This is possible because the excitation frequency was changed linearly during the simulation, allowing a corresponding frequency to be assigned to each simulation time point. The horizontal lines indicate the first natural frequency ($\lambda/2$ resonance) and the second natural frequency (λ resonance). The pressure vector plot in Figure 4.5 clearly shows when the excitation frequency "meets" the natural frequencies of the pipeline at $f_{\lambda/2}$ and at f_λ.

Since the excitation frequency was continuously increased in the simulation, the resonances initially build up slowly, reach their maxima, and then decay again. In the top view, the shape of the envelope resembles the pressure waveform visualized in the left part of Figure 4.5 (but should not be confused with it), which makes it very easy to identify the resonances in the pressure vector plot.

However, this is often insufficient for the acoustic evaluation of hydraulic systems, as the internal structures of a displacement unit also contribute to the oscillation behavior. Acoustically, they act as a resonator in extension of the pressure line and thus change the resonance behavior of the overall system. **Figure 4.6** shows the pressure vibration situation in the pipeline plus displacement unit on both sides.

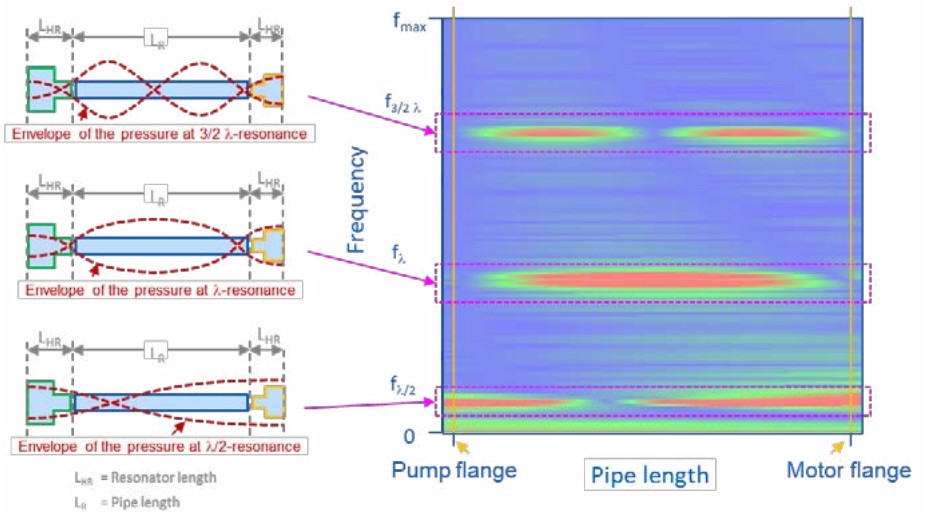

Figure 4.6: Resonances of the pump–pipeline–motor system

The resonator represents an equivalent model for the impedance of the displacement device. Until now, this had to be determined by measurement and is then represented in the system model by an equivalent model that is adapted as closely as possible to the measurement results using an optimization process.

In order to simultaneously impose a measured volume flow pulsation on the system model, Fluidon has developed the *hybrid pump model* [13], **Figure 4.7**. A modified Helmholtz resonator, which contains an additional throttle to increase damping, serves as the impedance replacement model. Experience has shown that it better suits for modeling the impedance of conventional hydraulic displacement units than the frequently used Norton model.

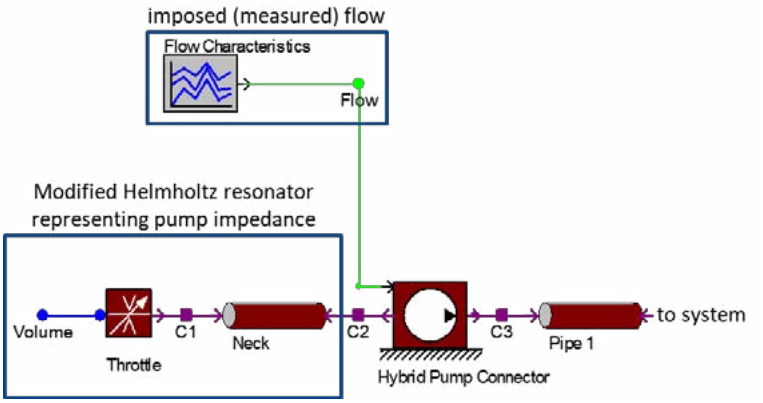

Figure 4.7: Hybrid pump model

Fluidon uses the secondary source method, which goes back to *Edge* and *Johnston* [14], to measure impedance. By using a frequency-variable excitation, the method was further developed in terms of results quality. It can be used on existing functional test benches with

relatively little effort [15]. If the pump impedance is known, the flow ripple can be calculated from a measurement on the same test bench setup with the secondary source switched off [16]. However, this requires good quality impedance measurement or the use of a good quality replacement model. A method that is independent of the pump impedance is measurement using a low-reflection line termination (RaLa) [4], [17].

4.5. Resistors and Valves

The simple resistance component (**Figure 4.8** left) is based on a calculation comparable to that for the double connector, which solves the characteristic equations and the continuity equation. While $p_1 = p_2$ applies to the connector

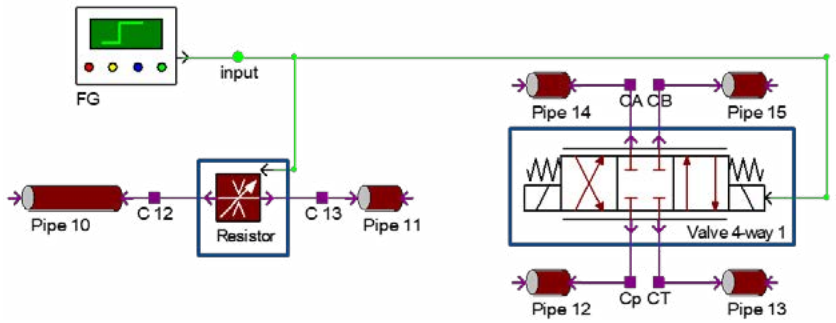

Figure 4.8: Resistance and valve component

In principle, valves can be modeled in 1D CFD as a combination of single hydraulic resistances with intermediate pipes and branches. Since a resistance cannot be directly coupled to a branch, but always requires an intermediate pipe, this approach leads to very extensive and confusing models, especially in the case of complex valve structures.

This is particularly true for valves with multiple effective control edges that are connected to each other via short channels, whose acoustic behavior is often negligible. The "valve" component was therefore introduced to efficiently map such components. It allows its connections to be flexibly linked to each other depending on a control signal. Optional characteristic maps for the effective opening cross-sections allow the mapping of almost any valve characteristics.

5. MODELING AND ANALYSIS OF COMPLEX SYSTEMS

The following section first describes the modeling of complex hydraulic pipe systems before presenting methods for analyzing vibration and resonance behavior based on this.

5.1. Model Creation of Complex Hydraulic Systems

Complex hydraulic systems are usually modeled on the basis of the circuit diagram and the associated CAD data. Steel pipes, valves, and manifold blocks can be mapped with sufficient accuracy in 1D CFD using CAD geometry and the corresponding material data. **Figure 5.1** shows an example of how the internal bores of a manifold block are taken into account in the model.

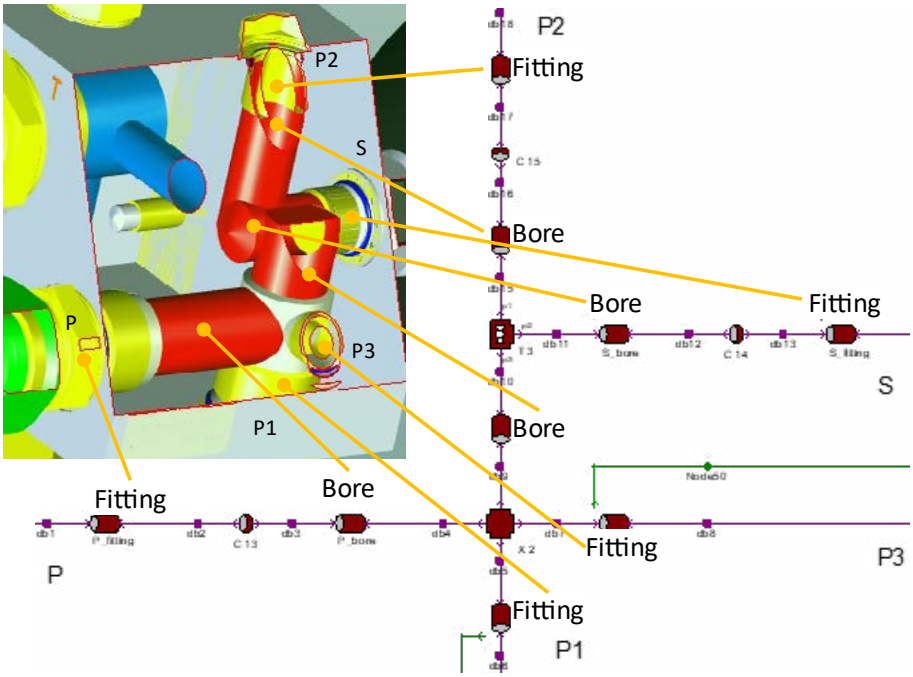

Figure 5.1: Depiction of a manifold block in the model

Hose crimp fittings are modeled as separate pipe sections. In many applications, return lines are not relevant to noise from an NVH perspective and can therefore often be neglected without significantly affecting the validity of the acoustic analysis.

As an example, the pressure-side model of the hydraulic system of a large mobile machine requires around 100 pipe components. The computing time for such a model on the *Fluidon Cube* platform [18] is around 9 hours (without parallelization).

5.2. Analysis of Vibration and Resonance Behavior

In many applications, the actual pulsation of the displacement units as excitation of the system is initially unknown, or it is useful to determine the system response independently of the excitation amplitude in order to obtain an amplitude-independent *vibration fingerprint* of the line system. For this purpose, a sine sweep with constant volume flow amplitude is applied to the system instead of the actual pulsation. The resulting system response is a direct measure of the admittance of the system. Admittance describes the frequency-dependent ratio of the system response to the applied excitation and is therefore a measure of the dynamic compliance of the fluidic system. It allows the identification of resonances and NVH-critical frequency ranges.

However, to analyze the vibration modes of a complex, branched piping system, it is not sufficient to evaluate the pressure curve at individual measuring points in the time or frequency domain. To systematically identify resonances and spatial vibration modes, Fluidon again uses the representation in the form of so-called *pressure vector plots* (**Figure 5.2**).

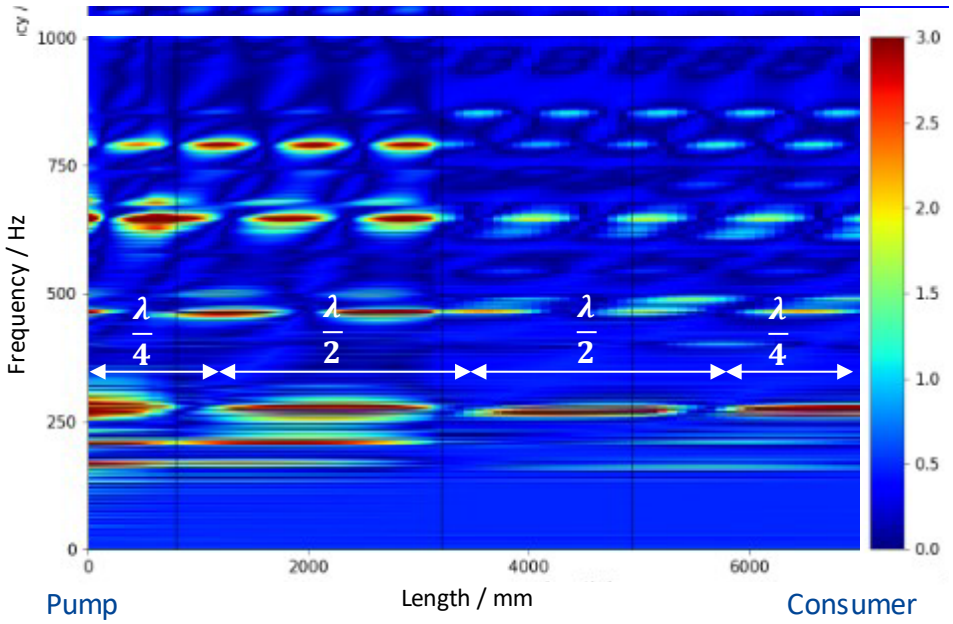

Figure 5.2: Pressure vector plot for analyzing resonances and vibration modes

As already introduced in Figure 4.5 and Figure 4.6, the x-axis describes the pipe length, for example from the pump outlet to a critical consumer. Vertical lines mark the transition between line sections, like a hose-pipe combination or a manifold block. The frequency is plotted on the y-axis, while the pressure admittance is represented as a color gradient. This visualization allows frequencies to be directly assigned to spatial vibration modes in the piping system.

The example shown clearly illustrates that a critical resonance vibration occurs at approximately 260 Hz, which is pronounced in the pipe branch shown over 3/2 wavelengths λ . To evaluate the overall system, such an analysis is performed for all relevant branches. The spatial characteristics of the critical vibration modes can be used to derive specific optimization measures, which are then evaluated using variant simulations.

Knowledge of the spatial vibration modes and dominant resonances in the pipe system forms the basis for the subsequent consideration of fluid-structure interaction. The pressure amplitudes can be used to directly calculate the dynamic forces acting and their transmission to pipes, fastenings, and adjacent structures.

6. FLUID-STRUCTURE INTERACTION

"A true, two-way fluid-structure interaction (FSI) exists when the flow is noticeably influenced by the structural change. However, the effect of the structural change on the flow is often so weak that it can be neglected. In this case, we refer to a one-way fluid-structure interaction." [19]

The article *Pressure Oscillation Analysis in Fuel Supply Systems* [20, pp. 337–358] describes how DSHplus takes bilateral FSI into account. However, the system of equations can be reduced so that only unilateral FSI is calculated. Based on the transient pressure and flow curves determined in the vibration fingerprint, the resulting hydrodynamic forces are calculated at selected points in the hydraulic system. This simplification significantly reduces the modeling effort and enables numerically very efficient simulations without significantly limiting the information content relevant to NVH issues. The aim is not to calculate deformations or stresses in detail, but to determine the time-dependent excitation forces that serve as input data for further structural dynamic or acoustic analyses.

The approach is particularly suitable for:

- Identifying NVH-critical line sections or system components
- Evaluating different plumbing concepts
- Early estimation of pulsation-induced continuous loads

To demonstrate the methodology, a practical pipe geometry is considered below.

6.1. Alternating Forces on a Double Pipe Bend

In addition to the acoustic pipe model, the spatial geometry of the piping system, as typically available in CAD planning, is required to calculate the fluid-dynamically induced forces. Based on the three-dimensional geometry, the piping system is divided into individual segments whose geometry is defined in the global coordinate system. **Figure 6.1** illustrates this transformation step from the CAD representation to the simulation model structure and shows an example of an assembly with several pipe bends and a connecting pipe section. Defining a boundary around this assembly makes it possible to specifically calculate the forces acting on the assembly.

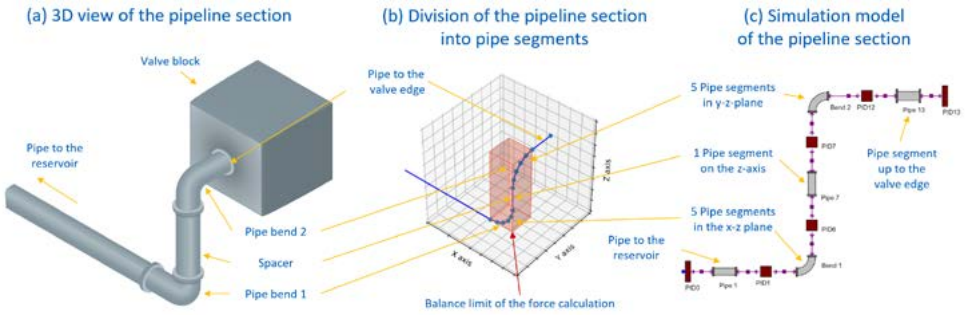

Figure 6.1: Preparation of the 3D representation for simulation

The forces are calculated by summing the time-dependent pressure and momentum components of all pipe segments within the balance boundary. Depending on the pipe routing and orientation in space, this results in force components in different spatial directions. The geometric arrangement of the example pipe already makes it clear in which directions forces can act preferentially, while other directions are in equilibrium in the static state. Changes in the operating state, for example due to pressure build-up or the start of flow, lead to corresponding changes in the distribution of forces on the assembly under consideration.

Figure 6.2 shows an example of such a simulation model and illustrates how the forces acting on a subassembly change over time. While pressure-related forces predominate in the static state, additional impulse forces occur when fluid flows through the pipe. Transient processes, such as the opening or closing of valves, lead to short-term changes in force, which are particularly noticeable in line bends and are often accompanied by visible or perceptible relative movements in real systems.

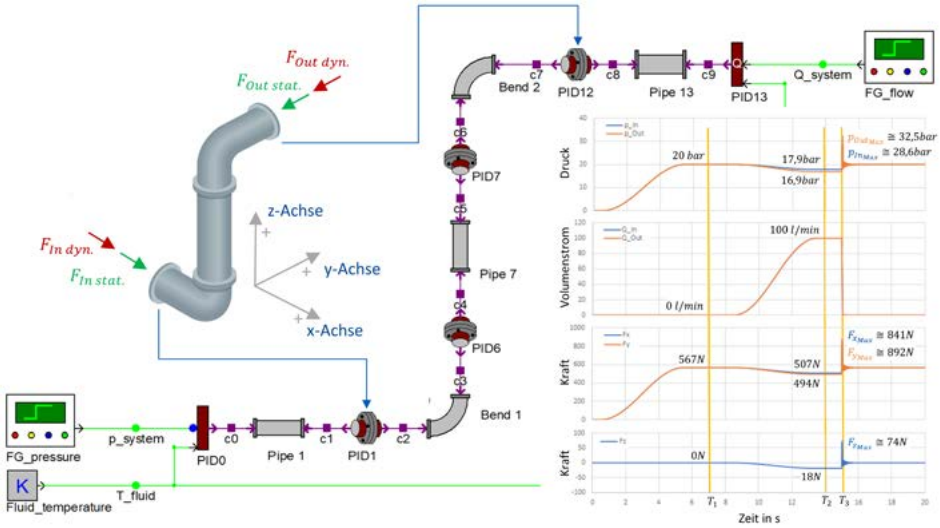

Figure 6.2: Simulation model of the pipe system

Similar to these temporary effects, permanent pressure and flow ripples induce dynamic forces, where resonance situations as described above lead to increased amplitudes.

Figure 6.3 shows the evaluation of a frequency-dependent excitation of the pipe system. With appropriate preparation of the simulation model, the force components shown can be calculated directly from the results of the vibration fingerprint in post-processing.

The illustration clearly shows that when certain excitation frequencies are reached, pronounced vibration modes of the fluid arise, which are directly reflected in increased dynamic forces on the assembly under consideration. The time- and frequency-dependent evaluation of the force components allows such resonance states to be clearly identified and spatially assigned.

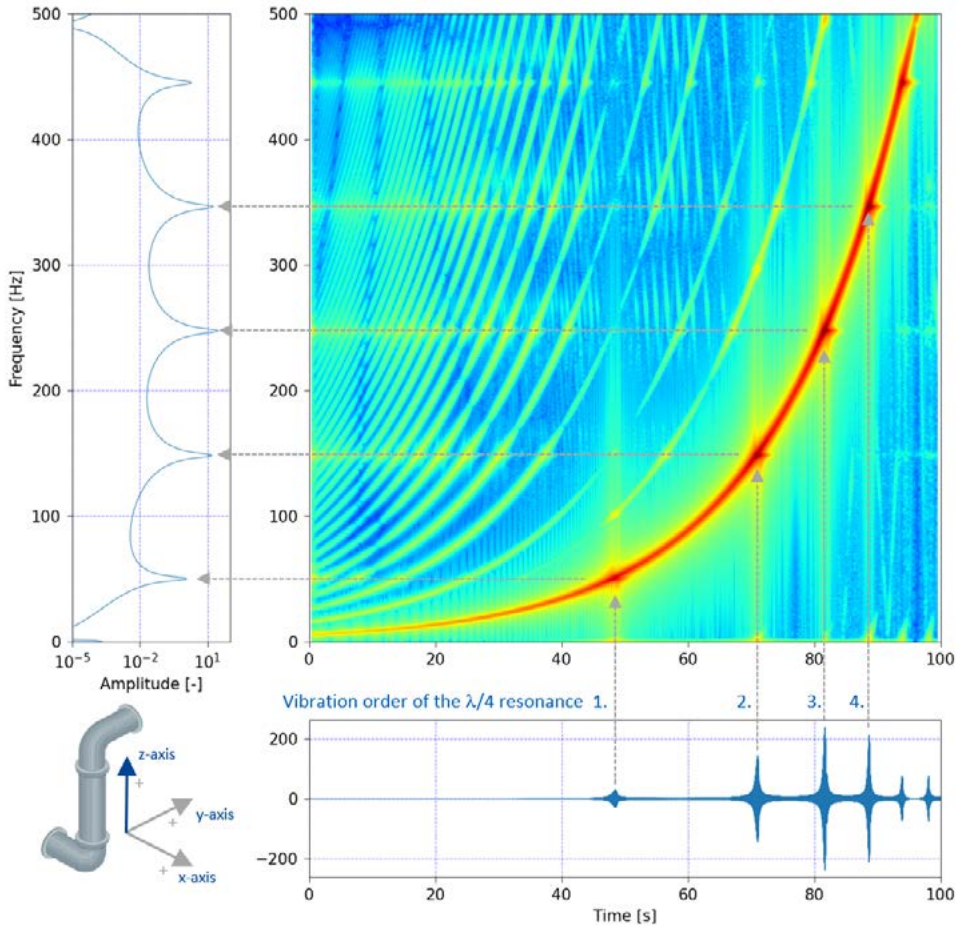

Figure 6.3: Analysis of the force component in the z-axis direction

The combination of pressure oscillation analysis and force calculation thus provides direct access to the structural mechanical evaluation of hydraulic systems. It enables dynamic alternating forces in relevant assemblies to be identified at an early stage and specifically incorporated into the design of line routing, mounting points, and structural measures. This approach is therefore a key tool for NVH-oriented system design.

7. SUMMARY AND NVH IMPLICATIONS

The results show that NVH problems in hydraulic systems are not exclusively attributable to rare extreme events such as pressure surges. Rather, flow ripple-induced continuous loads are a key cause of structural excitation and acoustic emissions and have a significant impact on the overall NVH impression of modern machines.

The numerically efficient simulation approach presented in this paper, based on transient 1D CFD in combination with simplified, unilateral fluid-structure coupling, makes it possible to identify and evaluate these effects early in the development process. NVH-critical excitation forces can be specifically localized and assigned to their cause in the hydraulic system.

Critical conditions can be avoided as early as the concept phase by making targeted adjustments to the line geometry, mounting concepts, or hydraulic boundary conditions. The approach thus represents a practical alternative to complex fully coupled FSI simulations and is particularly suitable for variant studies and the early design of structure-friendly and low-vibration line systems.

Overall, the methodology presented makes a significant contribution to the development of quiet, durable, and NVH-optimized hydraulic systems.

Current developments in magnetostrictive position sensors

Olaf Kissing

Temposonics GmbH & Co. KG, olaf.kissing@temposonics.com

Abstract.

A magnetostrictive position sensor with a flexible sensing element simplifies the installation in a hydraulic cylinder. Such a sensor should achieve the same performance as a sensor with a rigid sensing element. In addition, a magnetostrictive position sensor should provide further information in addition to the position, as data can be recorded directly on site in the hydraulic cylinder.

Keywords. Magnetostriction, position sensor, flexible sensing element, hydraulic cylinder.

1. INTRODUCTION

Hydraulic cylinders are used for many purposed, such as to open and close lock gates (Fig. 1), feed rolls in a rolling mill, move the arm of an excavator, or orient the wheels of a vehicle according to the steering angle. All these movements require the position of the piston rod to be detected and transmitted to the control system. Magnetostrictive position sensors have proven themselves in applications such as these.

Figure 1.1: Hydraulic cylinder for moving a lock gate

2. WHAT IS MAGNETOSTRICTION?

A magnetostrictive position sensor uses the principle of magnetostriction to determine a position. Magnetostriction is a magnetic effect in which the mechanical dimensions of a ferromagnetic material such as nickel, iron, cobalt, or their alloys change under the influence of a magnetic field. This is known as the Joule effect. The reverse of this effect is also possible: The magnetic properties of a material, such as permeability, change when its mechanical dimensions are altered. This behavior is known as the Villari effect.

When a current flows through a wire made of magnetic material, this current generates a magnetic field that surrounds the wire. If this magnetic field encounters an external axial magnetic field, a torsional force is generated at this location, which causes a slight mechanical twist. The external axial magnetic field is generated by a permanent magnet that surrounds the wire or is located very close to it. This behavior of a wire made of magnetostrictive material is known as the Wiedemann effect.

These properties are used to determine a position with a magnetostrictive sensor.

3. WHAT IS A MAGNETOSTRICTIVE POSITION SENSOR?

Fig. 2 shows a magnetostrictive position sensor. This type of sensor measures the distance between the pickup system and the position magnet. To do this, a short current pulse is generated in the sensor electronics and applied to the waveguide. This current pulse travels through the waveguide and creates a radial magnetic field. The position magnet, which marks the position to be measured, generates an axial magnetic field. The momentary interaction of these two magnetic fields generates a torsional wave in the waveguide, which propagates as an ultrasonic wave at a speed of approximately 2800 m/s. This wave travels in both directions, toward the end of the waveguide and toward the pickup system. The wave traveling to the end of the waveguide is extinguished by damping elements. This eliminates disruptive reflections of this wave.

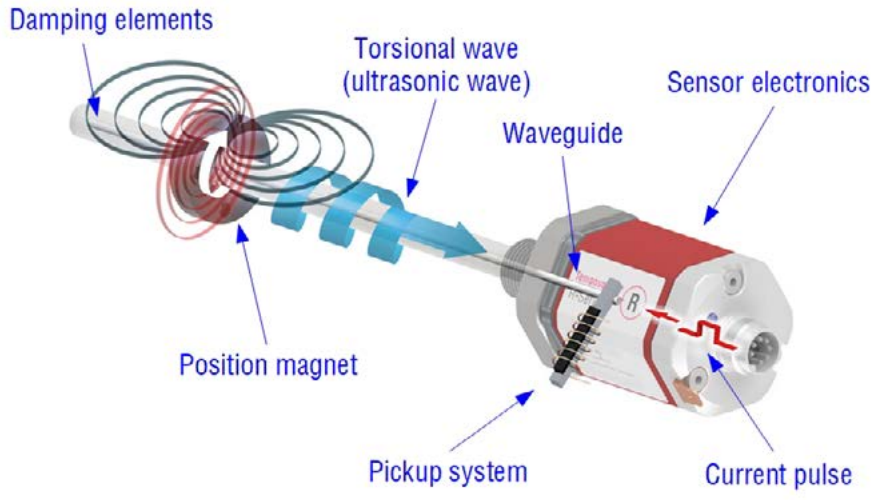

Figure 3.1: Design of a magnetostrictive position sensor

The wave traveling to the pickup system is converted into a voltage signal. When the current pulse is sent, a time measurement is started, which is stopped when the wave arrives at the pickup system. The speed at which the wave moves along the waveguide is called the gradient. The gradient of each position sensor is known, so that the position of the magnet on the waveguide can be determined based on the time measurement. The following applies:

Position = gradient × travel time

The main components of a magnetostrictive sensor are:

- Waveguide
- Position magnet
- Pickup system
- Sensor electronics

The waveguide can be described as the heart of a magnetostrictive position sensor. It is a thin wire with a diameter of 0.25…1 mm. The properties of the waveguide have a significant influence on the performance of the sensor. Important characteristics of a waveguide are:

- Magnetostriction coefficient: The coefficient indicates how far the magnetostrictive material expands when a certain field strength is applied.
- Wave attenuation: The amplitude of the wave is attenuated as the distance along the waveguide increases.
- Variation in propagation speed along the length: For accurate position measurement, it is necessary that the speed at which the wave travels along the waveguide is identical at every point along the waveguide.

These characteristics depend on the intrinsic properties of the material and the microstructure. They can be influenced by the material composition and manufacture of the waveguide. A nickel-iron alloy or similar is often used as the material for the waveguide. However, the exact composition of the material and the manufacturing process are a trade secret of the manufacturers, just like the recipe for Coca-Cola.

A permanent magnet is used as the position magnet. When using a magnetostrictive position sensor in a hydraulic cylinder, a rod-type sensor with a ring magnet is used in most cases, as shown in Fig. 2. The ring magnet surrounds the waveguide on all sides, ensuring a uniform magnetic field.

The pickup system detects the torsional wave and converts it into a voltage signal. The design and functionality of a pickup system are not relevant to this work. Interested readers can find more information in [Nyce, 2004].

The sensor electronics generate the current pulse that is applied to the waveguide and perform the time measurement. The time measurement signal is processed and made available at the output. The user can choose between different configurations such as analog, SSI, IO-Link, EtherCAT®, or PROFINET.

A magnetostrictive position sensor is an absolute measuring sensor that is characterized by high precision and repeatability. The measurement is contactless because the position magnet hovers above the rod. It is not necessary for the magnet to touch the rod. Such a sensor meets the requirements of both industrial and mobile hydraulic environments in terms of reliability and robustness in harsh environments.

4. INTEGRATION OF A MAGNETOSTRICTIVE POSITION SENSOR INTO A HYDRAULIC CYLINDER

A magnetostrictive position sensor is integrated into a hydraulic cylinder by inserting the sensor rod into the drilled piston rod (Fig. 3). The cylinder is sealed via the flange so that no hydraulic fluid can escape. The position magnet is mounted at the bottom of the piston rod so that the position of the piston can be detected at any time. The pressure-resistant sensor rod contains the sensing element with the waveguide. Only the flange with the sensor electronics housing is located outside the cylinder. This offers the advantage that no large attachments are required on the outside of the cylinder.

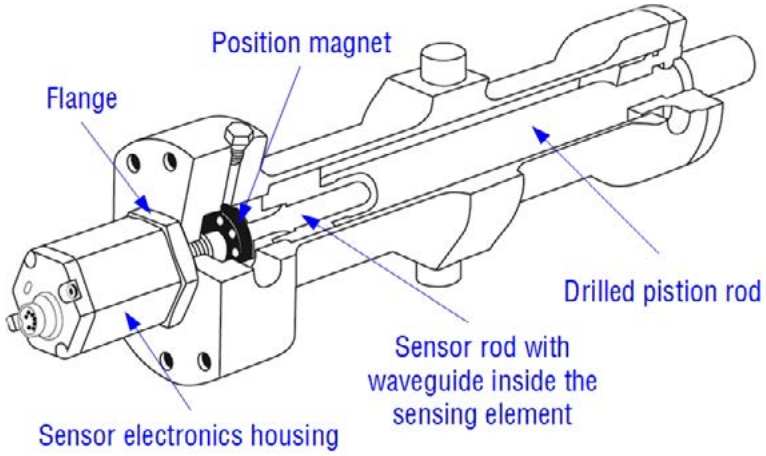

Figure 4.1: Integration of a magnetostrictive position sensor into a hydraulic cylinder

As described, a magnetostrictive position sensor measures the distance between the pickup system and the position magnet. The maximum distance that a sensor can measure is referred to as stroke length and can be selected in the range of 25…7620 mm for a rod sensor. When installing a magnetostrictive sensor in a hydraulic cylinder, the stroke length is usually slightly greater than the piston stroke of the cylinder. This ensures that the sensor can detect the entire travel path of the piston. The sensor rod usually has an outer diameter of 10 mm and a wall thickness of 1.5 mm. It protects the internal waveguide and withstands the hydraulic pressure inside the cylinder.

5. SENSOR WITH FLEXIBLE SENSING ELEMENT

As explained the stroke length of a magnetostrictive position sensor is slightly greater than the piston stroke of the hydraulic cylinder, and the sensor rod with the internal waveguide is rigid due to its compressive strength. Therefore, when installing the sensor, one piston stroke of space is required behind the cylinder. While this is usually possible when constructing the cylinder, there is often not enough space available after the cylinder has been integrated into the final application. If the sensor needs to be replaced, the lack of space behind the cylinder poses a challenge.

To reduce the space required for removal and reinstallation, the sensing element – essentially consisting of a waveguide and an enveloping protective tube – would have to be bent.

However, bending the waveguide impairs the propagation of the torsional wave. The more the waveguide is bent, the more the amplitude of the torsional wave is weakened. A weakening of the torsional wave makes detection at the pickup system more difficult and thus a reliable and precise position determination. If the waveguide is bent so much that it is plastically deformed, the microstructure of the waveguide is damaged. In this case, the propagation of the torsional wave is stopped at the damaged location. A position determination is no longer possible.

The following conditions therefore apply to a flexibly designed sensing element:

- Bending of the sensing element must not impair the function of the sensor: As described, bending of the waveguide weakens the signal of the torsional wave. The sensing element with waveguide must therefore be designed in such a way that this weakening does not affect reliable position determination.
- It must be possible to insert the flexible sensing element into the pressure-resistant sensor rod with an outer diameter of 10 mm and a wall thickness of 1.5 mm.
- The performance of the sensor with a flexible sensing element must be the same as that of a sensor with a rigid sensing element: In addition to reliable position detection, this applies in particular to linearity as well as shock and vibration resistance.

To meet these conditions, the interaction between the sensing element and sensor electronics must be adjusted. The choice of protective tube is also crucial: The protective tube must be stable enough to protect the internal waveguide, yet flexible enough to allow bending. After testing various tubes, a stainless-steel protective tube covered with a PU sheath was selected. The structure of this tube is shown in Fig. 4. It protects the internal waveguide from mechanical stress and, with the PU sheath, provides the necessary flexibility so that the waveguide can only be elastically deformed.

Figure 5.1: Schematic presentation of the structure of the protective tube in a bent state

As described, the amplitude of the torsional wave is attenuated when the waveguide is bent. With a suitable combination of sensing element and sensor electronics, reliable position measurement can be achieved even with a weaker torsional wave signal. Tests were conducted to determine the degree of bending of the flexible sensing element at which the position of the magnet on the measuring rod can still be reliably determined by adjusting the sensor electronics.

For example, a sensor with a flexible sensing element was wound in a curve of 100 mm and 165 mm and the linearity was measured (Fig. 5.2). Fig. 5.3 shows the linearity diagram of the sensor with flexible sensing element in a straight state after unwinding from a diameter of 165 mm. A laser interferometer is used as a reference to determine linearity. Despite the bending of the flexible sensing element, the internally set linearity limits of ± 0.1 mm are only minimally exceeded.

Figure 5.2: Sensor with flexible sensing element wound up in a diameter of 165 mm

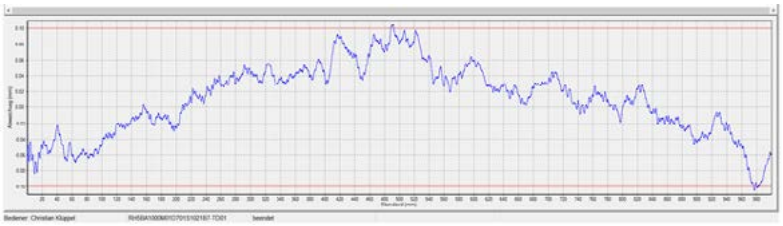

Figure 5.3: Linearity diagram of a sensor with flexible sensing element after unwinding from a diameter of 165 mm

Another test examined how different bending radii affect the amplitude of the torsional wave. To do this, the flexible part of such a sensor was pushed through devices with defined bending radii. The sensing element was pushed through the device up to the sensor electronics in order to assess how different bending radii dampen the torsional wave when it reaches the pickup system (Fig. 5.4). Table 5.1 shows how the signal strength changes as a percentage compared to the unbent state as the bending radius increases. By adjusting the sensor electronics, the signal strength decreases by only 3% even with an increasing bending radius. It should be noted that these tests were carried out under laboratory conditions. In harsh industrial environments, the permissible minimum bending radius must therefore be provided with a safety factor.

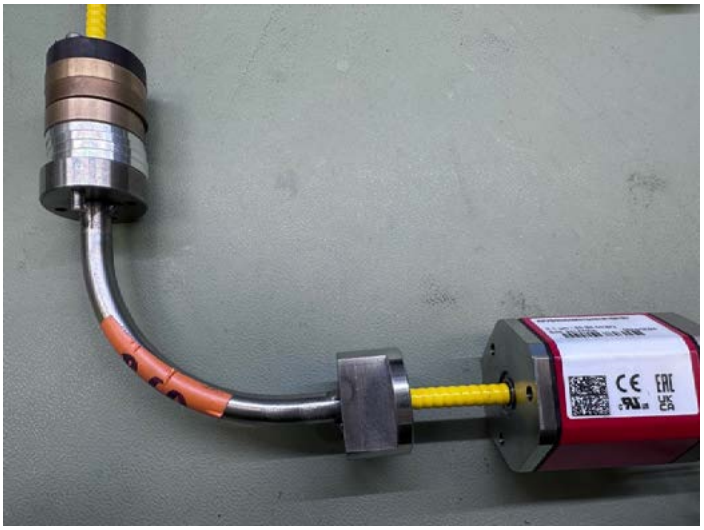

Figure 5.4: Sensor with flexible sensing element inserted into a device with a defined bending radius

Bending radius R	Amplitude of torsional wave
R = 0 mm (reference)	100 %
R = 80 mm	100 %
R = 75 mm	100 %
R = 70 mm	100 %
R = 65 mm	97 %
R = 60 mm	97 %
R = 55 mm	97 %
R = 50 mm	97 %

Table 5.1: Damping of the amplitude of the torsional wave depending on the bending radius

The tests show that a reliable magnetostrictive position sensor with a flexible sensing element can be constructed using a suitable combination of metal protective tube, waveguide, and sensor electronics. As shown in Fig. 5.5, the base unit of a magnetostrictive sensor, consisting of sensor electronics and sensing element, can be separated from the pressure-resistant sensor rod. While the pressure-resistant sensor rod remains in the cylinder, the base unit can be replaced. With a sensor with a flexible sensing element, only a space of approximately 150…200 mm behind the cylinder is required when installing and removing the base unit in the pressure-resistant sensor rod, regardless of the stroke length of the sensor. This means that a sensor with a flexible sensing element is a great simplification in

comparison to a sensor with a rigid sensing element regarding removal and reinstallation on site.

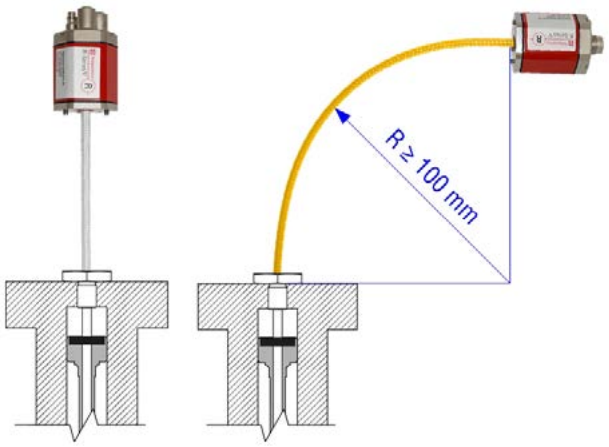

Figure 5.5: Installation of a base unit with rigid sensing element (left) and with flexible sensing element (right)

6. SENSOR WITH ADDITIONAL INFORMATION

In the context of Industry 4.0, a sensor should not only provide its actual data, but also transmit additional information [Anderl et al. 2015]. The actual data of a magnetostrictive sensor is the position of the piston in the cylinder and, if applicable, the velocity of the piston movement. In addition, such a sensor can transmit further information to the control system, such as:

- the total distance traveled by the piston,
- the number of cycles performed by the cylinder,
- the current, minimum, and maximum power supply to the sensor, or
- the quality of the measured sensor signal.

The total distance traveled by the piston and the number of cycles provide information about the operating life of the hydraulic cylinder and can be used to analyze maintenance intervals. The information on the sensor's power supply and the quality of the sensor signal describes the current status of the sensor. Users can use all this information to check both their system and the sensor during operation, thereby enabling predictive maintenance.

One aspect of development trends in sensor technology is the functional integration of different sensor components [Wertschützky 2018]. When integrated into a hydraulic cylinder, a magnetostrictive position sensor offers the advantage of being able to collect data “directly on site,” i.e., inside the cylinder. For example, the temperature of the hydraulic oil or the pressure inside the cylinder can be recorded by extending the magnetostrictive sensor. Currently, in order to record additional data, holes must be drilled and sealed in the cylinder, further sensors must be installed, and cables must be laid. Combining data recording in a single sensor reduces the cost of mechanical processing of the cylinder. In addition, by linking the data, conclusions can be drawn about the condition of the cylinder and thus the application. On the other hand, there are the costs of such an adaptation. In order for the

expansion of a magnetostrictive position sensor to be of interest to cylinder manufacturers and users, the costs must not exceed those of a separate sensor.

According to [Drese et al., 2025], sensors will become smarter in the future. Such smart sensors not only collect data, but also process it. In this context, a magnetostrictive sensor can be enabled to prepare the data currently collected for analysis and decision-making:

- By recording the piston travel, it is possible to process how often the piston moves in which area of the cylinder stroke.
- The number of cycles driven can be used to determine how smoothly or gently the piston moves through the cylinder (detection of stick-slip effects).

In this respect, this article is also a call to users, manufacturers, and scientists to work together to clarify what can and should be implemented and how.

Abstract.

Additive Manufacturing (AM) has established itself as a promising technology in the field of hydraulics, offering new opportunities for the design and optimization of components [1]. For converting classic designs into AM-compatible models, there are guidelines and methodologies available, including even specific approaches for manifolds [2]. However, the guidelines are usually very vague and provide limited concrete design specifications. In addition to this challenge, the available software solutions for the rapid creation of asymmetrical or bionic geometries are quite limited. Although there is a variety of software solutions on the market for designing AM components, their functionalities are not tailored to the requirements of AM. While conventional computer-aided design (CAD) is based on 2D sketches evolving into volumetric bodies, there is an increasing demand for advanced software solutions that facilitate freeform spatial design and provide constructive guidelines to enhance flow-optimized designs. This paper compares and evaluates various software and design methodologies to assess their suitability for additively manufactured hydraulic components.

In this paper we perform an analysis of the entire design process, including a comparison of pressure losses. The primary objective is to establish specific methodologies for the design of AM components. Results indicate significant shortcomings in conventional CAD software, which often limits designers' capabilities. To address these challenges, this study introduces an innovative design configurator implemented in the software Rhinoceros 3D® according to the approach of Biedermann [3]. This configurator facilitates the automated creation of manifolds by adjusting channel geometries to minimize pressure losses in hydraulic channels.

1. INTRODUCTION

The use of AM compared to conventional production has increased in recent years. Consequently, the demand for integrated software solutions for product development is also increasing, particularly those that enable the automated creation of three-dimensional freeform surfaces.

To analyze which software solutions are currently available and how advanced their level of automation is, four different CAD software are compared in Table 1 based on various evaluation criteria. The programs considered are Siemens NX®, SolidWorks®, Rhinoceros 3D® (including Grasshopper®) and nTopology®. The evaluation criteria include a general definition, the capability for generative design, and automation possibilities. Due to the significant potential for material and weight reduction, the topology optimization capabilities of each program are also compared.

Table 1: Comparison of different software solutions for designing additively manufactured components

	Siemens NX	**SolidWorks**	**Rhino 3D + Grasshopper**	**nTopology**
Definition	Characterized by functionality, performance & stability [4]	Software known for conventional manufacturing [5]	Graphical programming approach [6]	Interesting for AM purposes [7]
Generative design	Direct Modeling [8]	Direct Modeling [8]	Based on NURBS [9]	Implicit modelling by utilizing functions [10]
Automation possibilities	Using external software [11]	Design automation of a cube [12]	Design automation of cable routing [6]	No current data found
Topology optimization	Yes [13]	Yes [14]	Yes [15]	Yes [10]

Siemens NX® was selected because it represents a widely used software solution in industrial product development and is characterized by extensive functionality, high performance, and stability [4]. SolidWorks®, in contrast, was originally designed for conventional manufacturing processes. Rhinoceros 3D®, including Grasshopper®, follows a graphical programming approach, whereas nTopology® is particularly suited for AM applications. It was developed within the DfAM framework and utilizes advanced design methods such as topology optimization and lattice structures, enabling increased design freedom [6]. In this paper, a comparison is drawn between classical CAD design (conventional design) using Siemens NX® and an automated design approach in Rhinoceros 3D®.

Design Automation (DA) refers to the computer-based automation of repeatable tasks in the design and design process. The advantages of DA are manifold: it reduces the time and effort required for the design of components through the automated creation of geometric bodies as well as their easy adaptation. This enables efficient design adjustments, facilitates the iterative design process, and minimizes human errors as well as the risk of faulty designs. [16], [17], [3].

For the design of valve block channels, which are represented by paths between valve cavities and connections, DA is presented through iterative path generation based on Position-Based Dynamics (PBD) simulation. PBD is already applied in areas such as special effects in films, physics engines in video games, and form-finding techniques. [3], [18]

2. METHODS

In order to compare conventional and AM-optimized design methods, both approaches must first be defined. To do this, the selected procedure is presented in each case. Conventional design refers to the approach in which the design is created manually in a CAD program. The alternative is a design configurator that automatically creates paths between the components. The methods presented in this chapter reflect the actual approach used in the design development and outline optional additional steps. These methods should not yet be regarded as general design methodologies. The results presented in this paper elucidate various aspects of the design process and highlight potential improvements in fluid-dynamic performance.

2.1. Conventional design process for product optimization

There are various methods for product development, such as the widely used VDI 2221 [19]. These methods provide a structure for the individual steps of product design. In practice, method-based approaches that simplify certain aspects of the methodology are often employed. The approach adopted in this paper is frequently used at the institute to implement application-oriented product development and is also employed in industry.

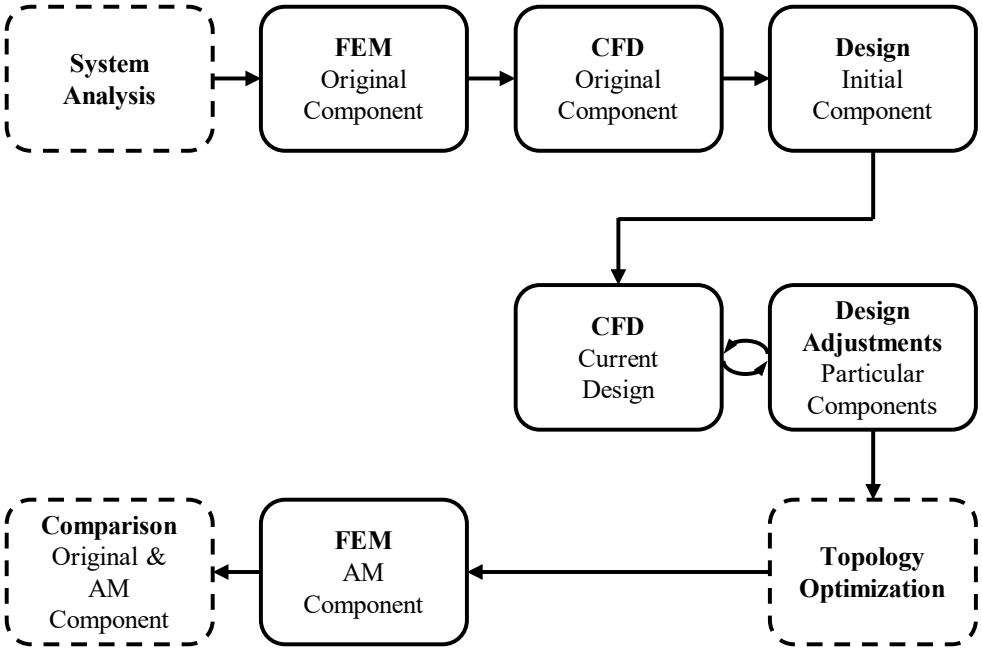

Figure 2.1. Methodological approach to the design of an AM manifold

The methodological approach follows the problem-oriented development process shown in Figure 2.1. This approach is based on established procedures for the structural optimization of hydraulic components and has been adapted to the specific requirements of a hydraulic manifold. It is divided into the necessary analysis steps and optimization processes, which lead, step by step, to a functional, production-ready optimization of the component. In addition, the process includes a comparison between the original and the new states of the manifold with respect to pressure drop, strength, and mass.

The steps shown with a dashed outline are not strictly required for the development of an AM manifold. In this paper, however, they are implemented to improve and validate the result. Topology optimization is generally advisable; since it was not implemented in the automated methodology used for comparison, it is presented here as optional. The mandatory steps for the (re)design of a manifold are the initial design, the iterative cycle of flow analysis and design adjustments, and strength verification. The intermediate topology optimization makes the FEM analysis a safety check; otherwise, it would be mandatory to verify the strength of the design.

The conventional design approach is applied to the manifold of a compact hydraulic power unit from a forklift. This manifold includes a high-pressure filter and two valves in the return line to the tank that controls the lowering of the fork. The primary functions implemented by the manifold are therefore “lifting” and “lowering” of the fork. The CFD simulation was performed in Ansys Fluent with an element size of 0,7 mm. During the lowering operation, a volumetric flow rate of 40 l/min was assumed. The fluid was modeled with a kinematic viscosity of 46 cSt and a density of 850 kg/m³. The thickness of the first prism layer was set

to 68 µm. The number of prism layers was limited to 10, with a growth rate of 1,2. The SST turbulence model was used.

2.2. Design Configurator

The procedure shown in Figure 2.2 represents an alternative design methodology. It is important to note that, within the scope of design development using the design configurator, no topology optimization has been implemented to date; instead, wall thicknesses are selected according to the system parameters, and the model is designed accordingly.

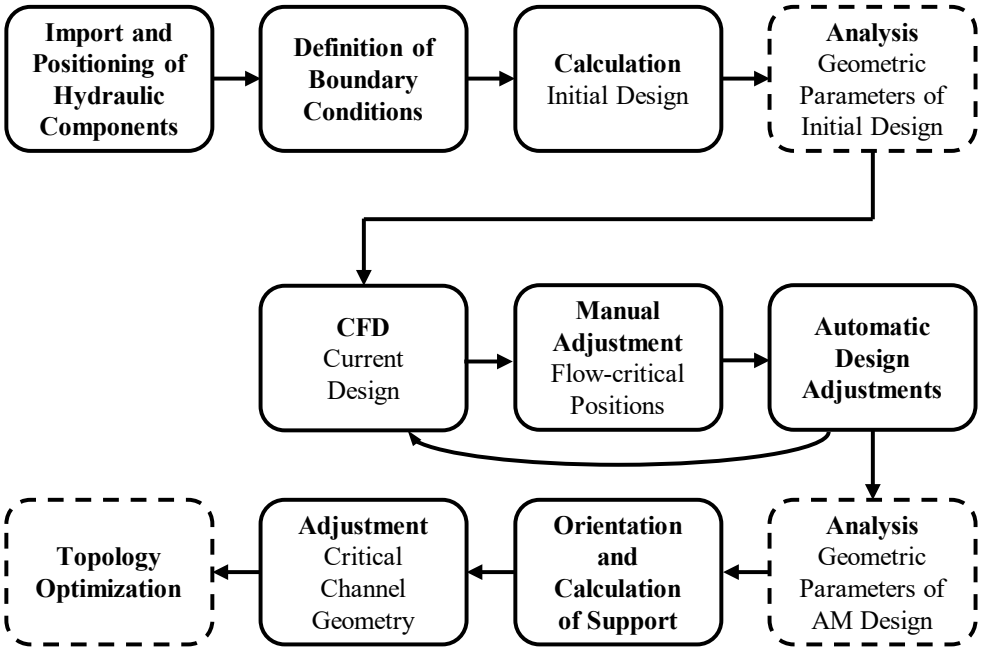

Figure 2.2. Methodological approach of the design configurator

The main differences to the conventional approach lie in the simplification of design adjustments using the configurator. Flow-critical areas can be modified in a targeted manner, and the rest of the model is automatically rebuilt. However, this carries the risk that manual channel adjustments may create new critical positions.

The design configurator used, which builds on the work of Manuel Biedermann, is implemented using Grasshopper®, a visual programming language and environment within the CAD software Rhinoceros 3D® [3], [20]. Version 8.1 of Rhino and version 1.0.0008 of Grasshopper are used. The path generation of the valve block channels is realized using a PBD algorithm through the Grasshopper plugin Kangaroo2 by Daniel Piker [18], [21]. The standard Kangaroo solver and its default settings are implemented. The implementation of the design configurator takes place on the valve block from Schmelzle, with the arrangement of the valve cavities based on Biedermann's layout [3], [22]. To implement the geometric boundary conditions, the blocks Anchor, Equal Angle, Coincident, Collider, Constant Tension, Direction, Dynamic Weight 1D, Length (Line), Load, and Rod are utilized in Grasshopper. With the help of these boundary conditions in the Kangaroo solver, various

geometric parameters of the design are modified. These include the channel length L [mm], the curvature radius R [mm], the curvature angle W [°], as well as the branching angles α, β, and γ.

In the first step, the hydraulic components, such as valve cavities and screw-in fittings, are imported and positioned within the build space of the valve block to be developed. During the second step, the channel routing is defined by initializing a path. This path is represented as an abstract line between the inlet(s) and outlet(s), with a distinction made between simple and branched paths. For simple channels with only one inlet and one outlet, a direct path is created, while for branched channels, branching points are used to account for multiple connections. Subsequently, the abstract line along the path is discretized with particles. Figure 2.3 shows the implementation of the first two steps in the design configurator.

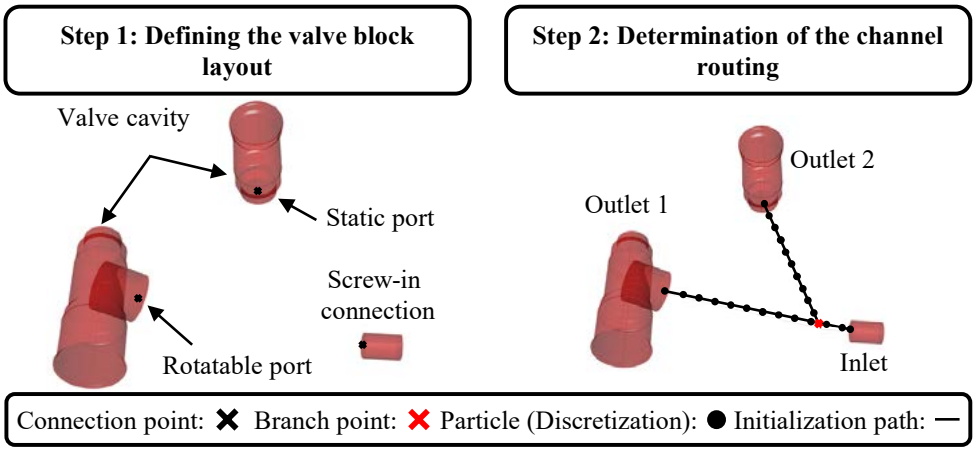

Figure 2.3. Defining the valve block layout and determining the channel routing

Within the third step, the boundary conditions of the paths or particles are defined, as they significantly determine the subsequent course of the channel path. The individual boundary conditions are weighted against each other, depending on the strength of this weighting, the influence of each boundary condition on the channel routing is determined. It may occur that two or more boundary conditions counteract each other, and a specific weighting must be provided for this purpose, as certain boundary conditions, such as collision avoidance, must be adhered to [6]. The boundary conditions are channel-specific.

In the fourth step, a suitable solver processes the defined boundary conditions using the PBD algorithm iteratively until either the convergence criterion is met or the maximum number of iterations is reached. Convergence is achieved when the threshold ϵ is reached. The threshold is calculated by dividing the square of the velocity of all path particles by the total number of particles N_{total} [3]. The solver gradually adjusts the position of the particles along the initial path in accordance with directions specified by the boundary conditions. The boundary conditions generate displacement vectors for each individual particle; the resulting displacement vector of a particle is obtained from the superposition of these various displacement vectors. Figure 2.4 shows the implementation of the boundary condition from step 3 in Grasshopper and step 4, illustrating both the initial and finished paths in the design configurator.

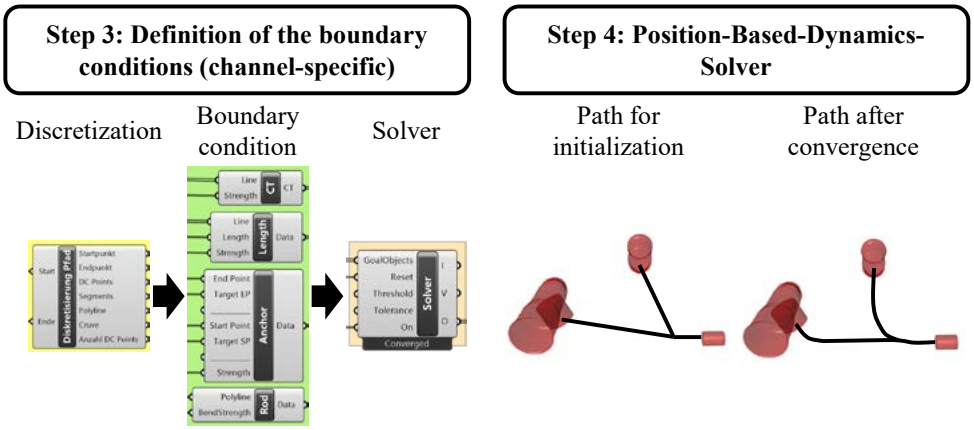

Figure 2.4. Definition of the boundary condition and Position-Based-Dynamic Solver

Finally, in the fifth step, the geometry of the valve block channel is constructed from the post-solver path by specifying the channel diameter and wall thickness. Figure 2.5 shows the CFD volume body and the AM channel geometry derived from the post-solver path.

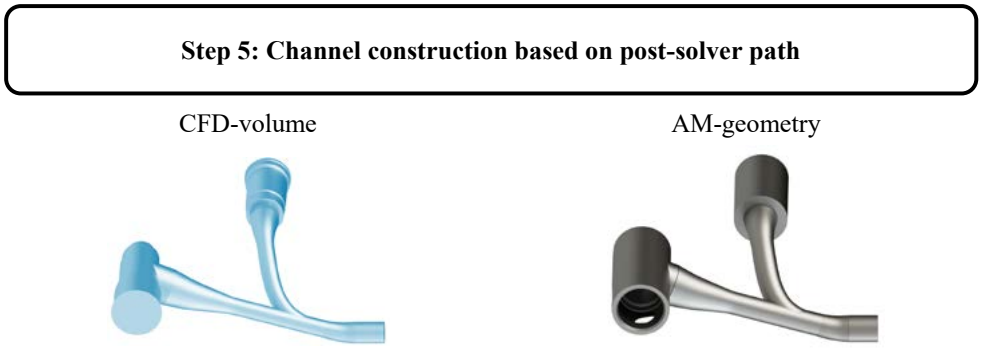

Figure 2.5. Finished valve block channel as CFD volume body and AM channel geometry

To illustrate the general applicability of the design methodology of the design configurator, various designs are created and examined. Based on this data set, a correlation analysis is conducted to determine guidelines for the design of the valve block channels for a specific operating point. To determine the Pearson correlation coefficient, the influences of the geometric parameters on the pressure loss are assessed using the correlation coefficient r. The correlation coefficient r is explained in detail in [24].

3. RESULTS

In this chapter, a fluid-dynamic comparison is made between the original forklift manifold and the component created using conventional design. This includes comparing the overall pressure drop across the component and presenting individual design adjustments at flow-critical locations. In addition, the results obtained with the design configurator are presented and compared in fluid-dynamic terms using a flow-path geometry.

Figure 3.1 shows a comparison between the original manifold and the component obtained through conventional design for AM. The component shown in a) is manufactured by cold extrusion followed by subsequent machining. Component b) is designed for AM, and the cavities likewise require finish machining. The individual optimizations that were carried out to achieve the final design are explained in detail. Compared to the original component, the new design saves 40 % in mass. When considering the change in pressure losses, a distinction must be made between two load cases: extension of the cylinder and retraction of the cylinder. During extension, 43 % pressure loss can be saved, and during retraction, 38 %.

a) b)

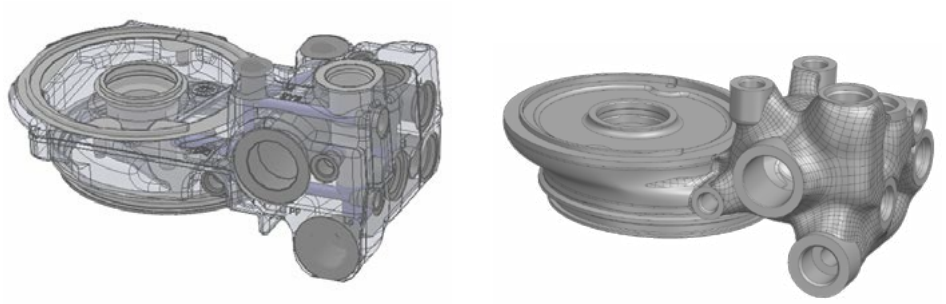

Figure 3.1. Results for the design of the valve block for a) conventional and b) additive manufacturing

The new layout of the hydraulic channels can be seen in Figure 3.2. Eliminating the 90° intersections when merging channels alone leads to a significant reduction in pressure losses.

a) b)

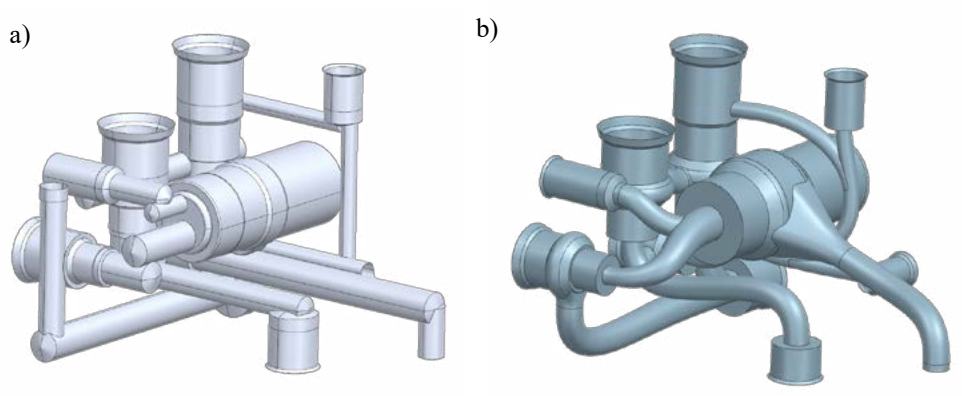

Figure 3.2. Channel route for the design of the valve block for a) conventional and b) additive manufacturing

Figure 3.3 shows the result of the CFD simulation for the old and new manifolds in the case of the cylinder lowering by the load mass. The 38 % reduction in pressure drop is evident from the color-coded contours in the CFD simulation.

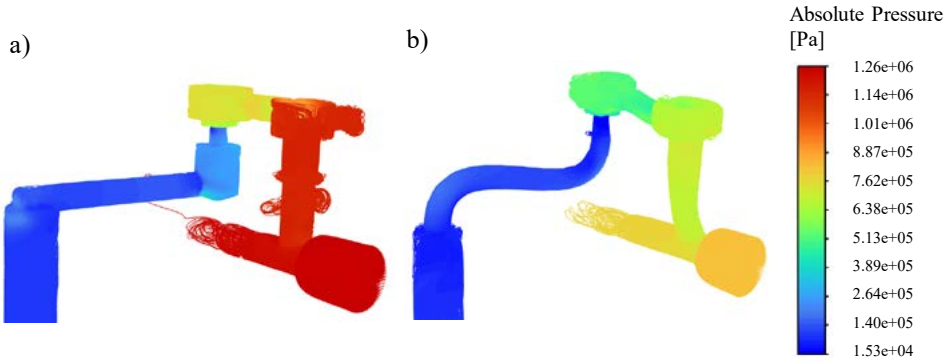

Figure 3.3. CFD-Simulation results of the manifold for a) conventional and b) additive manufacturing in the event of cylinder retraction (lowering)

The Figure 3.4 shows how the potential offered by the design freedom of AM can be exploited. Although the pressure loss is largely determined by the valve, the adapted valve outlet design and a flow-optimized connection can achieve an improvement of 35 %. The valve modification illustrates the approach used in conventional design. Components are optimized sequentially and verified in simulation. Flow paths are routed as NURBS curves between components without any optimization algorithm. At necessary locations, such as the connection to the filter, self-supporting channel cross-sections are implemented.

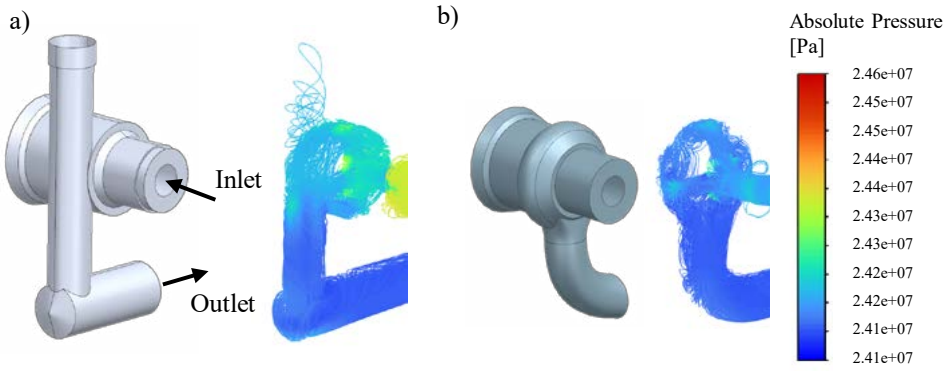

Figure 3.4. Valve design for a) conventional manufacturing and b) additive manufacturing

Conventional design highlights the substantial potential for efficiency gains; however, the design process itself is not particularly efficient. Once modifications are made, dependencies no longer hold, and repositioning components is feasible only with substantial effort. DA provides an alternative to this process. Thanks to the freely programmable and flexible extension of the design configurator, it is capable of creating a wide variety of channel designs and layouts. By adding or removing boundary conditions, as well as by inserting different components into the design space, customized valve manifold layouts and designs

are possible. Figure 3.5 illustrates this diversity by showing the possible modifications of a channel and the flexible adjustment of the valve manifold layout.

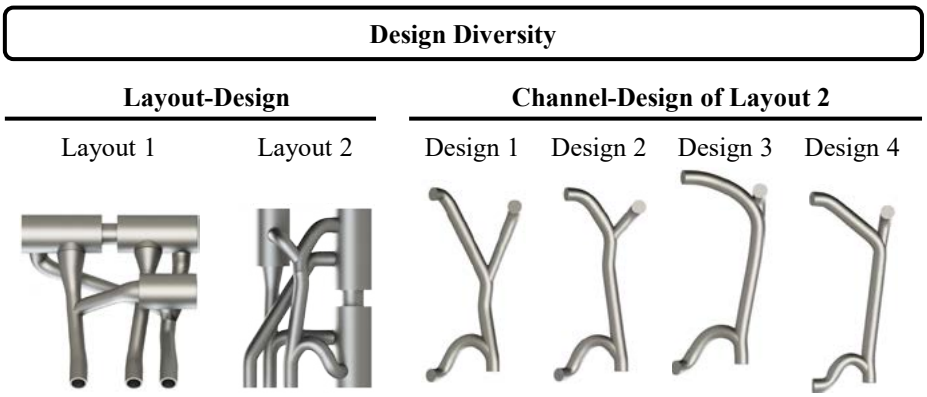

Figure 3.5. Realizable design variety using the design configurator

The design configurator enables the iterative optimization of channel flow due to its simple and rapid creation of various designs [23]. The workflow of this process is illustrated in Figure 3.6. Starting with the initial design, a CFD simulation is carried out and evaluated. In the evaluation, flow-critical positions are identified, and in the next step, the channel geometry is adjusted at these critical locations by modifying the boundary conditions in the design configurator. The resulting valve manifold layout is then generated, and the process is repeated until the predefined optimum is achieved.

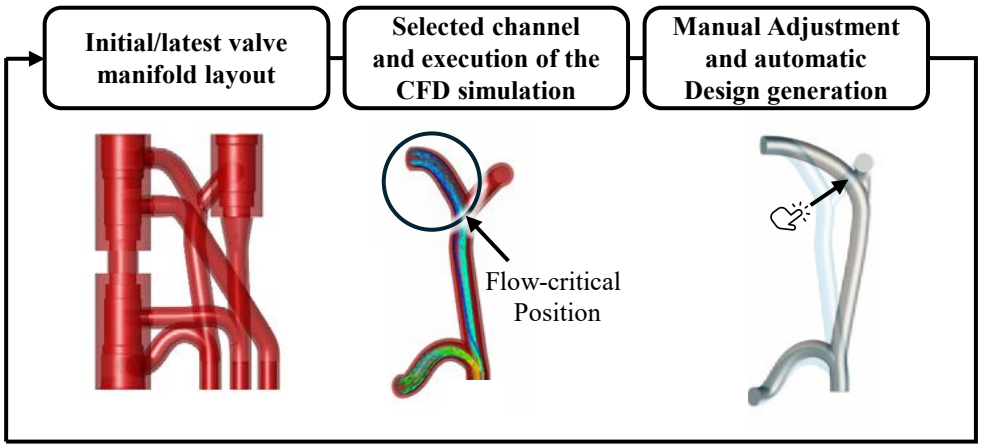

Figure 3.6. Workflow of flow optimization using the Design Configurator

The results of the case study for Layout 2 based on four channel designs are presented below. The case study examines flow optimization based on a defined operating point. The examined designs are iteratively created according to the workflow for flow optimization of the design configurator. To determine a local optimum, the pressure loss across the channel (Δp) is selected as an optimization parameter. Additionally, another parameter (the specific pressure loss) is introduced that describes the pressure loss across the channel divided by the channel length l ($\Delta p/l$) to determine the influence of geometry independent

from channel length. The pressure loss and the specific pressure loss of Designs 1 to 4 are shown in Figure 3.7.

The calculated results are determined using the simulation software ANSYS Fluent. The k-ω-(SST) solver is employed, and between 1000 and 3000 iterations are performed per design. HLP 46 hydraulic oil is used as the working medium for the simulation, with a density of 858 kg/m³ and a kinematic viscosity of 46 cSt. The mesh has the following characteristics: The minimum edge length is at least 0.5 mm, while the maximum edge length does not exceed 1 mm. The boundary layer consists of five layers, and the initial boundary layer has a thickness of approximately 66.71 µm with a growth rate of 1.2. The volume flow varies depending on the channel variant and ranges between 7.12 l/min and 125.61 l/min.

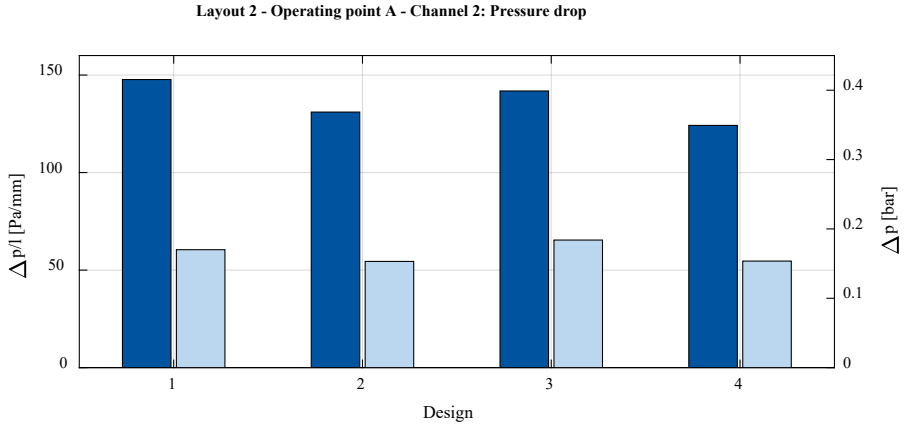

Figure 3.7. Pressure loss and pressure loss divided by channel length for designs 1 to 4

Design 2 has the lowest pressure loss at 0.153 bar. The specific pressure loss is 131.032 Pa/mm, making it the second lowest. Design 4 shows the lowest specific pressure loss with 124.187 Pa/mm; however, here the absolute pressure loss is at 0.154 bar, which is only slightly higher than that of Design 2. The reason for Design 4's poorer performance lies in its channel length; this measures 123.734 mm. The channel length of Design 2 is shorter and measures 116.896 mm. The shortest channel examined in this case study is the one of Design 1 with a length of 115.144 mm. For the case study, a correlation analysis is also conducted to investigate the correlation between various geometry parameters and the optimization parameter pressure loss. Conclusions regarding how to adjust the parameters cannot be drawn from the results due to the difficulty in classifying the geometry of the channels, as the geometric description depends on several individual parameters. The results of the correlation analysis indicate tendencies that certain parameters have a greater influence on the pressure loss of the channels, particularly the channel length should be mentioned.

For the investigation of operating point A, channel 2 from the Layout 1 and 2, the correlation coefficient is calculated to analyze the relationship between the number of occurring

curvature radii and angles with specific pressure loss (pressure loss divided by channel length), as well as channel length and absolute pressure loss. The correlation coefficient quantifies the potential influence of channel geometry on pressure loss. The significance is considered sufficient when a strong correlation exists with a correlation coefficient of at least ±0.5. The results from this analysis are presented in Figure 3.8, with the existing geometric parameters categorized into discrete ranges. This is due to the complex structure of the channels, which exhibits a variety of different curvatures with various parameters. Therefore, it is useful to categorize the geometric parameters into discrete ranges for a correlation analysis. The operating point considered has two inlets and one outlet. The volumetric flow rate at Inlet 1 is 12.88 l/min, and the volumetric flow rate at Inlet 2 is 7.12 l/min.

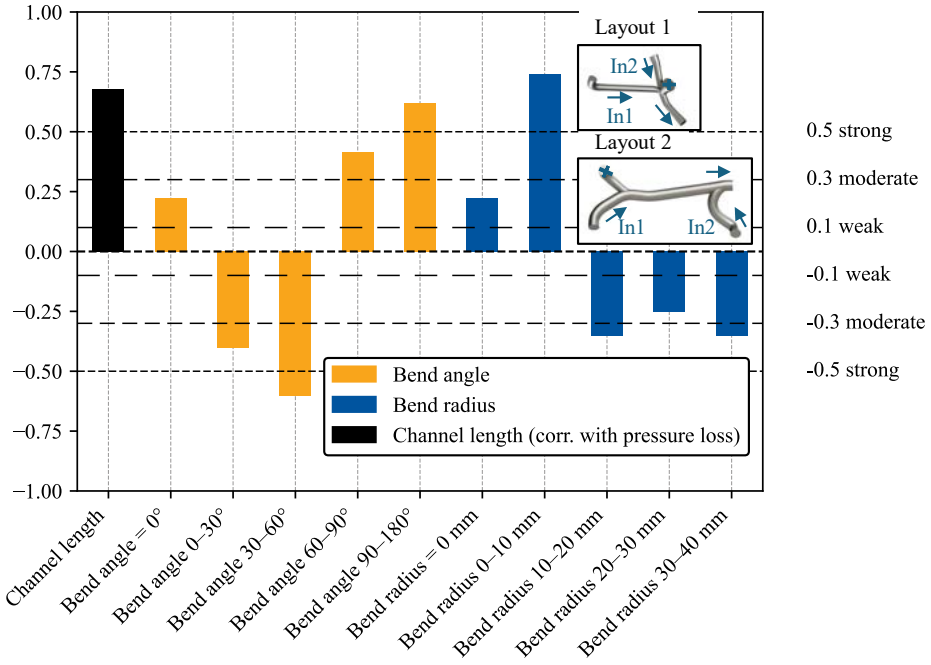

Figure 3.8. Correlation coefficients for operating point A – Channel 2

The analysis provides recommended design guidelines to achieve minimal pressure loss. The curvature angle shows two strong correlations. To reduce pressure loss, it is beneficial for the curvature angle to be in the range between 30° and 60°, where the correlation coefficient is strongly negative. Curvature angles from 90° to 180° should be avoided, as they exhibit a strong positive correlation; in this case, pressure loss increases with an increasing number of such curvature angles.

For curvature radii, a strongly positive correlation coefficient is observed in the range from more than 0 mm to 10 mm. Small radii should be avoided in design. The channel length shows a strongly positive correlation with pressure loss as well, leading to the conclusion that pressure loss increases with increasing channel length.

The design configurator was also used to automatically redesign the forklift manifold shown in Figure 3.1. The implementation process of this design configurator incorporated the use of parametric inputs. In the automated design process of the manifold, the flow-critical positions are identified and modified with minimal effort by utilizing the parametric input of the design configurator. With this a new manifold layout is devised by adjusting the position of the valve cavities or branches using parameters. By considering selected flow-paths in the CFD simulation and comparing them to the conventional valve block, the capabilities of AM are clearly visualized. Figure 3.9 shows the modification of a flow channel, which has led to a 44.6 % reduction in pressure loss.

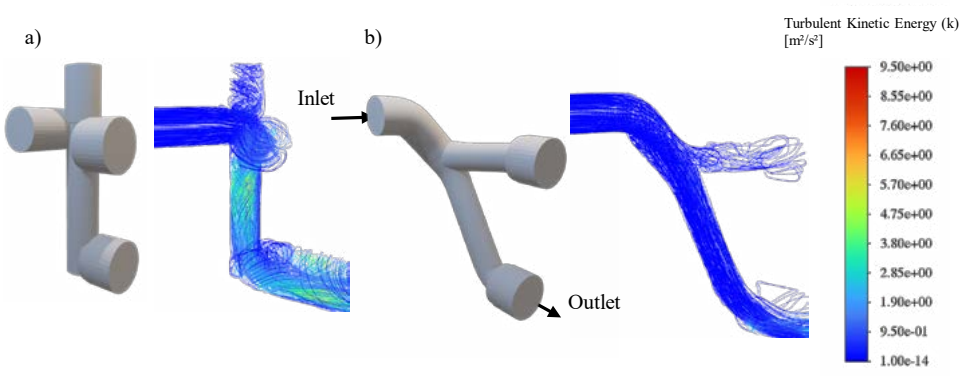

Figure 3.9. Channel optimization using design automation on the manifold

4. DISCUSSION

The analysis of pressure losses along one flow channel highlights the challenges of automated design optimization. Due to the high degree of design freedom, geometric characterization of the channel is very difficult, and losses cannot be attributed to individual parameters. An optimization focused solely on one geometric parameter, such as reducing channel length, does not lead to an optimal pressure-reduced flow in most cases within the valve block. Longer channels with geometries such as bends or branches often exhibit a lower specific pressure loss compared to shorter channels with the same geometries; however, this advantage is offset by extending the channel, resulting in a higher overall absolute pressure loss. For flow optimization of channel geometry, this means that a compromise must be found: between a preferably short channel length and bending as well as branching geometries that exhibit a lower specific pressure loss.

Although conventional design highlights the potential of the new AM design, its implementation is highly inflexible and time-consuming. A compromise would be to derive universally applicable rules that can be implemented in both design methodologies.

5. SUMMARY AND OUTLOOK

Based on the methods and results presented, two main conclusions can be drawn:

1. AM offers the opportunity to significantly reduce pressure drop in manifolds (up to a 43 % improvement).

2. DA enables the rapid generation of various manifold layouts that would be very time-consuming to achieve with conventional manufacturing.

These two findings reinforce both the use of AM in hydraulics and the development of automated design approaches. The next step toward establishing DA is the targeted adaptation of the algorithm for automated flow optimization. To this end, software solutions were already compared in the Introduction. In addition, simple design parameters must be defined so that knowledge-based engineering can be implemented. This includes, for example, defining suitable curvature radii, investigating channel intersections, and providing guidance on suitable self-supporting channel cross-sections. All of these goals are already being addressed within the HyRess research project to develop a guideline for designers. The resulting design guidelines are intended both to implement the constraints of AM and to achieve a flow-optimized component.

Abstract.

In this work, the possibility of replacing steel spools in proportional hydraulic valves with additively manufactured alternatives was investigated. Four materials were selected: E-Rigid Form, HTM 140, Aceaddity ceramic resin, and SuperHDT. Spools were printed with the same geometry as conventional steel parts, without any optimization, to allow for a direct comparison. The main focus was on the manufacturing process itself and the dimensional accuracy that could be achieved. For this purpose, the spools were measured in 3D and evaluated with respect to circularity and cylindricity, as these parameters are critical for proper valve function. Besides this, hydraulic tests with tap water [1] were also carried out in order to observe flow behaviour, pressure losses, and leakage. The results show that polymer and ceramic resins make it possible to manufacture functional prototypes that are lighter and corrosion resistant, but that dimensional stability and reliability still remain the main limitations.

Keywords: Additive manufacturing, Hydraulic valve spools, Polymer and ceramic materials, Geometric tolerancing (GD&T), Dimensional accuracy

1. INTRODUCTION

Spools are a crucial components in the hydraulic valves, being a movable part that is guiding flow of the fluid through the geometry of the valve. Valves come in various shapes and sizes, and their design us usually based on functionality as well as years of testing, optimisation and engineering practice [2]. Spool valves and so spools can be divided in hydraulics into conventional, proportional and servo valves. Each of those have their unique design based on their operation. In this study we will focus on proportional spools for valves that allow for continuous operation and management of flow, having in theory indefinite possible states between closed and fully opened. Proportional spools have specially made control notches

All Open Access articles are peer-reviewed, distributed under the Creative Commons Attribution-Non Commercial 4.0 International

that are distinctive for this type of valves and that are working as nozzle, through which fluid us flowing and is being restricted, thus providing the ability for flow control.

Usually spools for hydraulic spool valves are of cylindrical shape because they need to fit into a hole that is drilled, grinded or honed by the rotating tool. Spools are conventionally made from steel, because this gives them excellent dimensional accuracy, wear resistance, long term reliability and manufacturability, because steel is very well-known engineering material.

However, manufacturing spools from steel also comes with some drawbacks. Machining spools and production of steel in general is highly energy intensive process. Also, if spools and other components were to be used in the water or wet environment, each component must be made of non-corrosive materials such as Stainless-steel or other alternatives. Third drawback is the weight of the steel spools since metals are in general denser compared to modern engineering polymers.

This all got us thinking if it is possible to create light and cheap spools that could withstand forces applied to them under hydraulic pressure and could also be manufactured with energy-less-intensive process thus having lesser impact on the environment.

Since there is a lot of different options to choose from in the engineering alternative materials we focused our direction into mainly polymers. We also wanted to be able to design and produce those vales by ourselves, so we used materials that could be Additively Manufactured (AM) on our 3D printers [3]. We have chosen four different engineering resins that have good thermal or other physical properties such as tensile strength or corrosion resistance. We have decided that this study was the first step towards better and optimized spools that could be used in hydraulics [4-7], but at this stage no geometry optimisation has been done.

Currently, polymers are used in hydraulics mainly for sealing applications and rarely as moving components, critical to the operation of the valves. So, study about feasibility in terms of material properties and dimensional accuracy of the AM manufactured spools, made from alternative materials, had to be made.

Since environmental awareness has been more and more important in recent times, we want to promote environmentally friendly or at least acceptable, hydraulic fluids [1]. In our case we will be using tap water as a hydraulic fluid, which will test our spools in tougher conditions, because water offers worse tribological protection and has tendency to corrode materials which will increase stress on materials. Water also has some positive effects that are combined with environmentally friendliness like non-flammability, availability in large quantities, …

Scope of this study is to manufacture spools originating from same geometry and create them using AM and alternative materials. We will be focusing on manufacturing feasibility, dimensional measurements and material evaluation while conducting the experiments. Goal is to determine whether the polymers are viable materials for spools in highly demanding environments like an inside of hydraulic valves [4].

2. MATERIALS AND METHODS

2.1. Spool Geometry and Design Constraints

As mentioned, we have used the same geometry that conventionally manufactured spool is based on. This is a geometry of quite standard CETOP 3 4/3 proportional directional spool, with outer nominal diameter of 12 mm. To allow the proportional flow control, there are control notches made, 3 per each chamber connection. Notches have width nominal dimension of 2.5 mm and have a depth 2.6 mm. Since this geometry of the spool is not adapted to the Additive Manufacturing (AM) we had to print the spools with a supporting structures that were removed after the printing process. Reference spool is made from Stainless-steel AISI 440-C, firstly turned to rough shape, surface heat treated and then fine grinded to the tolerance specified.

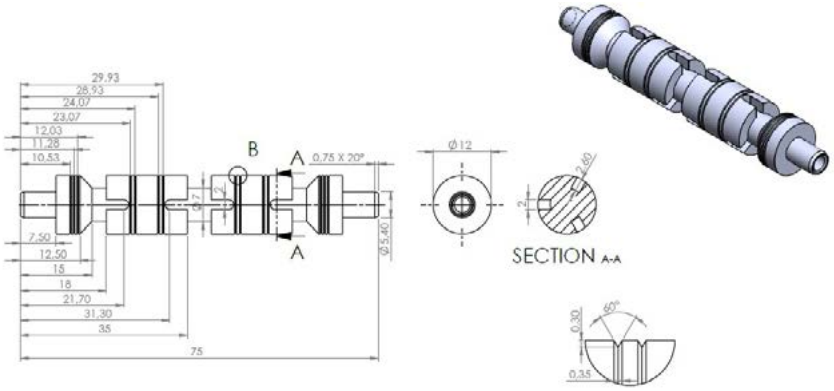

Figure 1: Detailed section from the manufacturing drawing of the spool for hydraulic proportional directional valves.

Usually, for practical application in water hydraulics it is mandatory for spools to achieve tight tolerances ranging from 0 to the negative value of 2 micrometres. This tolerance is crucial to ensure sufficient sealing between internal chambers of the valve by reducing the amount of leakage. Since we did not plan to do any postprocessing machining after 3D printing we did not expect to meet these criteria in full.

2.2. Used alternative materials

We have selected two polymer materials, one ceramic material and one hybrid/ceramic-reinforced resin. Another two polymer materials were from ETEC: High temperature mold material (HTM 140) with heat deflection temperature of 140 °C and Polyurethane-like resin named E-Rigid Form with very good tensile properties. Ceramic resin chosen was from Aceaddity and is named Ceramic Photopolymer 3D printing resin. According to manufacturer this resin contains 30 % ceramic particles. Lastly, we have chosen hybrid/ceramic-reinforced polymer resin SuperHDT that has excellent temperature resistance while still maintaining great load bearing ability. Most essential properties of each material can be found in the table below. In the results we will be presenting measured data with the short abbreviations of the names of each resin. Main advantages and material properties are shown in the Figure 2. Material properties are obtained from the manufacturers data and are dependant on the printing process.

Commercial name	E-Rigid Form	HTM 140	Ceramics 30 %	SuperHDT
Manufacturer	ETEC	ETEC	Aceaddity	3DMaterials
Material	Polyurethane-like polymeric resin	Polymeric resin	Polymeric resin, containing 30 % ceramic powder	Composite polymeric resin with nano-micro ceramic particles
Tensile strength [Mpa]	73	56	47.97 ± 10 %	39,5
Tensile modulus [Mpa]	3250	3350	819.52 ± 10 %	3
Elongation at break [%]	6	3,5	6.9 ± 10 %	<2
Temperature resistance [°C]	62.5	140	280	240
Essential properties	•Water resistance •High stiffness and dimensional accuracy. •Good for detailed geometries and tight tolerances. •Moderate resistance to water exposure; lower wear resistance compared to ceramics.	•Water resistance •Enhanced thermal stability. •Higher resistance to deformation under elevated temperature or prolonged stress. •Similar surface finish to E-Rigid Form, but slightly more brittle.	•Very high hardness and wear resistance. •Excellent corrosion resistance in water-based hydraulics. •Sintering shrinkage must be compensated in design. •Surface roughness and porosity depend heavily on post-processing.	•High density after sintering → improved mechanical strength. •Good dimensional stability and reduced brittleness. •Resistant to chemical attack and swelling in tap water. •Requires precise post-processing to meet hydraulic tolerances.

Figure 2: Alternative materials properties.

2.3. Additive Manufacturing process

Ceramics and SuperHDT were 3D printed using Stereolithography (SLA) process using desktop Anycubic Photon Mono M5 3D printer. SLA printing is a type of 3d printing process that uses photopolymeric resin and UV light to make printed parts. It has several crucial parameters, the most important being layer exposure time. This defines how long each layer is exposed to UV light from the illuminating display. Longer exposure time might make printed parts slightly larger, since more photopolymeric resin is hardening, but shorter times might create objects that are not fully hardened. Layer exposure time is mainly dependent on power of the light source and type of resin that is used for printing.

We used manufacturers recommendations to define parameters to manufacture and post-process the spools. Since recommended layer exposure time for SuperHDT was defined between 5.6 and 7 seconds for our printer, we have used both of these options. Similarly, when printing Ceramics, we used two different layer exposure times defined at 1.35 and 2 seconds.

HTM 140 and E-Rigid Form were manufactured by DLP process using Envisiontec (ETEC) D4K printer. Again, all manufacturers presets were used when defining printing and post-processing parameters. Post-processing in all cases was only cleaning the parts of any residual resin, supports removal and UV curing according to manufacturers specification. All spools that were compared during the research are shown on the Figure 3.

Figure 3: Spools made from alternative materials and standard spool made from AISI 440-C.

Additive manufacturing printers

ETEC D4K
The ETEC D4K is a professional DLP resin printer with a build volume of roughly 148 × 83 × 110 mm, prioritizing accuracy over size. It uses a 50 μm native XY voxel (with

enhanced modes down to ~25 µm) and typical 25–100 µm Z layers, enabling very consistent fine features. Recommended minimum wall thickness is ~0.5–1.0 mm, and dimensional accuracy is strong, with practical fit tolerances around ±0.05–0.15 mm for standard resins when well-calibrated.

Anycubic Photon Mono M5
The Anycubic Photon Mono M5 targets high detail at larger scale, offering a much bigger ~218 × 123 × 200 mm build volume. Its 12K LCD provides an ~19 µm XY pixel size, finer on paper than the D4K, with common 0.01–0.05 mm layers. Practical minimum wall thickness is ~0.5–1.0 mm, similar to DLP systems, while typical clearance fits require ~0.1–0.2 mm due to MSLA exposure and shrink effects.

2.4. Materials characterization

Dimensional properties

We have used different approaches to measuring the dimensional accuracy of 3D printed spools.

Firstly, we used Insize 3109-25A digital micrometre to measure the diameter of the spools. We took two representative spools of each material and took 6 measurements of the diameter per spool. After that, we have plotted all the results into a chart, where it is possible to compare the measured results for each resin.

Secondly measurements were performed on the Mahr MMQ 500 3D measuring machine. By using this, we wanted to measure the circularity and cylindricity. These two parameters are crucial for the geometry, so that spool fits properly into valve housing.

Cylindricity is a form of 3D geometric tolerance that controls how close the surface of the cylinders is to a perfect cylinder. Tolerance zone is the space between two coaxial cylinders within which the surface of a measured part must lie. It is basically a combination of circularity and straightness of the axis and taper.

Mass properties

After dimensional characterization we have also weighted the spools. We used laboratory Gram Lite EH scale to weight the spools and compare the results.

Tribological properties

For the tribological tests we prepared AM made steel discs made from Maraging Steel 1 (MS1) with a dimension of 25 X 25 X 6 mm representing the valve body. Steel discs were polished on automated preparation device RotoForce-3 to achieve surface roughness of 0.1 µm. Representing alternative materials, we made a pins with a dimensions of Φ 10 x 20 mm, with 12.5 mm radius on top.

Tribological tests were performed on a Camern-Plint TE 77 tribometer. In this test pin in sliding reciprocally on a printed disc with a frequency of 10 Hz. Stroke was 2.4 mm which is representative of a sliding distance inside valve housing. Normal load was 65 N. We used water as a lubricant. Testing period of each pin was 1 hour or 36 000 cycles. This was

determined in accordance with the normal load to show some kind of wear on each pin. 3 repetitions were done per each material pair. After the tests we evaluated the wear and coefficient of friction and averaged the results. Coefficient of friction was calculated from the ratio of normal and tangential force, that was dynamically measured during testing. Specific wear was calculated using the following equation (1).

$$Specific\ wear = \frac{\pi * d_{mid}^4}{64 * R} \quad (1)$$

Secondly, we observed the wear that was the result of the normal force and reciprocating motion between each material pair. Since we were using pure tap water as a lubricant, we were able to observe the rust that was forming on our MS1 discs.

Hydraulic properties

Since geometry of the spools was the same in all cases we did not expect any differences (improvements) in hydraulic measurable parameters. Mainly we wanted to determine if these materials are suitable for use in hydraulic environment. We used self-developed water hydraulic test rig capable of 11 kW hydraulic power or 350 bar at 30 l/min. Pump used is axial piston pump with 3 pistons. Spools were tested in the AM made valve housing which is connected to the also AM made mounting plate. AM valve has been optimised in terms of complex internal geometry to impose as low as possible resistance to the fluid flow [8]. AM mounting plate has been optimised as well, but mainly in terms of transducer placement, because we can measure the pressure extremely closely to the valve itself, thus reducing the uncertainty in the measurement coming from other sources.

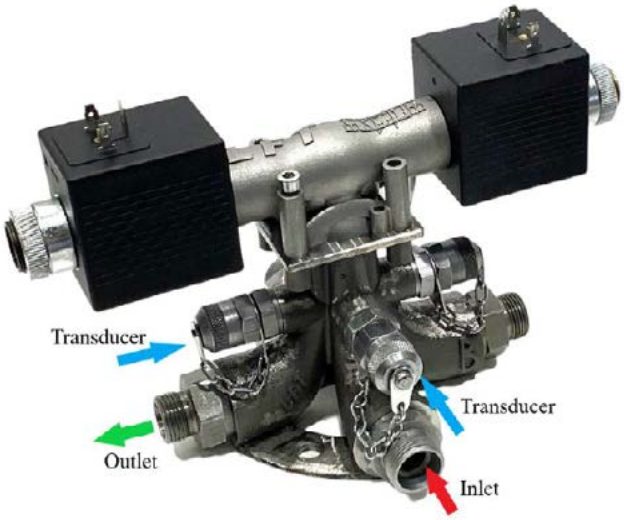

Figure 4: Valve in the testing assembly with magnets, mounting plate (AM) and hydraulic couplings.

Simple hydraulic scheme is shown on the Figure 5. As mentioned before, we have used 11 kW water hydraulic test rig. Each spool was tested separately to test its ability to withstand

the load in form of hydraulic pressure. We were measuring hydraulic pressure on the input and at the output from the valve. Mainly we wanted to determine if alternative materials are suitable for usage in real hydraulic applications. So, leakage test was performed first, followed by pressure drop characteristics dependent on the volumetric flow. Lastly pressure was increased in the pressure chamber till the breakage point of the spool itself. Leakage test was performed with spool in the middle neutral position. After applying the hydraulic pressure, we have measured the amount of leaked fluid on the neighboring A and B channels. For the pressure drop test we have gradually applied volumetric flow, and measured the pressure drop between the pressure (P) and working (A) port. Spool opening was kept constant at predetermined displacements, spaced by 0,25 mm. Since internal structure of the valve is symmetrical, we have switched position of the spool to the other side, just to confirm that both values were comparable.

Hydraulic tests were performed only using Ceramics and SuperHDT spools. This was due to the unavailability of the E-Rigid Form and HTM-140 resins during the stage of printing actual spools for usage in hydraulic valve.

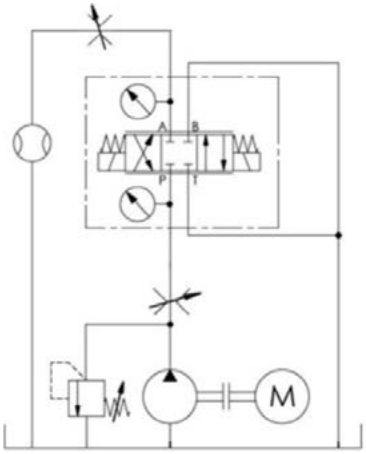

Figure 5: Simple hydraulic scheme for testing purposes.

3. RESULTS

3.1. Dimensional properties

Figure 6 is showing the measured results for each spool made from different materials. For the SuperHDT and Ceramics there are two sets of measurements, because these materials were printed at two different times of exposure per layer. It is evident that SuperHDT at both settings as well as E-Rigid Form and HTM 140 were printed with dimensions that were smaller than nominal dimension. Comparing these results to steel we can also see that distribution of measurement is quite large. Since steel spools were grinded to achieve the tolerance, the distribution of measurements is expectedly low. Largest distribution could be seen for the E-Rigid Form, but this is also the closest by the mean value to the nominal. HTM 140 was also relatively close comparing to the others, deviating from the nominal

dimension by approximately 80 µm. It is interesting to note that both printed Ceramic spools were measured above the nominal dimension. We can also clearly see the increase in the dimension for the Ceramic spool where we used higher exposure time. Sam principle can be observed for longer time of the exposure at SuperHDT.

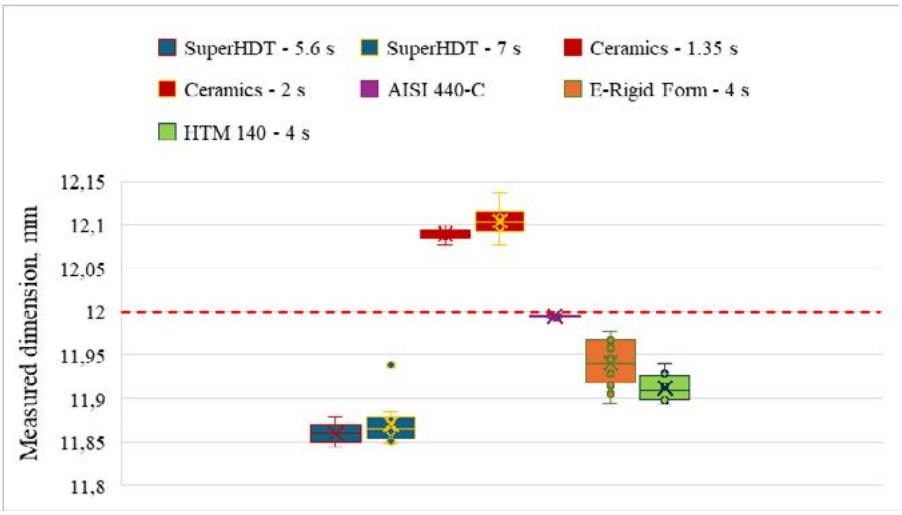

Figure 6: Measurements taken by micrometre plotted and compared according to 12 mm nominal dimension.

Cylindricity

In our case we measured each spool to determine the deviation from the perfect cylinder shape. Expected, from the previous circularity measurements, was that Ceramics printed at both exposures would perform the worst, which is actually the case here. Ceramics printed at 1.35 s exposure has a cylindricity 83.8 µm and printed at 2 s 112.3 µm. Again, we can see that elongation of exposure time made a result worse. HTM 140 resin preformed moderate with a cylindricity of 44.7 µm and E-Rigid Form 50.5 µm. Interestingly SuperHDT resin has a poor result at 5.6 s exposure time of 70.7 µm, but this result is greatly improved for increased exposure time at 7 s and was measured at 23.2 µm. Still the best performance was measured for the grinded Stainless-steel AISI 440-C spool at 2.4 µm.

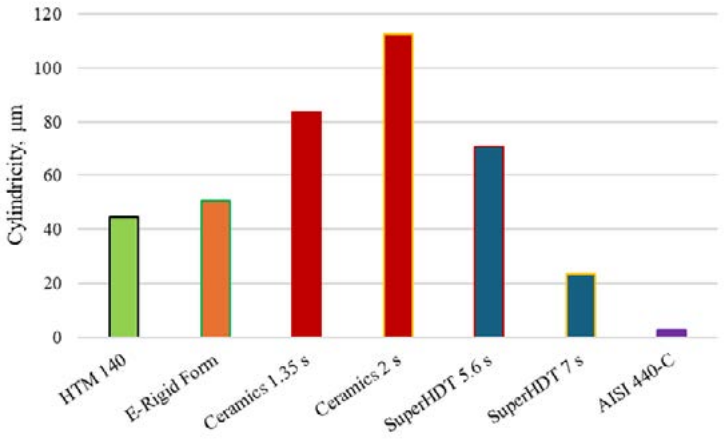

Figure 7: 3D measurement of cylindricity for each alternative material and standard AISI 440-C stainless steel.

3.2. Mass properties

Polymer spools weighted in at 6.21 g (E-Rigid Form) and 6.32 (HTM 140). Spool made from 30 % ceramics is weighing 7.01 g and partially ceramic spool (SuperHDT) 6.45 g. Our reference spool made from Stainless-steel has a measured weight of 44.82 g. In conclusion, all spools made of alternative materials are significantly lighter compared to the reference that is commonly used.

3.3. Tribological properties

Coefficient of friction

Firstly, we measured the coefficient of friction. This result is calculated based on the normal load and the measured value of tangential force needed to ensure reciprocating motion of the pin. Looking at the results of the measured coefficients of friction, we can observe how the values are changing per increasing cycle count. We can see the expected rising at the beginning where the load was applied and then all values star to converge towards certain values. Only E-Rigid Form is showing in this case that it would probably need more time and cycles to end the fluctuation in the results. No measurable differences between base and elongated exposure times were detected during testing for both Ceramics and SuperHDT, so we only included samples made with manufacturers recommended exposure times.

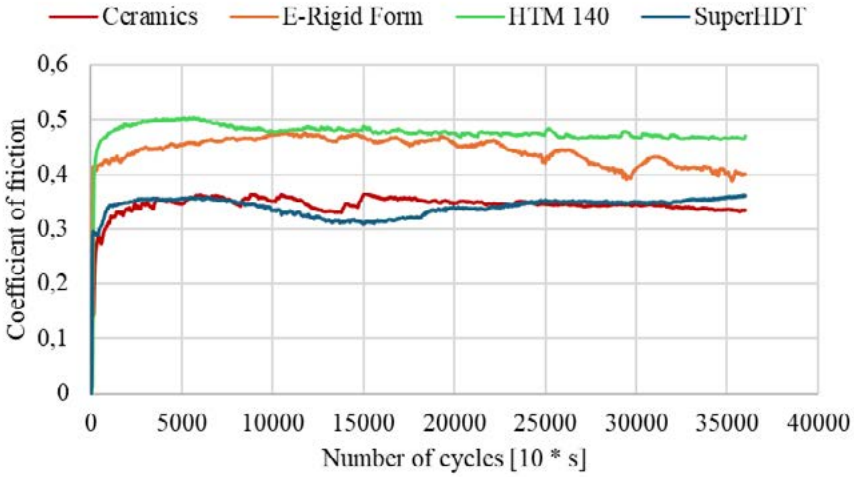

Figure 8: Coefficient of friction measured per 36000 cycles from the pin-on-disc tribological test.

Lowest averaged coefficient of the friction was achieved by the SuperHDT pin with a value of 0.342. Both polymeric pins did perform slightly worse with E-Rigid Form measuring 0.423 and HTM 140 measured 0.471. Here it is important to mention that only Ceramics had a noticeable sound when tribological test was performed. For comparison we have added the measured value of tribological pair AISI 440-C and MS1. It is very interesting that both ceramic and ceramic-powder-filled resin perform slightly better compared to steel-on-steel contact when lubricated with water.

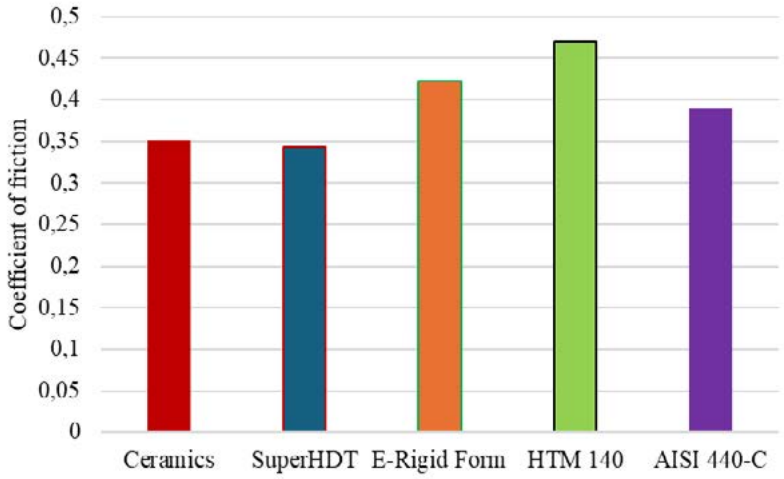

Figure 9: averaged value calculated of friction coefficient compared between alternative materials and standard AISI 440-C stainless steel.

Specific wear

It is evident that the smallest wear trace was left in the case of the Ceramics, because having the highest surface strength. Expectedly this also led to the smallest calculated specific wear of 0.223 mm^3/Nm. Impressively, HTM 140 also achieved quite low specific wear at 0.798 mm^3/Nm. Looking at the abrasion mark we can see that material was performing as a homogenous solid, without any material being compressed under the load force. Material degradation can be spotted in the case of E-Rigid Form. In the middle section of the pin abrasion mark it is evident that material did not withstand the load applied. Because of this, the highest Specific wear was calculated for this material at 1.986 mm^3/Nm. SuperHDT material had an abrasion circle on the pin with a diameter of approximately 4 mm with calculated specific wear 1.06 mm^3/Nm.

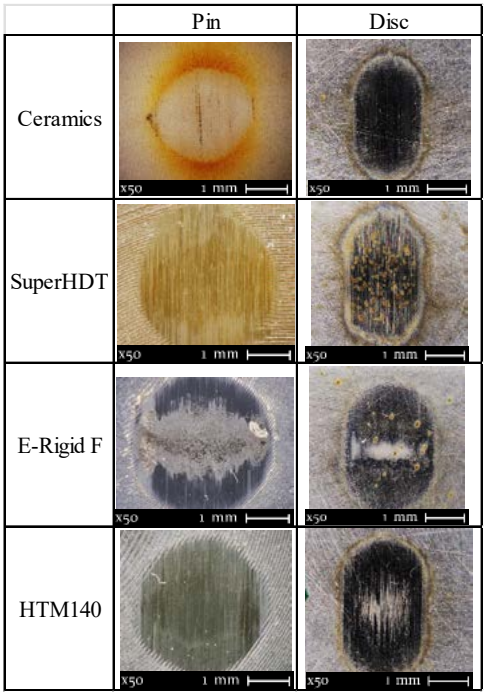

Figure 10: Digital microscope images of wear tracs on Pins from alternative materials and discs from MS1 steel.

Figure 11 is representing the measured specific wear values for each material.

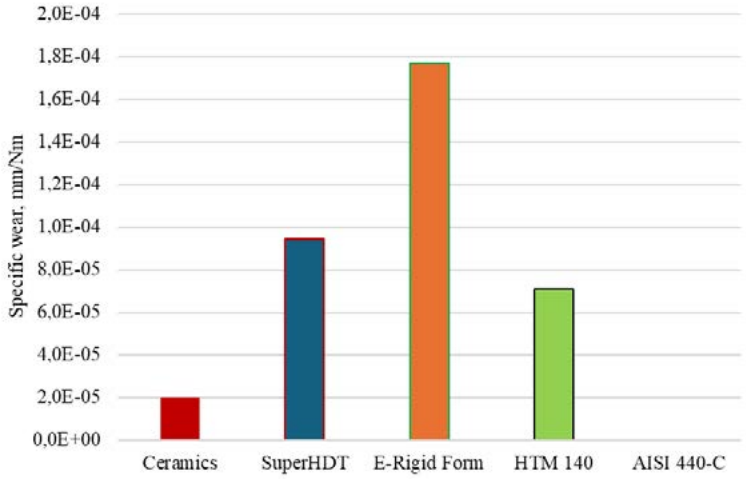

Figure 11: Specific wear for each material after tribological pin-on-disc test.

3.4. Hydraulic properties

Firstly, leakage of the hydraulic fluid was measured to determine the ability of the spools to sufficiently seal the internal chambers of the valve between themselves. Since circularity and cylindricity GD&T were not achieved, we did not expect the sealing and consequently to be sufficient and so that leakage to be quite high. This is confirmed on the Figure 12 where we can see that leakage measured was about 6 times higher in the case of two ceramic materials compared to AISI 440-C grinded spool. This was expected to have great consequences on the following results.

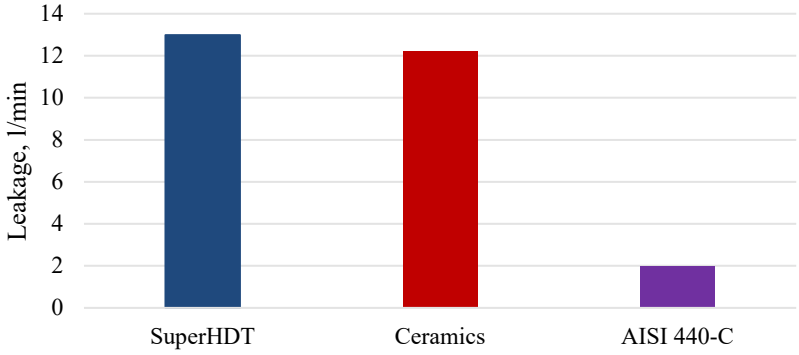

Figure 12: Measured leakage of hydraulic fluid between internal chambers of the valve.

Secondly, we measured the spool and valve characteristics during hydraulic operation. On the Figure 13, the results are shown for the 30 % valve opening. Effect of the internal leakage are quite obvious in this case. Since all measurements were supposed to show similar characteristics, due to leakage, the difference is quite noticeable. It is worth mentioning that results are shown at quite low pressure. This was done to prevent the spools from breaking under load prematurely. After determining the pressure drop per volumetric flow

characteristics, we have used 15 % valve opening at high pressure to determine how high hydraulic pressure the spools could withstand. SuperHDT spool did brake at 8.5 MPa of pressure, while spool made out of 30 % ceramics did not break at 7.5 MPa but the leakage was so high that we could not increase hydraulic pressure any longer due to limitations of our hydraulic aggregate. But Ceramic spool did brake once 10 MPa of hydraulic pressure was applied as an impulse.

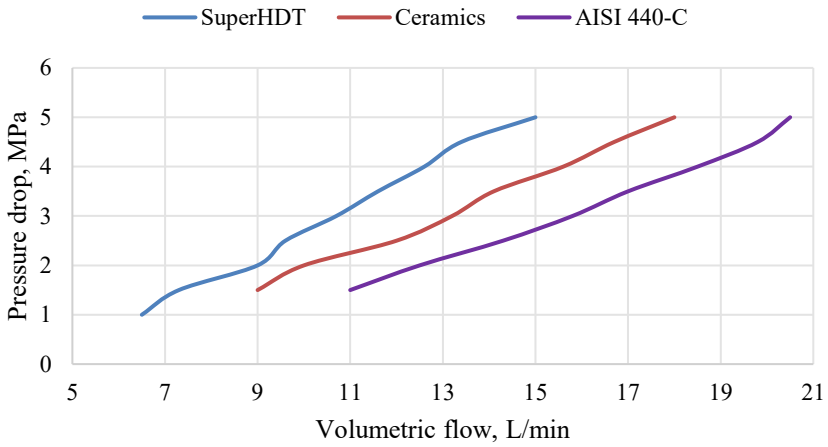

Figure 13: Measure performance of alternative spools compared to standard AISI 440-C steel spool.

Spools broken during actual hydraulic testing can be seen on the figure 14 below. Interesting, while also expected is, that both spools on the figure below did snap at the same location. This is obviously the weakest point of the spool geometry.

Figure 14: Spools from alternative materials, that were broken during actual hydraulic testing.

4. CONCLUSIONS

When comparing the additively manufactured spools with conventionally grinded steel spools, it is clear that the printed parts do not reach the dimensional tolerances required for efficient use in hydraulics. This was confirmed both by manual measurements and 3D evaluations, with circularity and cylindricity values outside the acceptable range. Some form of post-processing therefore appears unavoidable. On the other hand, the use of alternative materials results in spools that are about seven times lighter than steel, which can be advantageous in many applications. From a tribological point of view, the coefficient of friction is comparable, with ceramics and ceramic-filled resins even showing better performance than steel in certain cases. The weak point remains wear, which is significantly higher for all alternatives.

We have proven that simple spool geometry that was 3D printed could not withstand higher pressures that are usually applied to the hydraulic components. Both tested spools did brake at the pressures equal or less than 10 MPa. So, if there was an application of lower pressure hydraulics these spools might be feasible. For the lower pressure and power, we have proven that characteristics are relatively similar, but still the shape that is not reaching the defined GD&T tolerances, is mainly held back by the amount of leakage between the internal chambers of the valve.

For the further development, we are suggesting the improvement of manufacturing process in a way to create spools that are achieving or are at least closer to the tolerances that are required. Also, it would make sense to use materials that could withstand higher loads.

ACKNOWLEDGEMENTS

The authors would like to express their gratitude to Solidworld d.o.o. 3D advanced solutions for their support in manufacturing the spool prototypes and testing pins.

Special thanks are also due to Poclain Hydraulics d.o.o. for conducting the 3D measurements of the manufactured spools, which were essential for determining the geometric specifications presented in this study.

Abstract.

Demolition hammers are currently tested on mineral materials or on mechanical substitute base systems such as the steel ball energy absorber Dynaload. These bases are either destroyed during testing or not designed to replicate different materials. This work investigates a hydraulic substitute base as an equivalently effective, repeatable, adjustable, and low-wear alternative. Various arrangement concepts are evaluated. The selected concept combines a tool of a demolition hammer and a cylinder piston into a single impact body. The design approach uses a co-simulation that couples an FEM model of the impact mechanism with a hydraulic base model. Parameter studies show that by tuning hydraulic capacitance, resistance, and inductance, the tool displacement curves and dissipated energy can be targeted to approximate real materials. Therefore, this paper shows how a hydraulic substitute base could be adjusted. For concrete-like behavior (penetration depth ≈ 0.4 mm, energy absorption ≈ 83%), the simulation yields a required volume of 0.3 ml with mineral oil and an orifice cross-section of about 1.1 mm^2. With the identified adjustment ranges for capacitance and resistance, a hydraulic substitute base for a handheld rotary hammer with 4.2 J impact energy can be designed. The methodology can be transferred to other impact demolition hammers, such as hydraulic breakers, enabling reproducible testing.

Keywords. hydraulic substitute base, co-Simulation, rotary hammer testing.

1. INTRODUCTION

Demolition hammers are used to break up mineral materials or building materials. Their core is an impact mechanism that acts on the chisel at a frequency in the single-digit or double-digit Hz range. The resulting impact force crushes the material beneath the chisel tip. Prototype testing remains indispensable for developing such machines because model assumptions and simplifications in simulations leave residual uncertainties. However, tests on mineral materials are problematic. These materials are destroyed during the test, limiting long-duration testing. In addition, mineral materials are structurally inhomogeneous, which reduces the repeatability of test results. Especially for the tests required by EU directives to assess vibration emissions, high repeatability is essential [1]. Consequently, "artificial" test bases - also called substitute bases - are used [2]. They should replicate mineral materials in an equivalently effective way with low scatter. Existing solutions, such as the Dynaload system [3] specified in DIN EN ISO 28927-10 [2] for hand-held demolition hammers without rotary motion, are predominantly mechanical and only partially meet testing needs. For example, the mechanical substitute base Dynaload used for vibration tests is not designed to represent different materials via adjustable parameters [3].

This paper addresses the research gap stemming from the lack of an adjustable substitute base. It investigates alternatives to purely mechanical systems, with a focus on an adjustable hydraulic substitute base. Due to the low compressibility of hydraulic fluids, high impact forces can be damped while chisel displacements remain small. Hydraulic components also allow targeted adjustment of stiffness and damping [6]. The paper shows, using a rotary hammer as an example, how such a substitute base should be designed in order to combine equivalent effectiveness, repeatability, adjustability, and wear resistance.

2. STATE OF THE ART IN TECHNOLOGY AND RESEARCH

2.1. *Substitute Bases*

For experimental evaluation of demolition, substitute bases are used to reproduce the behavior of mineral materials and provide a reproducible test environment. In practice, predominantly mechanical substitute base systems are employed [2], [3].

A well-established representative is the Dynaload system, developed by the PNEUROP Tools Committee [3]. Dynaload is a standardized test device for evaluating vibration, noise, and performance of hand-held percussive tools according to DIN EN ISO 28927-10 [2]. The system consists of a metallic cylinder filled with steel balls, as shown in Figure 1. The tool transfers the impact wave to this column of balls via a metallic piston plate. Part of the impact energy is dissipated upon impact through elastic deformations and relative motions of the balls. About 15% to 20% of the impact energy is reflected back to the tool, creating a loading situation similar to working on a hard mineral material. The system is available in several sizes (cylinder diameters 20 mm, 40 mm, 60 mm) and can be fitted with various tool - piston combinations. These variants extend test-stand capabilities (e.g., rotary hammers can also be tested in hammer-drilling mode where the tool additionally rotates). PNEUROP test series showed that Dynaload provides high repeatability and is insensitive

to small manufacturing tolerances or wear; repeatability remained stable throughout the test day and from one day to another. [3]

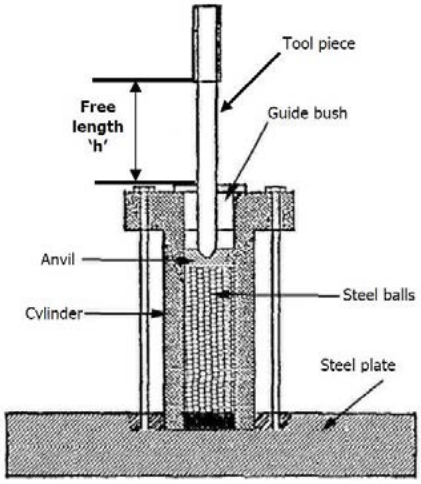

Figure 1: Mechanical steel ball energy absorber Dynaload [3]

For hydraulic breakers, the literature presents a test bench for determining impact energy as described in [5]. A key element is a shock- and vibration-absorbing base realized as a multilayer combination of sand, crushed stone, wood, and rubber, as shown in Figure 1. This design serves to decouple environmental influences and ensure repeatable measurements. [4]

The base is not intended to be adjustable. Moreover, it is reasonable to expect that the layered materials - especially crushed-stone layers - densify over time, changing their mechanical properties and affecting repeatability.

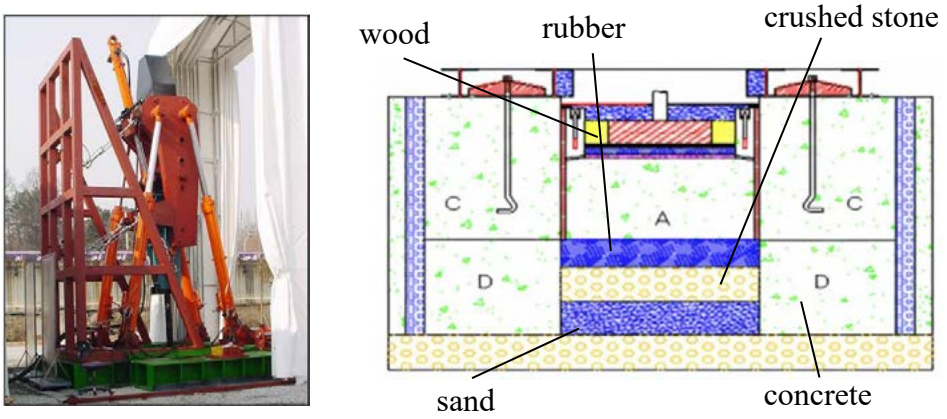

Figure 2: (left) test bench for hydraulic breakers; (right) impact absorbing base [4]. Text boxes were added by the authors.

In summary, mechanical substitute bases like Dynaload are suitable for standardized comparative measurements, but they cannot be tuned to different material properties and therefore cannot provide equivalently effective replication of different mineral materials. An advanced concept - such as the hydraulic substitute base presented by Klotz et al. offers the possibility to adjust both stiffness and damping by varying oil volume and orifice cross-section, thereby reproducing the behavior of different materials in a repeatable manner [6].

2.2. *Simulation of Hydraulic Impact Damping*

Hasenöhrl et al. investigate the shock-induced propagation of strain waves in a rotary hammer, taking into account the geometry of the impact body, using FEM simulation [7].

Klotz et al. describe a simulation environment enabling the determination of system parameters required to develop a hydraulic substitute base. The described co-simulation couples a structural FEM model of the impact mechanism with a hydraulic model of the substitute base, thus realistically representing the dynamic interaction between tool and base. In the FEM model, relevant impact events in the rotary hammer and at the hammer - tool interface are represented, modeling flying piston, firing pin, and tool as deformable bodies. The FEM model outputs the time-dependent displacement of the hydraulically pressurized piston area, which is passed to the hydraulic model via a co-simulation engine. The hydraulic model describes the substitute base as a hydraulic system comprising capacitance, and resistance. From piston displacement, the model computes the cylinder pressure history and the resulting reaction force, which is fed back to the FEM model. This bidirectional coupling captures energy flows between the impact mechanism and the substitute base comprehensively. By varying hydraulic parameters - especially the enclosed oil volume and the orifice cross-section - the influence on stiffness, damping, and energy absorption can be systematically investigated. Low hydraulic capacitance leads to a stiffer base with smaller penetration depth and higher peak pressures, whereas a larger orifice increases damping and thus energy absorption. In simulation, hydraulic damping could be varied between nearly 0% and 84% of the initial impact energy of the modeled rotary hammer. In this way, the interaction of hydraulic components can be tuned so that the substitute base reproduces the behavior of different mineral materials in an equivalently effective manner [6].

This simulation-driven approach allows different design variants to be evaluated before building hardware. The co-simulation thus serves as a tool for designing and parameterizing the hydraulic substitute base by revealing the relationships between geometric, hydraulic, and dynamic quantities and enabling virtual tuning to different base types.

3. CONCEPT SELECTION

3.1. *Requirements for a Substitute Base for Demolition Hammers*

For developing and testing demolition hammers, a test base is required that reproduces the behavior of mineral materials in an equivalently effective way. Because natural rock or concrete - due to inhomogeneity, anisotropy, and irreversible destruction under impact loading do not allow repeatable results, a substitute base is needed that can emulate the governing physical characteristics of the real material. From the authors' perspective, such

a base must satisfy four key requirements: equivalent effectiveness, repeatability, adjustability, and wear resistance.

Equivalent effectiveness means that the dynamic response of the substitute base - i.e., the time histories of penetration depth, contact force, and dissipated energy - matches those of a real mineral material as closely as possible. Only if the energy uptake and rebound of the base reflect typical building materials or rock tool loads can be represented realistically.

Repeatability describes the ability to reproduce identical impact events multiple times with minimal deviation, enabling comparisons of demolition hammers tested at different times and places.

Adjustability is required to emulate different base types such as concrete, granite, or limestone with varying stiffness and damping. An adjustable base allows systematic variation of material parameters and investigation of substrate influence on impact-mechanism behavior.

Finally, the substitute base must have high wear resistance to provide stable characteristics over many tests even at high impact frequencies and energies, enabling cost-effective testing.

3.2. *Evaluation of possible System Concepts for Substitute Bases*

Various technical concepts can in principle meet the requirements of equivalent effectiveness, repeatability, adjustability, and wear resistance. The following assesses mechanical, pneumatic, mechatronic, and hydraulic approaches for their suitability from the authors' perspective.

Mechanical systems combine springs, dampers, and mass elements. Very stiff bases can be realized, but their characteristics are only limitedly variable. Adjusting stiffness or damping typically requires part changes, increasing test effort. If damping relies on relative motion of components, wear and long-term stability can be problematic.

Pneumatic systems provide a soft, strongly damping characteristic due to the high compressibility of air. System parameters can be readily adjusted via pressure, volume, or orifice size. However, they are only of limited suitability for hard bases such as concrete or granite because the achievable stiffness is far below that of real mineral materials.

Electronic/mechatronic linear actuators or other controlled actuators could in principle emulate the interaction between tool and base. In practice, the high impact forces and very short strokes characteristic of demolition hammers impose stringent demands on structural stiffness and dynamics. Electric linear motors lack the required structural stiffness to absorb or dissipate these forces equivalently. Mechatronic concepts are therefore presently of limited suitability for reproducing the physical boundary conditions of a real mineral material.

Hydraulic systems combine high power density with low compressibility of the working fluid. As a result, they can represent both high impact forces and small deformations as observed in hard mineral materials. By adjusting enclosed oil volume and flow resistance, stiffness and damping can be tuned. At the same time, dissipative energy conversion in the fluid provides high repeatability with low wear. The simple adjustability of hydraulic components enables flexible adaptation to different material characteristics, making the system particularly suitable to meet the requirements of equivalent effectiveness, repeatability, adjustability, and wear resistance.

In summary, pneumatic and electric systems can reproduce the stiffness of mineral materials only to a limited extent. Mechanical systems have been developed but are impractical for adjusting damping characteristics and are prone to wear. Hydraulic systems therefore represent the most promising approach to achieve an equivalently effective, adjustable, reproducible, and low-wear substitute base. The following describes hydraulic concepts.

3.3. *Evaluation of possible Arrangement Concepts for Hydraulic Substitute Bases*

Two arrangement concepts were considered and are illustrated using a rotary hammer as an example. The first concept, as shown in Figure 3, is straightforward: the real mineral material is replaced by a hydraulic system consisting of a cylinder and other components. A commercial chisel is clamped in the rotary hammer as the tool. The hammer impacts a hydraulic cylinder via the chisel; the chisel and the cylinder piston are two separate bodies. Advantages include use of tools with original geometry, thus accounting for geometry effects on stress-wave propagation. Tools can be easily exchanged, allowing chisels of different length, diameter, and tip geometry. Another advantage is that the classical coefficient of restitution k can be used as a comparison metric, calculated from the velocities of the colliding bodies:

$$k = \frac{c_2 - c_1}{v_1 - v_2} \text{ [8]} \qquad (3.1)$$

where $v_1 - v_2$ is the relative velocity of chisel and base (i.e., cylinder piston) before impact, and $c_2 - c_1$ is the velocity difference after impact. A disadvantage is the wear at the chisel tip and on the hydraulic piston caused by the high-frequency impacts.

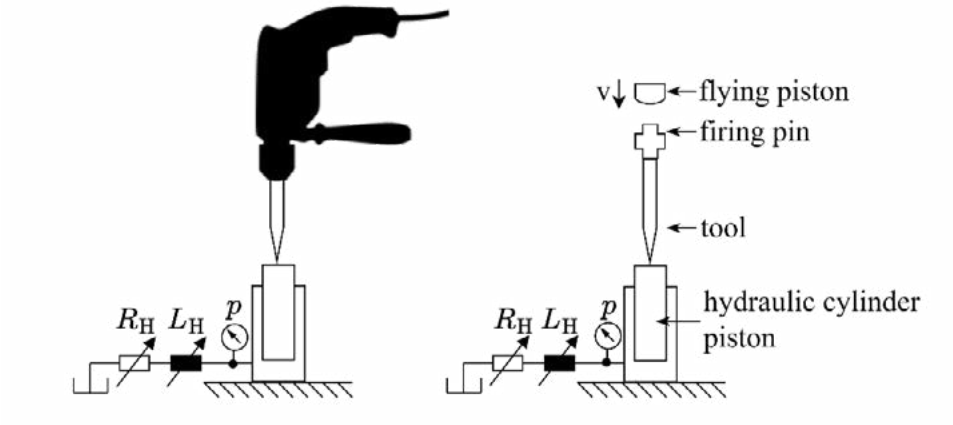

Figure 3: Arrangement concept 1: (left) The rotary hammer strikes a hydraulic cylinder piston with a standard tool; (right) Schematic representation of the relevant impact bodies.

Figure 4 shows the second arrangement concept. It differs from Concept 1 in a way that the tool acts as the cylinder piston. Therefore, no additional contact partner like the hydraulic cylinder piston in Concept 1 is needed. This arrangement has one fewer impact body than Concept 1. A drawback is that a coefficient of restitution according to Eq. (3.1) between tool and base cannot be computed, since the base in this concept is the pressure fluid and its "velocity" is hard to define. However, dissipated energy can be used as a comparison metric alongside penetration depth - specifically the ratio to the initial kinetic energy $\frac{E_{\mathrm{diss}}}{0{,}5 \cdot m_{\mathrm{fp}} \cdot \left(v_{\mathrm{fp}}(t_0)\right)^2}$. Concept 2 requires a custom-built cylinder that allows low-friction movement of the piston in the vertical direction and has a DSH-plus mount at the top. Cylindrical grinding can be used to produce a precisely fitting gap seal that is both low-friction and low-leakage. This eliminates the need for a friction-prone and flexible elastomer seal. The tool can be supported radially at the top and bottom to absorb radial forces transmitted by the rotary hammer.

Concept 2 is selected because of the advantage that the energy of the chisel is directly transferred to the hydraulic system, and a defined part of this energy is reflected back to the chisel. There is no additional contact partner. Due to the larger number of bodies between the flying piston and the hydraulics in Concept 1, more reflections of the incoming stress wave occur before they reach the hydraulics. With Concept 2, the impact characteristics can be influenced more directly by varying hydraulic parameters.

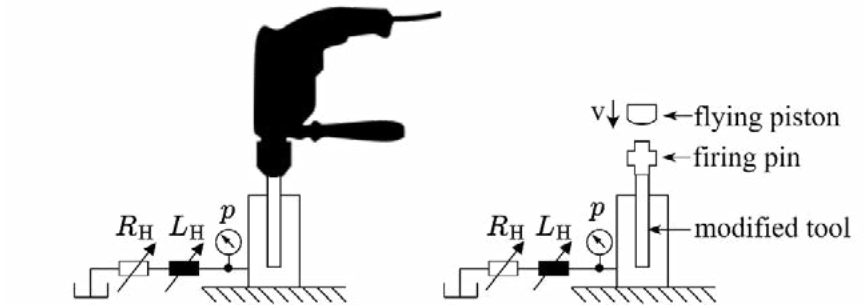

Figure 4: Arrangement concept 2: (left) The rotary hammer tool also functions as a cylinder piston; (right) Schematic representation of the relevant impact bodies of the rotary hammer.

4. HYDRAULIC SUBSTITUTE BASE

4.1. *Components of a Hydraulic Substitute Base*

A hydraulic substitute base for demolition hammers reproduces the mechanical interaction between tool and mineral material via a hydraulic system. The goal is to replicate the forces, displacements, and energy flows occurring during the impact process in an equivalently effective manner. The hydraulic substitute base can be described as a combination of hydraulic capacitance, hydraulic resistance, and hydraulic inductance. These elements determine the system's stiffness, damping, and inertia characteristics. [6] Their interplay allows the complex behavior of mineral materials to be replicated in an equivalently effective way; by varying these parameters, both stiffness and dissipated energy can be precisely adjusted. A hydraulic substitute base thus provides an adjustable, reproducible, and low-wear foundation for studying and developing percussive tools.

4.1.1. Hydraulic Capacitance

The hydraulic capacitance with elastically expanding vessel walls C'_{H} measures the compliance of a pressure chamber considering both fluid compressibility and wall elasticity: $C'_{\mathrm{H}} = -\frac{\mathrm{d}V}{\mathrm{d}p}$ [9]. Where $\mathrm{d}V$ is the volume change resulting from a pressure change $\mathrm{d}p$. It holds that $C'_{\mathrm{H}} = \frac{V}{K'}$ [9]. Where V is the chamber volume and K' the effective bulk modulus including both fluid compressibility K and wall elasticity [9]. Because the impact acts on a fluid in a hydraulic substitute base, at least one hydraulic capacitance is present. Low hydraulic capacitance leads to high stiffness and thus small tool displacements at high impact forces - behavior typical of hard rock. Larger capacitance produces a softer characteristic with greater penetration and lower peak pressures.

Figure 5 shows the penetration characteristic of a flat chisel clamped in a rotary hammer impacting concrete. The median penetration is 0.4 mm, with the maximum depth reached after 0.17 ms. Scatter during the intrusion phase is low. Using the co-simulation described in [6], a required hydraulic capacitance of $C'_{\mathrm{H}} = 4.4 \cdot 10^{-16}\ \frac{\mathrm{m^4 \cdot s^2}}{\mathrm{kg}}$ was determined to

achieve the same penetration depth without damping. In the simulation, the elasticity of the walls and possible gas components in the liquid were neglected: $K' = K$.

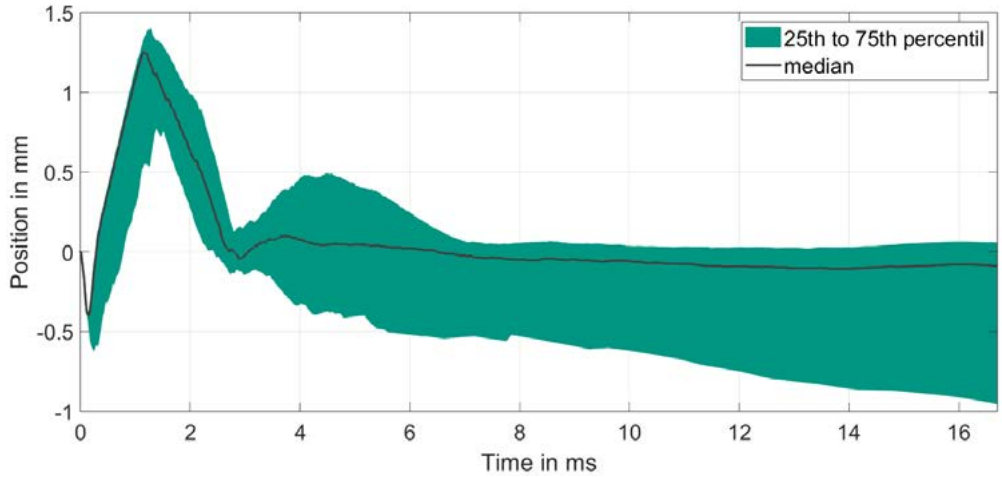

Figure 5: Displacement profile of 172 impacts of a rotary hammer with 4.2 J impact energy (Bosch GBH 4-32) on concrete C50/60 with 150 N feed force, recorded with a vibrometer.

The hydraulic capacitance can be practically varied via the adjustable oil volume to emulate different material stiffnesses. For mineral oils ($K \approx 1.6$ GPa), the volume required to achieve the penetration depth obtained in Figure 5 without damping is 0.7 ml. Softer materials require a larger volume. Harder materials require a smaller volume, which can be challenging to realize from a design standpoint.

If such small volumes are not feasible, a pressure fluid with a higher bulk modulus can be used to achieve the same capacitance at a larger fluid volume. Table 1 lists alternatives to mineral oil with significantly higher bulk modulus and thus higher system stiffness. At the same time, viscosity must be considered due to the precharge system and flow resistances. Very stiff media such as glycerol are highly viscous at room temperature, but blending with water allows adjustment to mineral-oil-like viscosity levels [15]. Replacing mineral oil with an ester fluid (HEES/HFDU, $K \approx 1.9$ GPa), allows the fluid volume to be increased by $\sim 20\%$ for the same capacitance without changing viscosity grade. For maximum stiffness, glycerol–water mixtures are an option. With about 10 wt% water, viscosity can be reduced to mineral-oil-like values ($\nu_{40°C} = 49\,{}^{\mathrm{mm}^2}/_{\mathrm{s}}$), while largely retaining the high bulk modulus ($K_{40°C} = \rho_{40°C} \cdot \left(u_{\mathrm{sound},40°C}\right)^2 = 1{,}222.1\,{}^{\mathrm{kg}}/_{\mathrm{m}^3} \cdot (1{,}862.9\,{}^{\mathrm{m}}/_{\mathrm{s}})^2 = 4.24$ GPa) [15], [16]. Ionic liquids offer high stiffness and good tribological properties at viscosities similar to mineral oil and are suitable as hydraulic fluids [10]. The bulk moduli in Table 1 refer to the properties of pure liquid. If the liquid contains free or dissolved air, the compression module of the fluid decreases and the hydraulic capacity increases. Figure 6 shows the influence of air on the compression modulus of a mineral oil. At low pressures, the influence of air is greater than at higher pressures. To avoid free air, the system must be

carefully vented. It is important to ensure during the design phase that no air pockets can form.

Table 1: Alternatives to mineral oil with higher stiffness

Fluid family	**Bulk modulus**	**Viscosity**
Mineral oil (HLP 46)	$K_{0\text{bar}} = 1.64$ GPa [10] $K_{200\text{bar}} = 1.86$ GPa [10]	$\nu_{40°\text{C}} = 47.07\ {}^{\text{mm}^2}/_{\text{s}}$ [10] $\nu_{100°\text{C}} = 7.36\ {}^{\text{mm}^2}/_{\text{s}}$ [10]
HEES (BIO-FR 46, ester fluid)	$K_{210\text{bar}} = 1.87$ GPa [11]	$\nu_{40°\text{C}} = 49.7\ {}^{\text{mm}^2}/_{\text{s}}$ [11] $\nu_{100°\text{C}} = 9.7\ {}^{\text{mm}^2}/_{\text{s}}$ [11]
HFDU (between VG 46 and VG 68)	$K_{210\text{bar}} = 1.87$ GPa [12]	$\nu_{40°\text{C}} = 55\ {}^{\text{mm}^2}/_{\text{s}}$ [12] $\nu_{100°\text{C}} = 12\ {}^{\text{mm}^2}/_{\text{s}}$ [12]
HFC (VG 46)	$K_{140\text{bar}} = 1.55$ GPa [13] $K_{200\text{bar}} = 1.9$ GPa [13]	$\nu_{40°\text{C}} = 46\ {}^{\text{mm}^2}/_{\text{s}}$ [14]
Glycerin (≥ 99 %)	$K_{20°\text{C}} = \rho_{20°\text{C}} \cdot \left(u_{\text{sound},20°\text{C}}\right)^2 =$ $1{,}261.3\ {}^{\text{kg}}/_{\text{m}^3} \cdot$ $(1{,}923\ {}^{\text{m}}/_{\text{s}})^2 = 4.66$ GPa [15]	$\nu_{40°\text{C}} = 227.39\ {}^{\text{mm}^2}/_{\text{s}}$ [15] $\nu_{100°\text{C}} = 12.07\ {}^{\text{mm}^2}/_{\text{s}}$ [15]
Ionic liquids (EMIM-EtSO4)	$K_{0\text{bar}} = 3.1$ GPa [10] $K_{200\text{bar}} = 3.32$ GPa [10]	$\nu_{40°\text{C}} = 39.44\ {}^{\text{mm}^2}/_{\text{s}}$ [10] $\nu_{100°\text{C}} = 7.66\ {}^{\text{mm}^2}/_{\text{s}}$ [10]

Another way to reduce penetration depth is to increase the precharge pressure. Simulations have shown that with a precharge of 350 bar, a penetration depth of 0.4 mm can be realized with a volume of 1.5 ml. A positive side effect of increasing the preload pressure is the reduced effect of dissolved air, as shown in Figure 6.

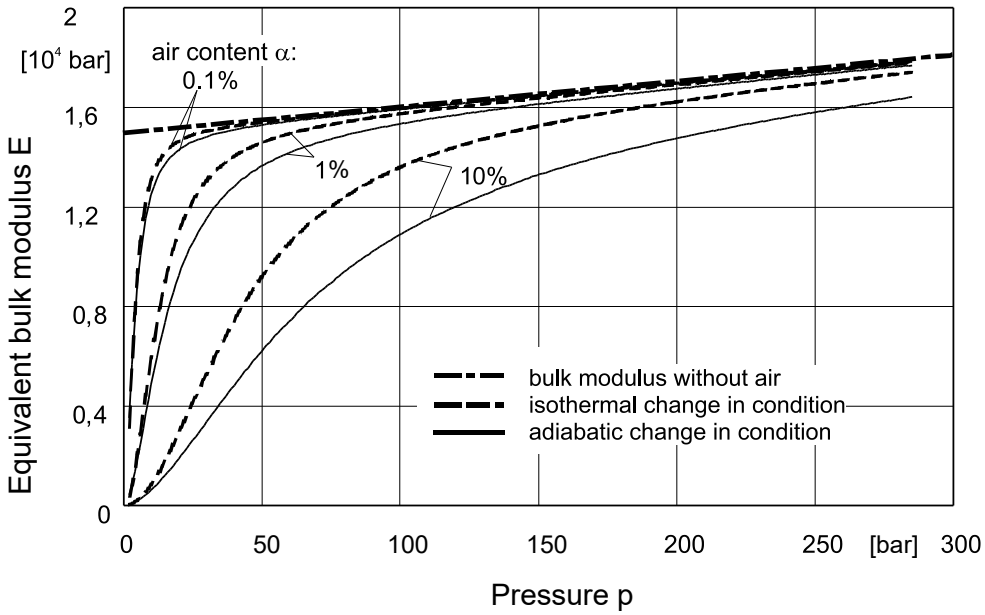

Figure 6: Equivalent bulk modulus of mineral oil-air mixture [17]

Figure 7 shows the measured penetration characteristic in concrete and the simulated penetration characteristic in the hydraulic substitute base for different parameter combinations. In the simulation, the elasticity of the walls and possible gas components in the liquid were neglected: $K' = K$.

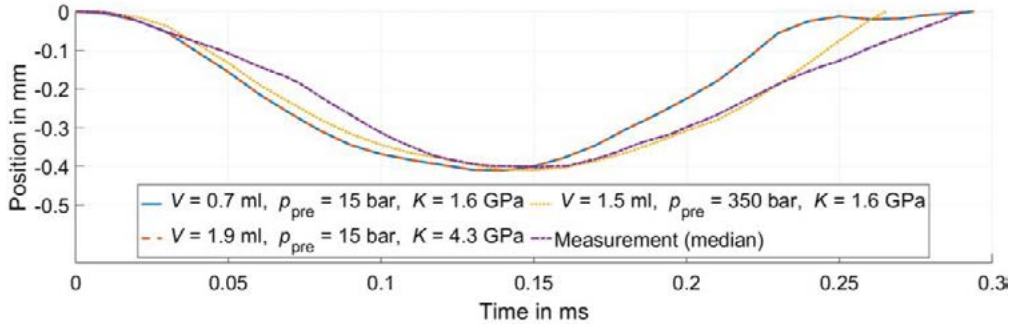

Figure 7: Measured and simulated profiles with identical penetration depth into the base. The cross-section of the orifice in the simulation is set to zero. The hydraulic resistance is therefore infinite. There is also no hydraulic inductance.

4.1.2. Hydraulic Resistance

Hydraulic resistance represents dissipative losses in the system and determines damping of the pressure history. It can be realized via orifices or throttles whose cross-section influences the outflow and thus pressure history. Compared with throttles, orifices show viscosity-

/temperature-independent flow behavior assumed turbulent flow occurs. As the orifice cross-section increases, energy absorption increases. Targeted adjustment of hydraulic resistance therefore allows tuning of the damping characteristic to different rock types. According to the guideline on the Dynaload steel ball energy absorber cited in DIN EN ISO 28927-10, about 15%– 20% of the impact energy in real materials is reflected back to the tool (rotary hammer) [3]; the remainder is dissipated in the base. Simulations have shown that, for 17% of the impact energy to be reflected back to the tool at a penetration depth of 0.4 mm, an orifice cross-section of 1.1 mm^2 and an oil volume of 0.3 ml are required.

4.1.3. Hydraulic Inductance

Hydraulic inductance describes the inertia of the fluid flow and is directly related to the moving fluid mass. It is determined by the geometry and length of the line as well as the fluid density. High hydraulic inductance affects pressure build-up in the system and causes a phase shift between force and displacement. This allows influencing the impact dynamics, particularly the temporal evolution of energy transfer between tool and substitute base. Due to the required low hydraulic capacitance, it is possible only to a limited extent to integrate inductances intentionally between capacitance and resistance. The additional line volume would simultaneously increase capacitance. A long pipeline with a small cross-section would also exhibit significant temperature dependence due to viscosity.

5. SUMMARY, DISCUSSION AND OUTLOOK

The paper demonstrates the advantages of a hydraulic substitute base for demolition hammers as an adjustable, low-wear, and highly reproducible alternative to conventional mechanical test bases. A coupled FEM–hydraulic co-simulation is used to identify the hydraulic capacitance and resistance required to replicate the penetration depth and energy absorption of concrete C50/60. This approach enables a material-realistic and transferable testing methodology for the development and assessment of demolition hammers.

Based on the requirements and mechanisms derived in this work, a prototype hydraulic substitute base will be designed, built, and instrumented. The challenge here is to achieve high stiffness. When using conventional pressure fluids in the design, the oil volume must be limited to 1.5 ml. If this is not possible for design reasons, a combination of alternative pressure fluids and a pressure preload can be used to increase the permissible volume. At the same time, care must be taken to ensure that the wall elements are constructed stiffly. One way to ensure high stiffness would be to manufacture the cylinder bore, as well as the bores for the pressure sensor and aperture, from a solid steel block. This eliminates the need for voluminous and elastic pipes or hoses. Consequently, the volume can be kept to a minimum. Keeping the pressure fluid chamber free of air is also challenging. The goal is to experimentally confirm the displacement and energy curves determined in co-simulation and to verify the identified adjustment ranges. If validation succeeds, the setup can serve as an adjustable, repeatable, and low-wear alternative to the Dynaload steel ball energy absorber and extend its scope of use, especially for material-specific studies. In addition, development of a larger hydraulic test rig is planned to enable testing of hydraulic breakers.

He started his industrial career in 1995 in the field of construction at the company Krupp Berco Bautechnik GmbH, Germany, where he was the Leader of the research group for hydraulic breakers. In 2000, he was with Bucher Hydraulics GmbH, Germany, where he led the construction and customer development for mobile hydraulics. Since 2005, he has been a Full Professor and the Director of the Institute of Mobile Machines (Mobima), Karlsruhe Institute of Technology (KIT), Germany. His research and teaching focuses on automation systems, drive concepts, hydraulics and simulation. In addition, he is Faculty Director of Mechatronics.

Hydraulic Artificial Muscles for Exoskeleton Actuation Solutions

Mathias Niebergall, Jonas Pfister, Roman Strobel, Jonathan Scheible

Mathias.Niebergall@thu.de, *Jonas.Pfister@thu.de* , *Roman.Strobel@thu.de* , *Jonathan.Scheible@thu.de*

Abstract

Exoskeletons are designed to enhance the human physical capabilities and to reduce physical strain for various applications in terms of e. g. medical rehabilitation, every day assistance or physical working performance. The actuation of active exoskeletons by means of hydraulic artificial muscles (McKibben principle) are convincing solutions due to their light weight, compactness, exceptional power capacity, remarkable resiliency, and low investment costs. [1] The artificial muscle presented comprises an inner elastomeric hose surrounded by a textile, braided and reinforced by aramid fibers. The muscle is activated by hydraulic fluid supply that cause a radial expansion of the inner pressurized hose and a corresponding axial contraction of the muscle as actuation effect [2], [3], [4], [5], [6], [7], [8]. This paper presents a mathematical-physical model of the hydraulic artificial muscle based on conservation of mass and conservation of energy. Prototypes of hydraulic artificial muscles have been developed for selected drive functions and experimentally tested.
Based on [9] a hydraulic muscle with a length (without fittings) of 200 mm and with an inner diameter (elastomer tube) of 6 mm and an outer diameter of ca. 10 mm (elastomer tube + fiber fabric) has been experimentally evaluated. Relating to the initial length of the hydraulic muscle a contraction of up to 32 % is reachable. With a pressure level of 10 MPa an advanced force density per mass of 110 kN/kg of the muscle is now accessible.
Due to its flexible structure, a hydraulic muscle is much more compliant and adaptable than a rigid hydraulic cylinder. This makes the muscle design ideal for wearable actuation systems. Additionally, the muscle is hermetically sealed, due to its closed design.
An exoskeleton test setup has been developed for experimental investigations. The paper finally discus hydraulic muscles for exoskeleton drive functions.

1. INTRODUCTION

New innovative actuator systems for exoskeletons with hydraulic artificial muscles are very attractive solutions due to their remarkable compactness, lightweight, robustness, and low investment costs. Various prototypes of hydraulic artificial muscles have been developed and built. A sectional view of a typical prototype is shown in Figure 1.1. The muscle has an inner elastomeric hose, surrounded by an aramid fiber textile sleeve, at both ends equipped with a typical hydraulic hose fitting. The fitting composed of a swage nipple and a swage ferrule, as well as a screw coupling with an O-ring sealing element.

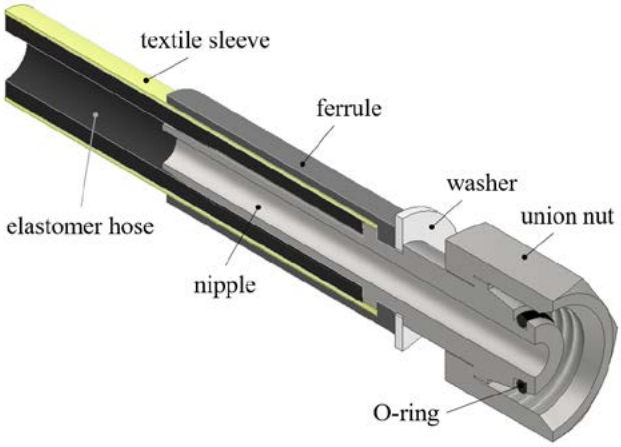

Figure 1.1 Sectional view of the hydraulic artificial muscle [9]

This publication focuses on the following topics:

- introduction of a quasi-static theoretical model of the hydraulic muscle (chapter 2)
- description of the experimental test set up (section 3.1)
- experimental investigations on hydraulic artificial muscles with three muscle length and two muscle diameters for the verification of the model equations (section 3.2)
- experimental high-pressure test (10 MPa) to determine the high force density of a hydraulic artificial muscle (chapter 4)
- an exoskeleton application solution for hydraulic artificial muscles (chapter 5)

The contraction of the hydraulic artificial muscle is illustrated schematically in Figure 1.2. Fluid supply activates the initially non-pressurized muscle with the radius R_0, the initial length L_0 and the fiber angle α_0 (compare Figure 1.3). The pressurized hose surface leads to radial hydraulic forces with increasing circumferential stress in the surrounding textile reinforcement sleeve. With radial displacement of the inner pressurized bladder over the

whole length of the muscle, the fiber angle and the radius increases up to α_1 and R_1 respectively. The corresponding axial contraction of the hydraulic artificial muscle to the length L_1 is the actuation effect.

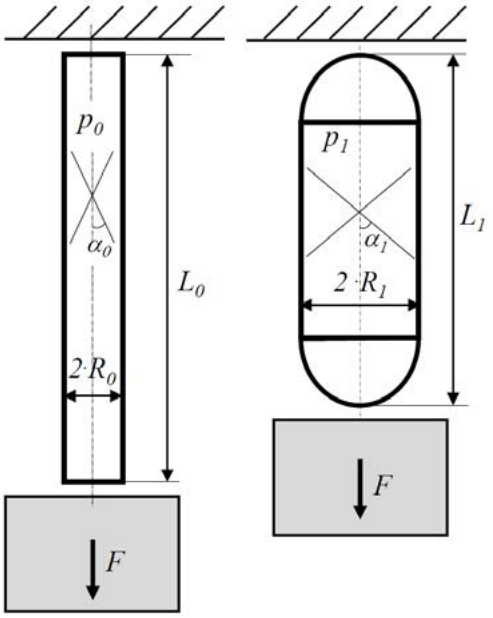

Figure 1.2 Sketch of the simplified non-pressurized muscle (left) and the pressurized activated muscle (right)

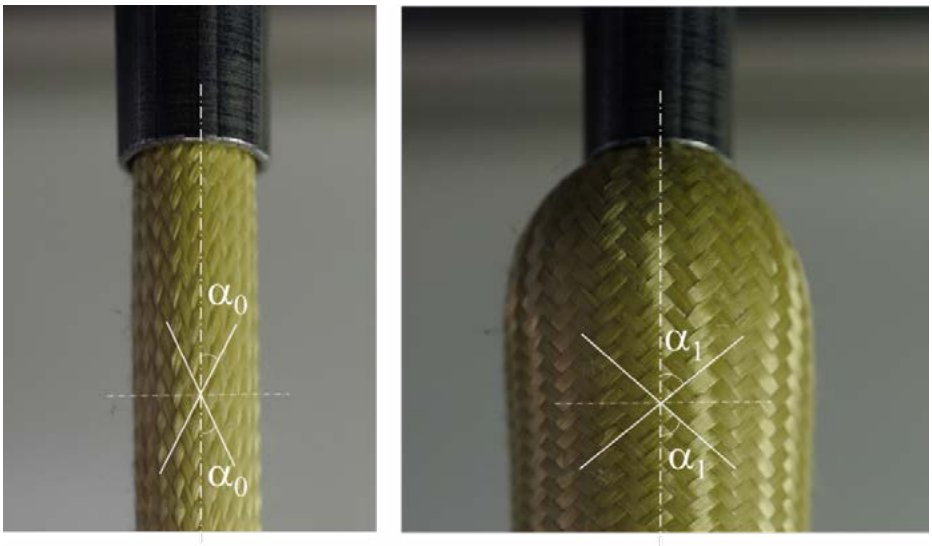

Figure 1.3 Fiber angle of a non-pressurized muscle α_0 and of a pressurized muscle α_1 [9]

2. STATIC MODEL OF HYDRAULIC ARTIFICIAL MUSCLES

In the last decades fluidic (pneumatic or hydraulic) artificial muscles have been investigated and discussed in several studies (e. g. Schulte (1961) [2], Chou, Hannaford (1996) [3], Tondu and Lopez (2000) [4], Tiwari, Meller et al. (2012) [5], Pan et al. (2020) [6], Mori, Suzumori (2009) [7], Zhang et al. (2022) [8]).

The physical approaches for fluidic artificial muscles are typically based on energy conservation, virtual work principles, and on a simplified cylindrical geometry. In general, the fluidic work is done by increasing the volume of the muscle, and leads finally to the mechanical work, done by the muscle as it contracts and changes length. [5]

For the below-described mathematical-physical modeling of the hydraulic artificial muscle, following assumptions are taken into account:

- quasi-static consideration of the actuation process
- compressible muscle including elastomer hose, textile sleeve and fluid
- homogeneously distributed volume flow q
- constant change in constant homogeneously distributed density of the fluid ρ
- cylindrical tube shape (the volume around the end cap sphere (compare Figures 1.2 and 1.3) will be later subtracted)

Initially an artificial muscle approach to mass conservation has been derived and subsequently the relationship to energy conservation is discussed.

Conservation of mass.

The continuity equation (2.1) has here the following components:

- the mass flow supplied to the hydraulic muscle (inflow),
- the mass flow of displacement of the muscle (deformation), and
- the mass flow of elasticity behaviour of the muscle (compression),

$$\underbrace{\rho \cdot q}_{inflow} + \underbrace{\rho \cdot \frac{d}{dt} \cdot \int_V dV}_{deformation} + \underbrace{\rho \cdot \frac{1}{\kappa} \cdot \dot{p} \cdot \int_V dV}_{compression} = 0 \tag{2.1}$$

with the mass density of the fluid ρ, the flow rate into the muscle q, the change of the muscle volume dV, the compression number of the muscle κ, and the change of pressure dp/dt. The compression number κ indicates the pressure required for the elastic muscle deformation.

The balance of volume flow, in case of equal density of the fluid, is shown in equation (2.2), which takes into account the inflow rates (+) and outflow rates (-) via the signs.

$$q - \frac{d}{dt} \cdot \int_V dV - \frac{1}{\kappa} \cdot \dot{p} \cdot \int_V dV = 0 \tag{2.2}$$

Integration over time from the initial state at t_0 to the final contraction state at t_1 yield to the equation of the volumes (2.3).

$$\int_{t_0}^{t_1} q\ dt - \int_V dV - \frac{p}{\kappa} \cdot \int_V dV = 0 \tag{2.3}$$

The change of the muscle volume dV can be described by infinitesimal steps of the two main influencing variables: the radius of the muscle R and the length of the muscle L (compare Figure 1.2 and equation (2.4)).

$$dV = \left(\frac{\partial V}{\partial R}\right)_{L_0} \cdot dR + \left(\frac{\partial V}{\partial L}\right)_{R_1} \cdot dL \tag{2.4}$$

The partial derivatives of (2.5a) are (2.5b) and (2.5c).

$$V = R^2 \cdot \pi \cdot L \tag{2.5a}$$

$$\left(\frac{\partial V}{\partial R}\right) = 2 \cdot R \cdot \pi \cdot L \quad \text{(2.5b)}, \qquad \left(\frac{\partial V}{\partial L}\right) = R^2 \cdot \pi \tag{2.5c}$$

Integration of (2.4) leads to the deformation relationship (2.6) with respect to the state limits (R_1, L_1) of the actuated muscle (compare Figure 1.2).

$$V = \int dV = \int_{R_0}^{R_1} \left(\frac{\partial V}{\partial R}\right)_{L_0} \cdot dR + \int_{L_0}^{L_1} \left(\frac{\partial V}{\partial L}\right)_{R_1} \cdot dL \tag{2.6}$$

The solution is the volume of muscle deformation (2.7). Here the term V_1 represents the radial expanded and contracted volume, and the term V_0 the initial volume of the muscle.

$$V = \underbrace{R_1^2 \cdot \pi \cdot L_1}_{V_1} - \underbrace{R_0^2 \cdot \pi \cdot L_0}_{V_0} \tag{2.7}$$

Based on (2.3) and (2.7) equation (2.8) describes the proportions of the change in volume of the artificial muscle.

$$\int_{t_0}^{t_1} q\ dt - \left(R_1^2 \cdot \pi \cdot L_1 - R_0^2 \cdot \pi \cdot L_0\right) - \chi \cdot \left(R_1^2 \cdot \pi \cdot L_1 - R_0^2 \cdot \pi \cdot L_0\right) = 0 \tag{2.8}$$

with the compression factor $\chi = p / \kappa$ as dimensionless parameter that describes the average compliance during the muscle actuation.

Conservation of energy.

The energy conservation of hydraulic artificial muscles (2.9) follows from the inclusion of pressure in equation (2.8).

$$\underbrace{\int_{t_0}^{t_1} q \cdot p \, dt}_{supply} - \underbrace{\left(R_1^2 \cdot \pi \cdot L_1 - R_0^2 \cdot \pi \cdot L_0\right) \cdot p}_{deformation\,/\,actuation} - \underbrace{\chi \cdot \left(R_1^2 \cdot \pi \cdot L_1 - R_0^2 \cdot \pi \cdot L_0\right) \cdot p}_{elastic\ deformation} = 0 \quad (2.9)$$

In the literature (e. g. [2], [3], [4], [5], [6], [7], [8]), deformation energy is equated with the mechanical work of displacement in the form (2.10a), that lead here to equation (2.10b).

$$-\int_{L_0}^{L_1} F \, dL = \int_{V_0}^{V_1} p \, dV \quad (2.10a), \qquad -\int_{L_0}^{L_1} F \, dL = p \cdot (R_1^2 \cdot \pi \cdot L_1 - R_0^2 \cdot \pi \cdot L_0) \quad (2.10b)$$

The second term of the displacement work in equation (2.11) replaces the muscle deformation term in (2.9). Thus, the conservation of energy approach has the following form:

$$\int_{t_0}^{t_1} q \cdot p \, dt - \int_{L_1}^{L_0} F \, dL - \chi \cdot \left(R_1^2 \cdot \pi \cdot L_1 - R_0^2 \cdot \pi \cdot L_0\right) \cdot p = 0 \quad (2.11)$$

Due to the rounding of the end caps after the muscle contraction (compare Figure 1.2), equation (2.11) can be corrected by taking the V_R volume (2.12) into account.

$$V_R = \underbrace{R_1^2 \cdot \pi \cdot 2 \cdot R_1}_{cylinder} - \underbrace{\frac{4}{3} \cdot R_1^3 \cdot \pi}_{sphere} \quad (2.12)$$

Then the conservation of energy approach for hydraulic artificial muscles has finally the following form (2.13):

$$\underbrace{\int_{t_0}^{t_1} q \cdot p \, dt}_{supply\,(E_s)} - \underbrace{\int_{L_1}^{L_0} F \, dL}_{actuation\,(W)} - \underbrace{\chi \cdot \left(R_1^2 \cdot \pi \cdot L_1 - V_R - R_0^2 \cdot \pi \cdot L_0\right) \cdot p}_{elastic\ deformation\,(E_e)} = 0 \quad (2.13)$$

The energy conservation approach (2.13) contains the hydraulic energy supply E_s to the muscle, the mechanical work W done and the energy share of the elastic compression / energy storage (and where appropriate energy losses) E_e of the muscle. For the verification of the energy balance (2.13) the mechanical work W, the energy supplied E_s and the Energy of the elastic compression E_e are experimentally determined and presented in the following chapter 3.

The compression factor $\chi = p_m / \kappa$ is a dimensionless parameter that describes the average

compliance during muscle deformation, by means of

- the average measured pressure p_m during the muscle contraction, and
- the compression number κ, that indicates the average pressure required for muscle contraction, dependent on the muscle geometry.

Here the compression factor χ was determined using equation (2.13), rearranged according to the compression factor when all other data were available as measured data (compare section 3.2). Due to the experimental determination of χ, it also includes the energy losses (in case of relevance) during the contraction of the artificial muscle.

3. EXPERIMENTAL ANALYSIS OF HYDRAULIC ARTIFICIAL MUSCLES

The experimental investigations of the artificial muscles and the verification of the model equations (2.13) have been carried out with an appropriate test setup. The experimental equipment is presented in section 3.1 and the test results are discussed in section 3.2.

3.1. Description of the experimental equipment

The test setup for hydraulic artificial muscles is shown schematically in Figure 3.1 and the test chamber of the test setup is shown in Figure 3.2 as photography.
The hydraulic artificial muscle (1) is suspended in the test chamber and loaded with a defined weight (8). The muscle is activated by a volume flow of a pressure fluid (mineral oil) from a hydraulic power unit (2). The muscle contraction is controlled by means of a 4/3-way valve.

The functional tests of the artificial muscle are monitored by measurement technology using the following components:

- pressure sensors (5) for monitoring the pressure load of the muscle,
- flow rate sensor (3) for measuring the volume flow into the muscle,
- force sensor (4) for monitoring the quasi-static load,
- laser distance sensor (7) for detecting the muscle contraction,
- displacement sensors (6) for the measurement of the muscle diameter,
- camera (9) for visual recording the changing fiber angle of the textile shell, and
- amplifier (10) for recording and logging the measurement data.

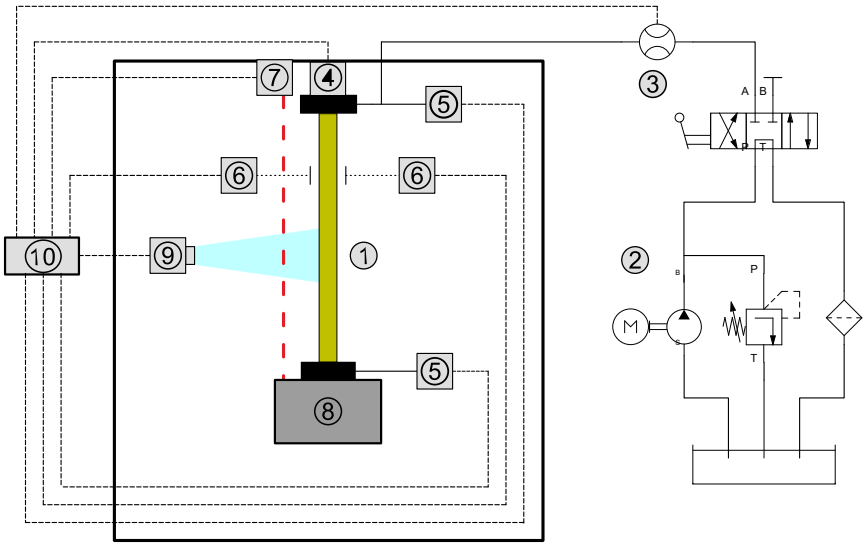

Figure 3.1 Schematic representation of the test setup with hydraulic test environment (dashed lines denote electrical signal lines)

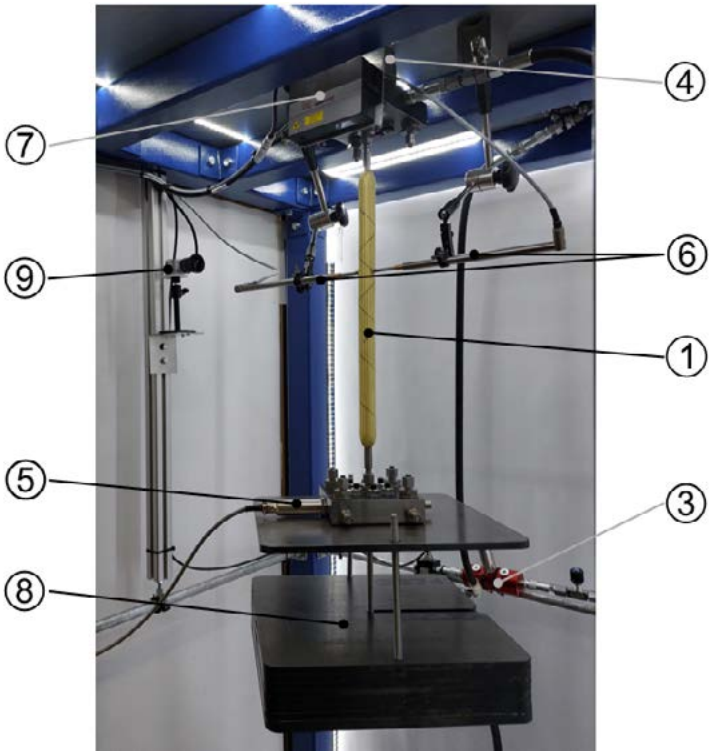

Figure 3.2 Photo of the test setup for experimental investigations of hydraulic artificial muscles (here exemplarily a pressurized muscle (1) with a length of 0.6 m and 100 kg load)

3.2. Experimental investigations of the hydraulic artificial muscle

Non-pressurized hydraulic artificial muscles with three different initial lengths L_0 of 0.3 m, 0.45 m and 0.6 m and with two different initial outer diameters D_0 of 8 mm and 10 mm have been configured for muscle tests. The artificial muscles have been activated by a volume flow q with an increase of the corresponding pressure p up to 5 MPa. The actuation effect is the contraction of the artificial muscles caused by a quasi-static load of 310.8 N for the D08-muscle (D_0 = 8 mm, α_0 = 24°) or 993.6 N for the D10-muscle (D_0 = 10 mm, α_0 = 17°) respectively. The pressurized artificial muscles have an expansion of the outer diameter to D_1 (α_1 = 44° for the D08-muscle, α_1 = 48° for the D10-muscle) and they are shortened to the respective length L_1. Relating to the initial length L_0 of the non-pressurized muscles, and the measured length changes (L_0 - L_1), the contractions ε can be calculated with equation (3.1).

$$\varepsilon = \frac{L_0 - L_1}{L_0} \cdot 100\% \tag{3.1}$$

The experimental initial data (L_0, $D_0 = 2\,R_0$ and F), the measured test results in the contracted state of the muscle (L_1, R_1), and the calculated test results from measured data (ε, κ, χ, E_s, W, E_e) are summarized in Table 3.1. The contraction ε of the artificial muscle show a dependence on the muscle diameter and on the load force. The compression number κ for the contraction of the artificial muscle show a dependence to the muscle length.

The associated measurement results are shown exemplary for the D10-muscles with their three initial lengths (0.3 / 0.45 / 0.6 m) in Figure 3.3. The calculated energy shares, based on equation (2.13), associated to the measurement results, are shown in Figure 3.4. The energy supplied for muscle contraction E_s corresponds to the sum of mechanical work W and elastic energy E_e, due to the compression number κ (or factor χ).

Table 3.1 Measurement data and calculation results of the initial state ($_0$) and the contracted state ($_1$) of the tested hydraulic artificial muscles

	D08 - muscle			D10 - muscle			unit
initial muscle length L_0	0.3	0.45	0.6	0.3	0.45	0.6	m
initial outer diameter D_0	8	8	8	10	10	10	mm
load force F	310.8	310.8	310.8	993.6	993.6	993.6	N
muscle length L_1 (5 MPa)	0.2405	0.3582	0.4804	0.2211	0.3280	0.4443	m
inner radius R_1 (5 MPa)	5.1	5.3	5.2	11.6	11.8	11.6	mm
contraction ε (5 MPa)	20.9	20.9	21.3	27.0	27.6	26.8	%
compression number κ	0.80	1.44	2.09	4.20	4.84	5.30	MPa
compression factor χ	1.56	1.00	0.78	0.342	0.307	0.301	-
supplied energy E_s	53.59	70.33	86.34	121.21	182.52	241.48	J

4. ARTIFICIAL MUSCLES WITH HIGH FORCE DENSITY

For the investigation of the maximum force performance as well as the force density of the artificial muscle a hydraulic test setup has been developed, that is shown in Figure 4.1 with the measuring equipment. Here the muscle has to be clamped within the test setup to prevent its axial contraction during the recording of the blocked force. The muscle has an initial length of L_0 = 200 mm, a diameter D_0 = 10 mm, and a mass including fittings and filled with fluid of m = 0,120 kg. The measured force characteristic curve dependent on pressure of the blocked muscle is shown in Figure 4.2. Because of the clamping the blocked force rises with increasing pressure up to a high pressure of 10 MPa and a force level of F_t = 14200 N. Calculated with (4.1), the force density per mass of the muscle is δ_F = 110 kN/kg.

$$\delta_F = \frac{F_t}{m} \tag{4.1}$$

The improvement in power density is based on a significantly higher pressure level (10 MPa) compared to 5.6 MPa in [9] due to improved form-fit connection between muscle and fitting.

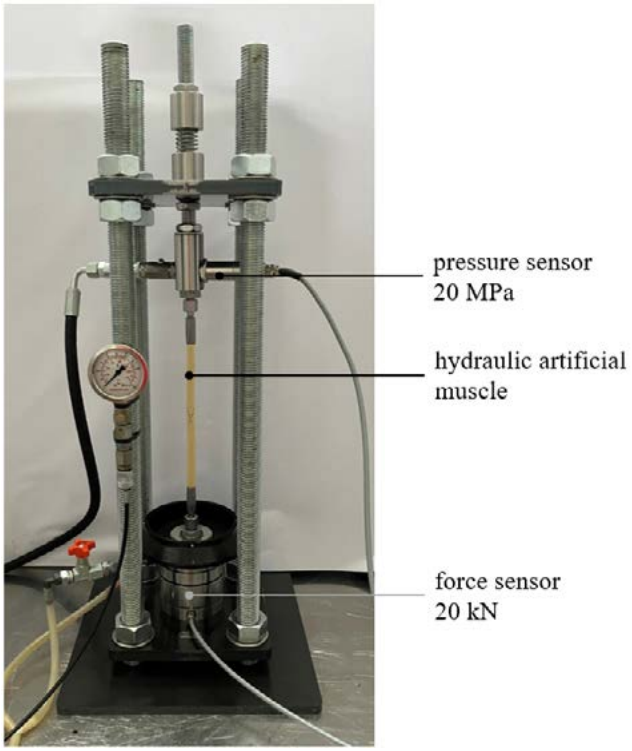

Figure 4.1 Test setup for determining the force density of hydraulic artificial muscles

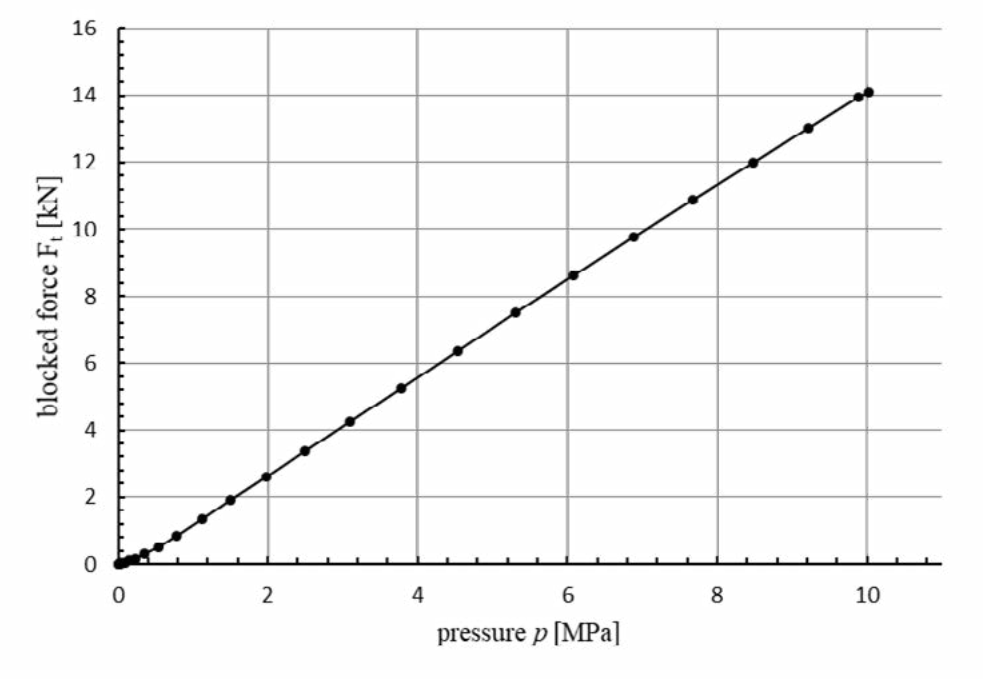

Figure 4.2 Measured blocked force of the clamped muscle in Figure 4.1

5. HYDRAULIC EXOSKELETON APPLICATIONS

Hydraulic artificial muscles are much more compliant and adaptable, due to their high force density advantages as well as because of their flexible textile braided structure compared to rigid electromechanical drives or conventional hydraulic cylinders. The muscles are hermetically sealed, due to the closed design using elastomeric hoses. For these reasons, the hydraulic artificial muscles are ideally suited for wearable actuation systems. For experimental investigations, an exoskeleton test setup has been built that enables the testing of selected exoskeleton drive functions as shown in Figure 5.1.

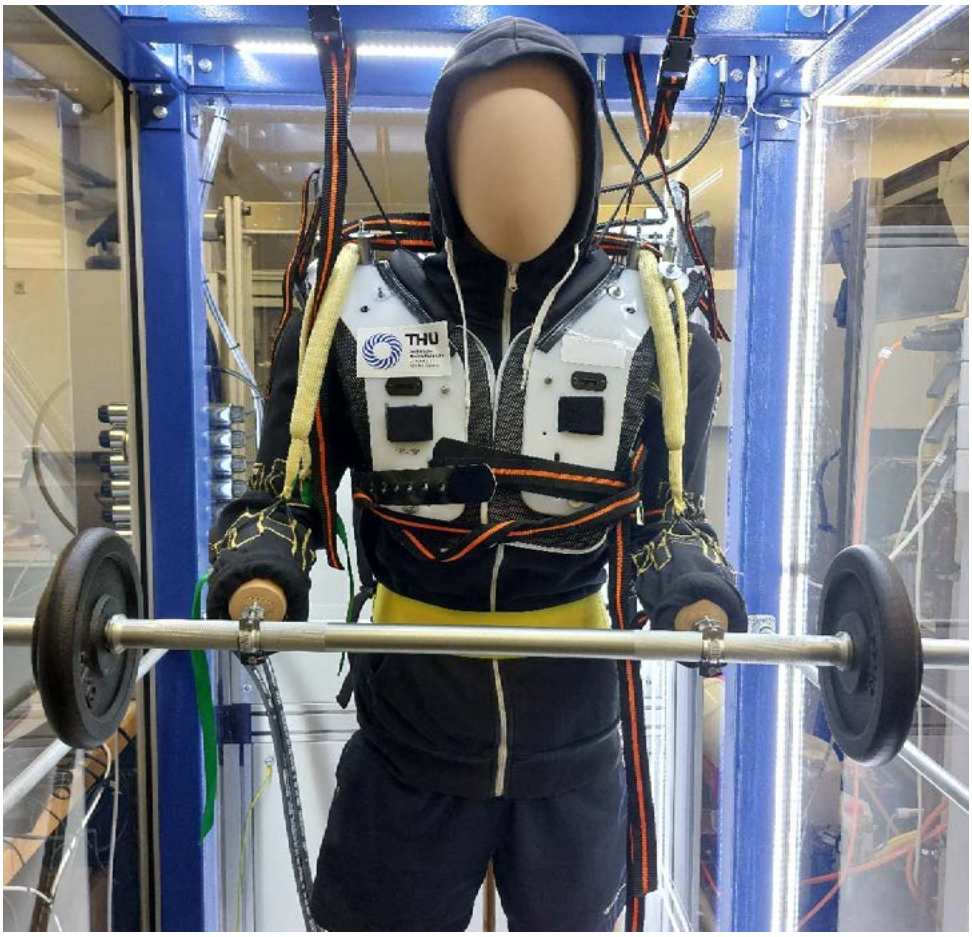

Figure 5.1 Exoskeleton test setup for power support for the upper body (here 20 kg)

6. CONCLUSION

The actuation of active exoskeletons by means of hydraulic artificial muscles are convincing solutions, due to their light weight, compactness, exceptional power capacity, remarkable resiliency, and low investment costs.

A mathematical-physical model of hydraulic artificial muscles is initially presented, based on an approach of conservation of mass and conservation of energy (chapter 2). For the test of the model equations, hydraulic artificial muscles with three different initial length and two initial diameters have been prepared and experimentally investigated. The experimental results confirm the model equations, taking into account adjusted compression factors that describe the elasticity or the energy storage capacity of the muscle (chapter 3).

With a further experiment the maximum blocked force of a hydraulic artificial muscle (length 200 mm, diameter 10 mm) under high pressure requirements of 10 MPa has been determined. It results in a measured blocked force of 14200 N with a very competitive force density per mass of δ_F = 110 kN/kg (muscle mass m = 0,120 kg) (chapter 4).

An exoskeleton test setup has been built for experimental investigations that enables the testing for selected exoskeleton drive functions. These investigations demonstrate that hydraulic artificial muscles are much more compliant and adaptable, due to their high force density advantages as well as due to their flexible textile braided structure compared to rigid electromechanical solutions or conventional hydraulic cylinders. The closed muscle design using elastomeric hoses enables a hermetically sealing.

In summary, the hydraulic artificial muscles are ideally suited for wearable exoskeleton actuation systems (chapter 5).

New hydrogen fuel lines from carbon steel tubes and their qualification for high-pressure hydrogen applications

Christian Lessmeier, Christian Möller, Lars Danhäuser, Helwig Brabander

BENTELER Steel/Tube GmbH & Co. KG, Paderborn

christian.lessmeier@benteler.com

Abstract

Recent advancements in steel tube technology have led to the development of carbon steel tubes specifically designed for hydrogen fuel lines in mobile machinery or in automotive applications. These developments address the material and safety challenges associated with hydrogen as an energy carrier on the pathway to climate neutrality. Especially the development and proof of operational safety for carbon steel tubes made from new materials for high-pressure hydrogen is challenging.

This paper provides insights into qualification process of the BENTELER HYRESIST® Mobility tubes for high pressure hydrogen applications. These fluid line tubes developed by BENTELER Steel/Tube from a ferritic-pearlitic carbon steel are an economic alternative to austenitic stainless-steel tubes, which are the current state of the art for hydrogen fluid lines. The main content of this paper will be the properties of the new steel grade, the hydrogen testing and its results under high-pressure hydrogen conditions of this steel in general and as a hydrogen fluid line, as well in the context of the current hydrogen fluid lines regulations.

The general hydrogen compatibility of the new steel material was proven by a burst disk test with pressurized hydrogen. Additionally, tubes made from this steel underwent a testing procedure where the tube is subjected to a cyclic loading under high-pressure hydrogen at different temperatures, followed by a hydraulic burst test to proof lifetime safety. These dynamic investigations were carried out using processed tubes in combination with fittings as a prototype hydrogen fluid line. The methodology successfully demonstrated the general hydrogen compatibility of the BENTELER HYRESIST® Mobility tubes. Finally, the paper will conclude with an evaluation of this innovative solution for high pressure hydrogen lines in relation to the current state of the art.

1. INTRODUCTION

The practical evaluation and the prediction of hydrogen embrittlement in steels are despite numerous scientific studies a persistent problem. There is no generally accepted load-independent material criterion for the hydrogen sensitivity of steels under pressurised hydrogen. The reduction of area or elongation at fracture in the quasi-static tensile test is often used as a technological comparison value. It is often neglected that actual loads of real components under hydrogen typically occur by multiaxial loading and under dynamical load conditions. Occasionally, notched specimens are used, although the test result is critically dependent on the notch sharpness.

Fracture mechanics tests, such as determining the crack propagation rate as a function of the stress intensity factor, are effective methods for the investigation of hydrogen embrittlement resistance. However, these tests are not suitable for small and thin-walled tubes because the extraction of standard CT-samples is not possible because of the specimen size.

For the newly developed high-pressure tubes BENTELER HYRESIST® Mobility by BENTELER Steel/Tube a different testing approach was chosen. The tubes for hydrogen application made from a specially developed ferritic-pearlitic carbon steel are tested by an approach that is presented below. This approach is focusing at 70 MPa (700 bar), which is a pressure stage that is especially needed for automotive or other mobile machinery applications. It uses the burst disk test according to DIN EN ISO 11114-4 and a dynamical cycling internal pressure test, which is linked to a subsequent hydraulic burst-test. Moreover, the experimental method and its results are compared to the current automotive standards.

2. HYDROGEN COMPATIBILITY TESTS USING THE BURST DISC TEST

The evaluation of the hydrogen embrittlement resistance of steels can be carried out using the burst disc pressure test developed by Fidelle et al. [1-5], in accordance with DIN EN ISO 11114-4 [7]. In this test, a disc-shaped specimen is clamped and subjected to continuously increasing gas pressure until bursting or crack initiation occurs (Fig. 2.1). The embrittlement effect of hydrogen (H_2) is quantified by comparing the burst pressures under hydrogen (P_{H2}) and helium (P_{HE}), with helium serving as an inert reference gas. The ratio P_{HE}/P_{H2} is used as a measure of the material's susceptibility to embrittlement. It should be noted that this ratio depends on the pressure increase rate, which must be kept constant during each test.

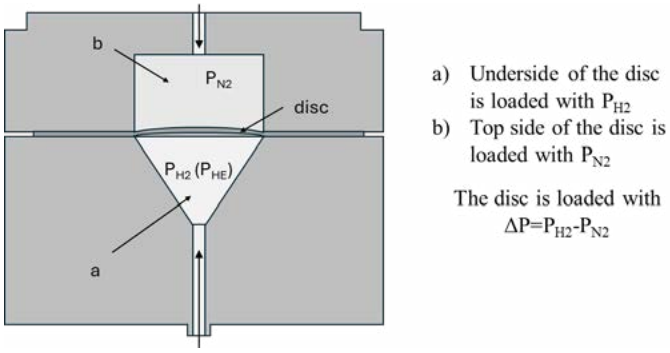

Figure 2.1. Principle of the burst disk testing according to DIN EN ISO 11114-4 [7]

restricted

Based on extensive measurements on steels that have proven successful in practice or have failed under hydrogen exposure, Fidelle identified a burst pressure ratio of $P_{HE}/P_{H2} = 2$ as a critical value, which was adopted by DIN EN ISO 11114-4. The ratio of P_{HE}/P_{H2} is also known as hydrogen embrittlement index (HEI). For materials with values of the HEI < 2, no component failure due to hydrogen embrittlement is expected.

A key advantage of this approach is that the strength and the ductility of the material are reflected in the test result. The loading conditions are particularly favourable for the effect of pressurized hydrogen and resemble those in pressure vessels or hydrogen-carrying fuel lines.

2.1. Experimental boundary conditions

According to DIN EN ISO 11114-4 (method A), the test disc must meet specific properties and dimensions. It must be flat and the surface is produced either by grinding or machining to ensure an appropriate surface finish. The dimensions are as follows: The diameter measures 58 mm, the thickness 0,75 mm and the flatness deviations is less than 1/10 mm with a surface roughness Ra < 1 µm.

If an evaluation of the steel at an operating pressure exceeding 30 MPa is required, a disc thickness greater than 0,75 mm shall be used. Due to the hydrogen pressure of 70 MPa in automotive fuel lines, the test discs had thicknesses ranging from 1,49 to 1,52 mm. Tests were conducted using hydrogen (purity > 99.9995 mol-%) and helium (both gases with H_2O < 3 µl/l), with pressure increase rates evenly distributed between 0,3 and 40 MPa/min. For complete material evaluation, 15 tests (six with helium and nine with hydrogen) as specified in DIN EN ISO 11114-4, method A, are considered sufficient. For disc thicknesses above 0,75 mm, the burst pressure Pr´ must be systematically corrected to account for deviations from the test of a disc with standard wall thickness. The corrected burst pressure Pr´ is determined by the following equation (2.1):

$$Pr' = \frac{Pr \cdot 0{,}75}{e_m}, \text{where } e_m \text{ is the mean disc thickness} \qquad (2.1)$$

Corrected burst pressures are shown as a function of the pressure ramp rate. The pressure ramp rate is calculated by dividing the actual burst pressure by the test time and is expressed in MPa/min. For each hydrogen test, the ratio Pr'_{He}/ Pr'_{H2} is determined, where Pr'_{He} is the theoretical helium burst pressure associated with the same pressure increase rate as the hydrogen test (obtained by regression from the corrected helium burst pressure), and Pr'_{H2} is the corrected hydrogen burst pressure. The ratios Pr'_{He}/ Pr'_{H2} shall be represented in relation to the pressure increase rate. The hydrogen embrittlement index (HEI) of a material is the maximum of these ratios. A material with an index not exceeding 2,0 is considered hydrogen compatible.

2.2. Specimen preparation

Since it is not possible to extract a disc with a diameter of 58 mm directly from a small thin-walled tube, a forged specimen of the same material was first cut out from a continuously cast billet. To eliminate the dendritic cast structure, the material was forged at about 1100 °C into a round bar of 58 mm diameter. Following the cutting of 2 mm thick discs from the round bar, both sides were grinded to achieve thicknesses of 1,49-1,52 mm and fulfill the surface roughness requirements according to DIN EN ISO 11114-4. Through a subsequent

restricted

heat treatment, a ferritic–pearlitic structure was established, comparable to the microstructure of a cold-drawn tube with a small wall (fig. 2.2). For both microstructural conditions, a grain size class of 10 was identified, together with comparable hardness values of approximately 125 HV1, which correspond to an estimated tensile strength of about 400 MPa. Consequently, the burst disc specimens exhibit microstructural characteristics and mechanical properties analogous to those of hydrogen fuel lines manufactured from the same material.

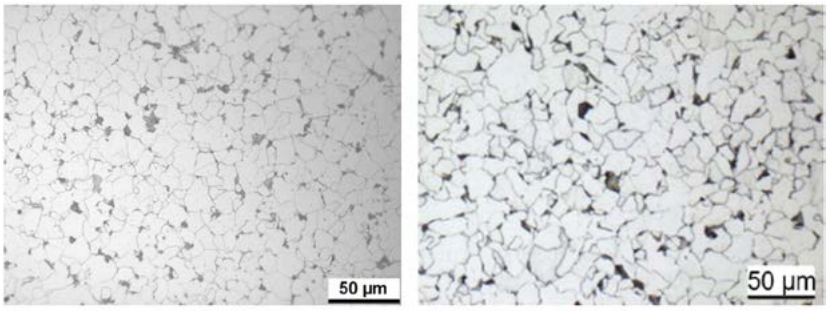

Figure 2.2. Comparison of microstructure between tube (left) and disk (right)

2.3. Results

The burst disc pressure tests were carried out in accordance with DIN EN ISO 11114-4 (Method A). Fig. 2.3 shows the corrected hydrogen and helium burst pressures as a function of pressure rise rate, as well as the resulting burst pressure ratios. All burst pressure ratios are significantly below the critical value of 2,0. According to DIN EN ISO 11114-4 (Method A), the hydrogen embrittlement index (HEI) of a material corresponds to the maximum value of this ratio, which in this case is 1.16. Based on this HEI, the examined tube material can be considered compatible with hydrogen at a pressure of 70 MPa.

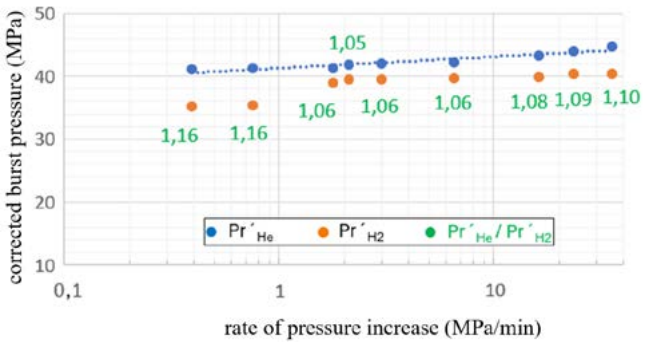

Figure 2.3. Corrected hydrogen and helium burst pressures as a function of pressure rise rate

3. CYCLIC PRESSURE TESTING OF HIGH-PRESSURE TUBES

To evaluate the potential sensitivity of steels to hydrogen in practical applications, it is essential to characterize their cyclic behaviour. The aim is to prevent the failure of components due to real world conditions, which could otherwise have severe consequences. To guarantee the durability of steel components exposed to hydrogen, fatigue tests under maximum loading conditions and varying temperature conditions are recommended.

The tested components consist of the hydrogen-carrying tube (seamless cold-drawn, outer diameter: 6.35 mm, wall thickness: 1.675 mm) with an outside corrosion protection layer and with tube fittings at both ends. The corrosion protection coating was realized as BENTELER ZISTA®SEAL and BENTELER ZISTAPLEX®. ZISTA®SEAL is a flexible chromiumVI-free zinc coated tube with a thin sealer as a top coat, offering good corrosion protection, even after tube processing. ZISTAPLEX® is a tube with a flexible duplex coating consisting of chromium (VI)-free zinc coating with an additional red coloured organic coating, offering high corrosion protection, even after tube processing. The tube fittings also play a key role in the functional and practical design of hydrogen fluid systems, as they must ensure gas-tightness under high hydrogen pressure and stability against mechanical impacts. Moreover, a 316L stainless steel tube of the same size with identical tube fittings was used as a reference.

3.1. Mechanical and microstructural characterisation of the tube

The mechanical properties of the high-pressure hydrogen tubes made of BENTELER carbon steel are listed in Table 3.1. The seamless cold-drawn and normalized BENTELER HYRESIST® Mobility (BHM) series-tube has a ferritic-pearlitic structure with a grain size class of 10 (see fig. 2.2 above).

Table 3.1. Mechanical characteristics of the high-pressure hydrogen tubes (BHM1) with outer diameter: 6.35 mm and wall thickness: 1.675 mm

	Yield Strength $Rp_{0.2}$ (MPa)	Ultimate Tensile Strength R_m (MPa)	Elongation A (%)
BENTELER HYRESIST® Mobility 1	≥ 250	≥ 370	≥ 35

3.2. Experimental Procedure and Results

For cyclic tests with hydrogen internal pressure, respectively three high-pressure tubes with a length of 100 mm and with fittings on both tube ends (Fig. 3.1) were subjected to cyclic ageing with up to 50,000 pressure cycles at three different temperatures of +20, -40 and 60 °C. In one cycle of 20 to 30 seconds, the hydrogen pressure in the tube was increased from 0 to 87.5 MPa and then decreased back to 0 MPa. The maximum value of 87.5. MPa is equivalent to a nominal working pressure of 70 MPa (700 bar) multiplied by a safety

restricted

factor of 1.25, according to EC79 or ISO 19887. The pressure test gas was hydrogen with a purity of >99.999 mol-% (hydrogen 5.0).

Following this cyclic ageing, hydraulic pressure tests were conducted until failure of the tubes. The determined burst pressure was compared with that of a non-preloaded reference tube to assess the effects of cyclic ageing under a pressurised hydrogen atmosphere. This hydraulic burst pressure tests were carried out at 20 °C and the results are shown in Table 3.2. No significant difference between the burst pressures of the tube samples preloaded with hydrogen and the reference samples (without hydrogen contact) can be observed. This proves the excellent hydrogen resistance of the BHM1 steel tube.

Table 3.2. Results of cyclic internal pressure tests and burst pressure tests

Temperature (°C)	**Pressure cycles**	**Burst pressure (MPa)**
BHM1 – *Reference without hydrogen*		
20	0 (reference)	330,0
BHM1 – cyclic loading with hydrogen		
20	10.000	339,7
-40	10.000	332,5
-60	50.000	329,3
Stainless steel (1.4404) – reference without hydrogen		
20	0 (reference)	350,0
Stainless steel (1.4404) - cyclic loading with hydrogen		
20	10.000	338,5
-40	10.000	343,3

Having a closer look at the results, it is remarkable that the BHM1 tube has a slight increase in burst pressure under the influence of hydrogen at 20 and -40 °C. At -60°C, the burst pressure is reduced by only 0.2%. While the burst pressures of the austenitic stainless-steel tube decrease by 3.3% under the same conditions (20 and -40°C, no testing at -60°C). Summarized, the BHM1 high-pressure tube even shows a very slightly higher resistance to high-pressure hydrogen embrittlement than the stainless-steel tube made of 316L (1.4404).

restricted

4. TESTING APPROACHES AND STANDARDS

To provide a comprehensive context for the present work, the following paragraphs introduce an alternative testing approach which is under development for small sized tubes (4.1). Furthermore, the current standards for automotive applications are summarized (4.2).

4.1. Perspective on hydrogen service life testing of tubes and tube materials

As an alternative to the component testing described above, research is currently working on further efficient qualification procedures to assess the service life of tubes made of new materials under the influence of pressurized hydrogen.

In the project *hydrogen lightweight tube* (funded by the German Federal Ministry for Economic Affairs and Energy (BMWi), funding code 03EI3070A) the use of longitudinally welded lightweight tubes for hydrogen use is qualified. The tubes are manufactured from strip steel, which was developed based on innovative material concepts. Regarding hydrogen qualification, the project is characterised by the development and testing of efficient test methods for hydrogen compatibility, especially for tubes with small outer diameters and thin walls.

Since the influence of hydrogen can lead to a significant reduction in fatigue life in the high-cycle fatigue range [6], an evaluation of cyclically stressed tube will be performed by life-time experiments, commonly referred to as “Wöhler”- tests. The required lifetime of the tube to be qualified in this project is below 10^6 cycles and falls within the time-dependent fatigue region of the “Wöhler”-curve. For this purpose, a test method is being developed with which the necessary material tests (low cycle fatigue) can be carried out quickly and cost-effectively in a specially adapted autoclave under pressurized hydrogen.

A second testing method using the C-ring technique, which enables easy sample production from thin sheets and tubes, is tested for the fatigue strength characterisation of products and materials under pressurized hydrogen. The project includes adapting this solution to the specific tube geometry and extending it for fatigue tests under pressurized hydrogen. This offers an additional quite simple method to characterize the fundamental hydrogen compatibility under pressurized hydrogen loading. This innovation enables targeted, geometry-specific material qualification and, in the future, cost-effective further developments and implementation into simple quality assurance measures.

restricted

4.2. Automotive standards for hydrogen compatibility testing of components

For the North American market, the applicable standard is ANSI HGV 3.1 – "Fuel system components for compressed hydrogen gas powered vehicles". In Europe, until July 2022, EC/EG 79/2009 was applied for the type approval of hydrogen-powered vehicles, together with the associated regulation EU 406/2010, which specified a detailed test sequence for high-pressure lines consisting of four tests. This sequence included an initial corrosion test, a cyclic gas pressure endurance test, a hydraulic pressure cycle test, and a final external leakage test. These tests were widely used and can still be considered state of the art. [8, 9]

The current applicable European regulation for type approval of hydrogen vehicles primarily refers to UN Regulation No. 134 (UN GTR 134), which, however, is vague regarding the test requirements for high-pressure hydrogen fluid lines. The incomplete description of the state of the art in the European regulatory framework has been addressed by the international standard ISO 19887-1: *Gaseous Hydrogen — Fuel system components for hydrogen-fuelled vehicles - Part 1: Land vehicles*. It has been developed based on the ANSI HGV 3.1 and is being published in October 2024 for hydrogen land vehicles. It's translated European derivatives might follow. Hydrogen rail vehicles are excluded in Part 1, but Part 2 of ISO 19887 for rail vehicles is under development. [8,10]

The qualification framework defined in HGV 3.1 and ISO 19887-1, contains a durability assessment of hydrogen fluid line assemblies by a multi-stage verification regime that integrates endurance (continuous operation), overpressure resilience, and post-cycling leak integrity evaluation.

The endurance test reproduces the thermomechanical and hydrogen-assisted degradation processes expected in operational vehicle environments, thereby serving as an accelerated surrogate for long-term service exposure. Most significant characteristic of this continuous operation test is the completion of the endurance cycling up to a maximum pressure of 875 bar of firstly hydrostatic pressure and secondly hydrogen pressure cycles for each 50 000 cycles at different temperatures (-40 °C, room temperature and +85 °C). The maximum pressure is set according to the specific pressure class of the application as defined in the normative pressure classification tables of both standards, starting from H25 (250 bar) up to H70 (700 bar). Maximum test pressure is calculated with a factor of 1.25 to 875 bar for a nominal working pressure (NWP) of 700 bar.

After the endurance test the assembly undergoes a hydrostatic strength test using an overpressure that exceeds the nominal working pressure by at least a factor of 2.5, enabling the detection of subcritical defects, microstructural degradation, and plastic deformation phenomena that may have accumulated during cyclic loading. The final stage comprises a leakage assessment performed at defined pressure conditions to evaluate the integrity of all sealing interfaces, welded joints, and mechanical connections. The compliance with the mentioned acceptance criteria in combination with additional tests like corrosion resistance, automotive fluid exposure and a bending test (for the proof of material ductility) ensures that the fluid line assemblies retain its structural reliability, hydrogen compatibility, and leak-tightness throughout the simulated design service life.

The requirements for high-pressure hydrogen fluid lines of ISO 19887-1 are aligned with ANSI HGV 3.1, except that the material selection for high-pressure components is not limited to non-corrosive austenitic stainless steels. This opens the possibility for the series

restricted

use and qualification of material innovations such as e.g. the hydrogen fluid lines from carbon steel tubes, which is presented in the previous chapters of this article. [8, 10]

5. CONCLUSION

In summary, it can be stated that the presented test series successfully demonstrates the hydrogen compatibility of the high-pressure tubes BENTELER HYRESISIT Mobility. This enables the qualification of components made from these tubes, e.g. as a hydrogen fluid line assembly. According to current regulatory requirements, several standards govern the commercialization of hydrogen vehicles, covering both fuel cell and hydrogen combustion technologies.

In these standards, in addition to demonstrating the basic material compatibility under hydrogen exposure, component tests for fuel lines are required. These tests essentially replicate the expected operating conditions of the components over their service life. Both verifications were provided in a modified form within the experiments presented.

The technological neutrality regarding the material selection for hydrogen fuel lines of ISO 19887-1 enables the possible future use of innovations such as the high-pressure fuel line tubes (BENTELER HYRESIST® Mobility). These tubes are made of carbon steel specifically developed for the application in hydrogen fuel systems, other hydrogen mobile machinery or similar stationary applications. Altogether this innovation is supporting the cost-efficient development of hydrogen-powered vehicles and further hydrogen applications.

Abstract

High-power precision optical systems are essential for cutting-edge technology – from laser additive manufacturing and gravitational-wave interferometry to directed-energy drone defence. The encountered intense thermal loads typically require liquid cooling, even though pressure ripples and flow-induced vibrations in the coolant can undermine mechanical precision and degrade optical accuracy.

This paper introduces a multidisciplinary engineering methodology for systematically analysing and mitigating vibration issues in liquid cooling systems for highly mechanically sensitive applications. The approach integrates 1D acoustic simulation, 3D vibro-acoustic analysis, 3D computational fluid dynamics (CFD), 1D/3D thermal simulation, mechanical design, materials science, and experimental validation into a unified workflow. Its performance is demonstrated on a representative cooling circuit which, in its original state, generates unacceptably high oscillating flow forces that impair the optical performance of the overall system.

The first step in the methodology is the development of a system-level, frequency-domain 1D model to determine the baseline oscillating pressure, flow rate and force distribution throughout the cooling circuit and identify the driving mechanism of the disturbances. To cover complex components (e.g., hoses or pumps), surrogate models derived from 3D simulation or from direct experimental measurements are integrated into the 1D framework. Based on the initial results for the forces and the associated system sensitivities, mitigation measures are derived which enable a reduction of the disturbing forces by more than 90 %.

By systematically integrating multiple engineering disciplines into a unified framework, this approach represents a significant advancement over traditional, isolated analysis techniques. The ability to iteratively refine models across multiple domains ensures a robust and optimised solution for mitigating flow-related disturbances. The methodology is particularly valuable for applications requiring ultra-high precision, where even minor perturbations can severely impact system performance.

1. INTRODUCTION

High-precision, high-power optical machinery is indispensable in the modern world. It enables ultra-accurate medical diagnostics, such as optical coherence tomography for retinal imaging, and is vital to cutting-edge, optics-based manufacturing methods (laser-based manufacturing, additive manufacturing, optical lithography). It underpins major scientific breakthroughs, such as the use of laser interferometers to detect gravitational waves, and plays a critical role in defence as well, for instance by countering drone attacks with directed energy weapons. The high thermal loads commonly encountered in such machinery typically require liquid cooling to prevent degradation in optical performance and structural failure.

However, in high-precision applications, liquid cooling is not free of cost: The presence of a coolant enables *hydraulic communication* even between components of the cooling circuit that are far apart from each other. As a result, mechanical or flow disturbances – for example, originating at the pump – can propagate to sensitive components such as a directly cooled laser beam source and adversely affect their optical performance. The issue is illustrated on the example of a cooling circuit for a high-precision optical manufacturing system.

1.1. Cooling System Under Consideration

In its baseline configuration, the cooling circuit comprises an external gear pump (displacement volume per rotation of 2.85 cm³ and $z = 9$ teeth per gear), two microchannel heat exchangers (see Figure 6 for dimensions), a return tank, interconnected piping and flexible PVC hoses. A CAD model of the duct system is shown in Figure 1:

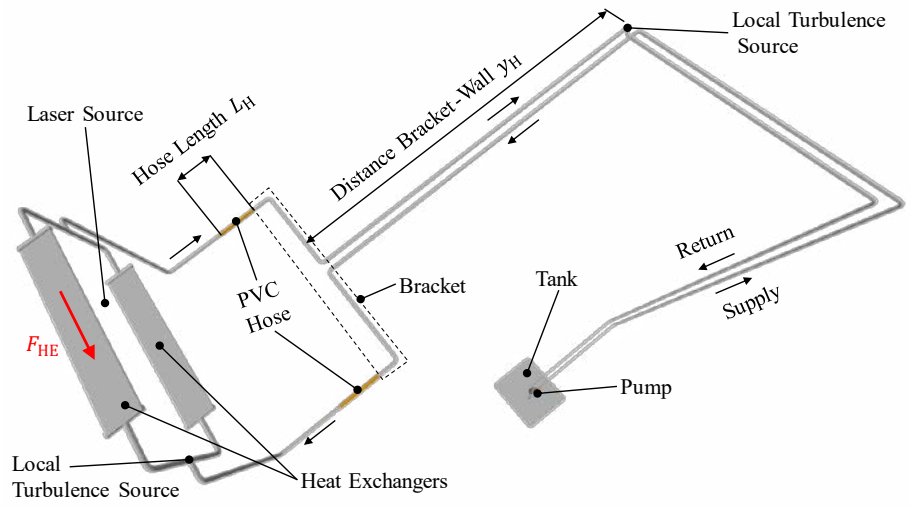

Figure 1: Cooling system under consideration.

The highly mechanically sensitive laser source is directly mounted between both heat exchangers. To be able to adjust the laser beam's orientation during operation, the beam

source – and thus its piping – must be suspended in a movable manner. This is achieved by two hoses within the routing.

1.2. Precision Losses and their Mitigation

During initial commissioning of a prototype of the system, it was observed that the operation of the cooling system was associated with unacceptably high optical precision losses due to unbalanced forces acting on the laser beam source, see Figure 1.

In order to effectively suppress the disturbing oscillatory forces, suitable – preferably passive – mitigation measures are to be taken. Because the mechanical design of the rest of the machine is already comparatively mature, major structural changes on the laser source and its support and actuator system are not possible anymore. Therefore, a direct reduction of the hydraulic excitation is necessary. Due to space constraints, the use of bulky resonators and silencers is not possible, leaving the adjustment of the position and length of the already existing hoses as the only viable option.

Before any mitigation strategy can be designed, the operating modes of the system need to be identified. The duct circuit acts as an oscillatory system which consists of fluid (coolant) and solid (duct walls, valve housing) elements. Both the fluid and the solid elements possess compliance and inertia. Thus, the unsteady forces and moments exerted by the duct system on the laser source result from the response of this oscillatory system to external as well as internal stimuli. In many applications, the inertia and most of the compliances of the solid parts can be neglected (weak fluid-structure interaction), such that the oscillatory forces acting on the duct structure are primarily a result of the pressure fluctuations at directional changes (e.g. bends) or area changes (e.g. conical sections) of the duct system.

In this case, the estimation of the oscillatory forces and moments reduces to determining the unsteady pressure and flow field in the duct system – a field commonly referred to as *duct acoustics*.

2. FUNDAMENTALS OF DUCT ACOUSTICS

In order to investigate the flow and pressure oscillations in a duct system by numerical analysis, a suitable model depth must be selected for each component. Depending on the properties of the individual component, either a 0D, 1D or 3D model must be chosen.

2.1. 0D vs. 1D vs. 3D Models

0D models are most suitable if the internal degrees of freedom of a component are not of relevance to its transmission behaviour. This is the case if the travel time L/c of a pressure wave of speed c through a component of characteristic length L is substantially smaller than the period $1/f$ of the frequency of interest, i.e. $fLc^{-1} \ll 1$. A typical example would be the model of a small return tank, where the pressure can be assumed to be uniform throughout the component and internal wave propagation is not of concern. Also, for a sufficiently short pipe section, compressibility effects can be ignored, such that the flow rate is constant along the section length. If the product fLc^{-1} is not small with respect to unity, wave phenomena within the component need to be considered. If the wave propagation primarily occurs along a single dimension (e.g. along the longitudinal axis of a slender pipe section), 1D models

suffice. If even this simplification does not apply and substantial changes of state variables might occur along more than one spatial dimension, one is required to resort to 2D or even 3D models. For most components encountered in duct acoustics, 1D models suffice.

2.2. Frequency vs. Time Domain Analysis

Irrespective of the chosen model depth, a choice must be made whether the system analysis is to be carried out in the time or frequency domain. Table 1 provides an overview over various aspects that drive the decision between time and frequency domain analysis.

Table 1: Comparative capability analysis of time vs. frequency domain analysis.

Aspects	Time Domain	Frequency Domain
Analysis of Transients (Valve closure & pump ramp-up)	✓	✗ (Only linearised)
Consideration of system nonlinearities (Cavitation, large amplitudes)	✓	✗ (Only linearised)
Determination of Steady-state modes, resonances & transfer functions	✓ (Slow)	✓
Acoustic optimisation (Silencer design, shifting of resonances)	✓ (Very slow)	✓
Efficient for large range of frequencies	✗ (Large amounts of data, extremely slow)	✓

For the cooling circuit under consideration, only steady-state oscillations are of interest and the amplitudes are small, such that frequency-domain simulation can demonstrate its advantages. If the analysis is limited to the frequency domain, the computationally efficient *transfer matrix method* can be employed.

2.3. Transfer Matrix Method

In the case of a 1D hydraulic system model, both pressure p and flow rate Q are required to uniquely describe the flow state at a given cross-section. Thus, to characterise the relation between the states at the inlet and outlet of any 1D component in the frequency domain, the concept of a transfer function has to be generalised to a transfer matrix $\boldsymbol{T}$. This generally frequency-dependent and complex-valued function relates the phasor vectors at the inlet with those at the outlet:

$$\begin{pmatrix} p^*_{\mathrm{In}} \\ Q^*_{\mathrm{In}} \end{pmatrix} = \boldsymbol{T} \begin{pmatrix} p^*_{\mathrm{Out}} \\ Q^*_{\mathrm{Out}} \end{pmatrix} = \begin{bmatrix} T_{11} & T_{12} \\ T_{21} & T_{22} \end{bmatrix} \begin{pmatrix} p^*_{\mathrm{Out}} \\ Q^*_{\mathrm{Out}} \end{pmatrix} \tag{2.1}$$

For example, the transfer matrix $\boldsymbol{T}_{\mathrm{Pipe}}$ of a straight circular pipe of length L and cross-sectional area A, filled with an inviscid fluid of sonic speed c, is given by:

$$\boldsymbol{T}_{\text{Pipe}} = \begin{bmatrix} \cosh\left(\frac{\mathrm{i}\omega L}{c}\right) & \frac{\rho c}{A}\sinh\left(\frac{\mathrm{i}\omega L}{c}\right) \\ \frac{A}{\rho c}\sinh\left(\frac{\mathrm{i}\omega L}{c}\right) & \cosh\left(\frac{\mathrm{i}\omega L}{c}\right) \end{bmatrix} = \begin{bmatrix} \cos\left(\frac{\omega L}{c}\right) & \frac{\mathrm{i}\rho c}{A}\sin\left(\frac{\omega L}{c}\right) \\ \frac{\mathrm{i}A}{\rho c}\sin\left(\frac{\omega L}{c}\right) & \cos\left(\frac{\omega L}{c}\right) \end{bmatrix} \tag{2.2}$$

The transfer matrix of a series connection of two components A and B is readily obtained by matrix multiplication of the respective matrices T_{A} and T_{B}. Further details regarding the interconnection and usage of transfer matrices can be found in the literature [1][2]. By combining multiple matrix elements, a system model as described in section 3 can be set-up. For components whose transfer matrix cannot be determined by analytical estimates, experimental methods have to be employed.

2.4. TMM Test Bench

For the experimental determination of the transfer matrix of a specific component, a so-called transfer matrix method (TMM) test bench as shown in Figure 2 is used [3].

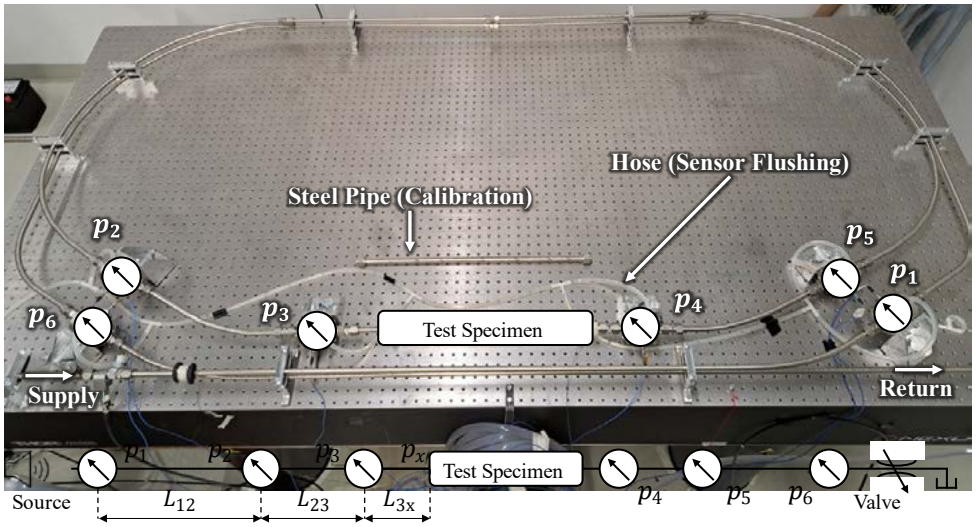

Figure 2: AVL Transfer Matrix Method Test Bench.

The test bench consists of up to six unsteady ("dynamic") pressure transducers, a load valve and a suitable acoustic source. The source as well as the valve must be located either before the first sensor or after the last sensor. The acoustic source excites the system and creates a wave pattern that is characteristic for the system under investigation.

2.4.1. Transfer Matrix Determination

To determine the transfer matrix $\boldsymbol{T}$ of a component experimentally, the phasors of pressure and flow rate at both the component inlet and outlet must be known to solve equation 2.1 for the matrix elements T_{ij}. Since there are only two equations for four unknowns T_{ij}, two

distinctly different measurements have to be carried out to create four independent equations. This is typically achieved by adjusting the load valve to force a different wave pattern. For the specific case of a symmetric transfer behaviour of the investigated component, only one measurement is required.

Compared to measuring unsteady pressures, non-invasive measurement of unsteady flow rates is technically challenging. To overcome this, the TMM replaces the direct measurement of a single flow rate with the measurement of two unsteady pressures by utilising a rearranged form of equation 2.1:

$$p_{\mathrm{In}}^{*} = p_{\mathrm{Out}}^{*} \cdot T_{11} + Q_{\mathrm{Out}}^{*} \cdot T_{12} \rightarrow Q_{\mathrm{Out}}^{*} = \frac{p_{\mathrm{In}}^{*}}{T_{12}} - p_{\mathrm{Out}}^{*} \frac{T_{11}}{T_{12}}. \tag{2.3}$$

Thus, if two pressures and the TFM elements of the components between the pressure sensors are known, a flow rate can be determined. Because their TFM elements can be calculated with high accuracy by equation 2.2 (or more advanced models), steel pipes are used between the sensors. In the actual measurement, three instead of two sensors are used for state determination in order to expand the frequency range that can be analysed. Based on the three pressures per side and known transfer behaviour of the steel pipes between the sensors, the states at the inlet and the outlet of the test specimen can be estimated by solving the following equation system for the unknown phasors p_x^* and Q_x^* at a location x (only shown for sensors 1, 2 and 3, see Figure 2):

$$\underbrace{\begin{pmatrix} p_1^* \\ p_2^* \\ p_3^* \end{pmatrix}}_{\vec{b}} = \begin{bmatrix} \cosh\left(\frac{\mathrm{i}\omega L_{1x}}{c}\right) & \sinh\left(\frac{\mathrm{i}\omega L_{1x}}{c}\right) \\ \cosh\left(\frac{\mathrm{i}\omega L_{2x}}{c}\right) & \sinh\left(\frac{\mathrm{i}\omega L_{2x}}{c}\right) \\ \cosh\left(\frac{\mathrm{i}\omega L_{3x}}{c}\right) & \sinh\left(\frac{\mathrm{i}\omega L_{3x}}{c}\right) \end{bmatrix} \underbrace{\begin{pmatrix} p_x^* \\ \frac{\rho c}{A} Q_x^* \end{pmatrix}}_{\vec{x}} = \boldsymbol{A} \begin{pmatrix} p_x^* \\ Z_{\mathrm{C}} Q_x^* \end{pmatrix} \tag{2.4}$$

The determination of the states – and thus the transfer matrix of the specimen – becomes challenging if the signal-to-noise ratio assumes small values. Disturbing noise levels are particularly relevant in the low-frequency range. The accuracy of experimental results in this part of the spectrum can be improved by optimising the sensor spacing.

2.4.2. Numerical Conditioning and Sensor Spacing

When solving a linear equation system $\vec{b} = \boldsymbol{A}\vec{x}$ like equation 2.4 for $\vec{x}$, the sensitivity to errors (i.e. noise) in $\vec{b}$ can be quantified through the so-called *condition number* $\kappa(\boldsymbol{A})$. It is defined as the ratio of the largest to the smallest singular value of $\boldsymbol{A}$. Large condition numbers imply that small errors in the measured pressures $\vec{b}$ can lead to large errors in the estimated acoustic states $\vec{x}$, whereas condition numbers close to unity indicate a well-conditioned system with minimal noise amplification. Since – for a given (angular) frequency ω and sonic speed c – the sensor spacings are the only variables affecting the conditioning of matrix $\boldsymbol{A}$, the condition number κ can serve as a design metric for sensor placement: by selecting appropriate sensor spacings, the measurement matrix can be made robust for the frequencies of interest, improving the reliability of reconstructed acoustic quantities.

Analytically, it can be shown that κ is independent of the absolute distance L_{3x} of the sensor array relative to the specimen – only the relative sensor spacings L_{12} and L_{23} affect numerical conditioning, as shown in Figure 3:

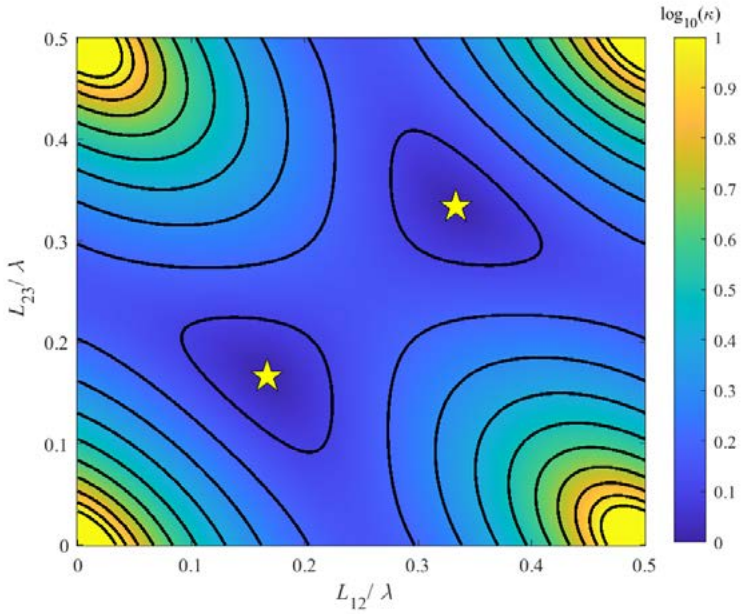

Figure 3: "Heatmap" of the condition number κ for a TMM three-sensor array.

The theoretical minimum occurs when the three measured pressure phasors are spaced 120° apart. Under this condition, $\kappa = 1$, which corresponds to perfect numerical conditioning. To achieve this, the relative sensor spacings must be chosen to:

$$\frac{L_{12}}{\lambda} = \frac{L_{23}}{\lambda} = \frac{1}{6}. \tag{2.5}$$

In the equation above, $\lambda = c/f = 2\pi c/\omega$ refers to the wavelength. In practice, selecting sensor spacings close to $\lambda/6$ for a frequency of interest ensures low condition numbers and reliable results. Conversely, sensor spacings approaching 0 or multiple integers of $\lambda/2$ lead to near-linear dependence of the measurement rows and result in severe noise amplification. Physically, this occurs because the equation system "expects" practically identical pressures which – due to noise – will not be recorded in practice.

3. System-Level Model

Based on the fundamentals presented in section 2, a high-fidelity augmented 1D system model of the cooling circuit can be set up for system analysis and optimisation. Depending on the complexity of the respective component, either analytical or surrogate models from various sources are chosen to represent its passive properties in the system model, as it is shown in Figure 4:

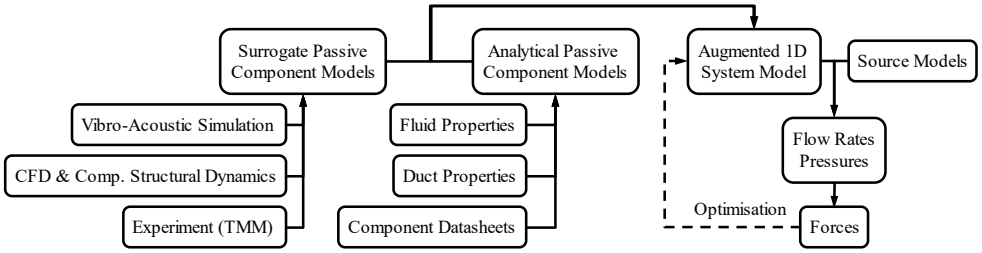

Figure 4: Data sources for the multidisciplinary augmented 1D system-level model.

3.1. Analytical Component Models

The geometry of most components of a duct system can be described by bulbous (i.e. acoustically "short", $fLc^{-1} \ll 1$) cuboids and slender cylinders. The acoustic behaviour of such components (e.g. tanks and pipes) can be estimated with sufficient confidence based on analytical relations alone. To parameterise the respective component models, the properties listed in Table 2 are required:

Table 2: Required properties for parameterisation of analytical component models.

Category	Property
Fluid properties	Mass density ρ
	Sonic speed c or bulk modulus K
	Viscosity η or kinematic viscosity ν
Duct material properties	Young's modulus E (potentially frequency-dependent and complex)
	Poisson's ratio μ
Duct geometry	Section length L
	Inner diameter d (or equivalent for non-circular sections)
	Wall thickness e
Operational conditions	Average flow rate $\overline{Q}$ (to assess flow regime)
	Average fluid temperature $\overline{T}$ (for fluid properties)
	Mean pressure level $\overline{p}$ (for fluid properties)

If the fluid is not a pure substance or a ubiquitously used, well-documented mixture, one must resort to e.g. manufacturer's data sheets to obtain the relationships between the thermodynamic state of the fluid and the respective fluid property.

3.2. Surrogate Component Models

In contrast to acoustically short or slender, tubular geometries, the transmission behaviour of components with complex internal geometries usually cannot be calculated purely by theory. In this case, surrogate component models have to be utilised. For the present system, the pump, the PVC hoses as well as the heat exchanger must be represented through surrogates.

3.2.1. Pump Surrogate Model

Like other positive displacement machinery, the pump's acoustic behaviour can be characterised through its source impedance (passive property) Z_P and its source flow ripple Q_P^* (active property, see section 3.3.1) according to a NORTON equivalent circuit [4]. Ideally, both these properties are determined experimentally through a TMM test setup as outlined in the standard ISO 10767-1:2015 [5]. If such measurements are not available (e.g. during the conceptual phase), reasonable estimates can often be made through semi-analytical approaches as shown below.

The source impedance Z_P of positive displacement pumps – as seen from the duct system – generally exhibits the characteristics of a simple hydraulic spring, damper and mass system:

$$Z_\mathrm{P} = \frac{C_\mathrm{P}}{\mathrm{i}\omega} + D_\mathrm{P} + \mathrm{i}\omega M_\mathrm{P} \tag{3.1}$$

The model parameters C_P, D_P and M_P are directly related to the characteristics of the fluid enclosed between the gears and the pump flange. Due to the comparatively small size of the pump, the impedance will be governed by the hydraulic stiffness C_P in the frequency range of interest. This stiffness is typically substantially smaller than what would be expected from an estimate based on the enclosed fluid volume alone since the additional compliances of sealings and the pump casing are present. STULEMEIJER reports on the *effective fluid volume* of pumps with a known displacement volume per revolution [6]. This data can be used to construct a semi-empirical correlation to estimate the effective fluid volume of the pump in question and thus its hydraulic capacity. The dissipative and inertial contributions can be neglected here due to the pump's size and the frequencies of interest.

3.2.2. PVC Hose

The surrogate component model for the PVC hoses can be derived in three different ways: 1D theory (i.e. analytically), 3D vibro-acoustic analysis, or experimentally on the TMM test bench. The first two methods require knowledge of the geometry and the material behaviour of the hose, which is determined by a dynamic mechanical thermal analysis (DMTA). In contrast, the experiment on the TMM test bench does not require prior knowledge of the material behaviour of the hose or the geometry of the test specimen.

The results of the three different methods, represented as a mass-spring-mass model are shown in Figure 5. Differences between 1D theory and 3D vibro-acoustic simulation can be explained by the fact that 1D theory cannot capture 3D effects (e.g. ballooning at the transition from steel pipe to PVC hose). The experimental data from the TMM test bench is in good agreement with the other two methods. The stiffness C from vibro-acoustic

simulation aligns better with the measurement since the stiffness-enhancing clamping effect at both ends of the hose are taken into account. If at least another measurement with a different hose length is performed, a length-dependent surrogate model for the PVC hose can be derived.

The significant deviations between simulation and measurement at low frequencies can be explained by the increasingly bad condition number κ (frequency range $f < 10$ Hz), while the low sensor coherence γ^2 – indicative of e.g. a low signal-to-noise ratio – explains the discrepancies at high frequencies (frequency range $f \geq 200$ Hz).

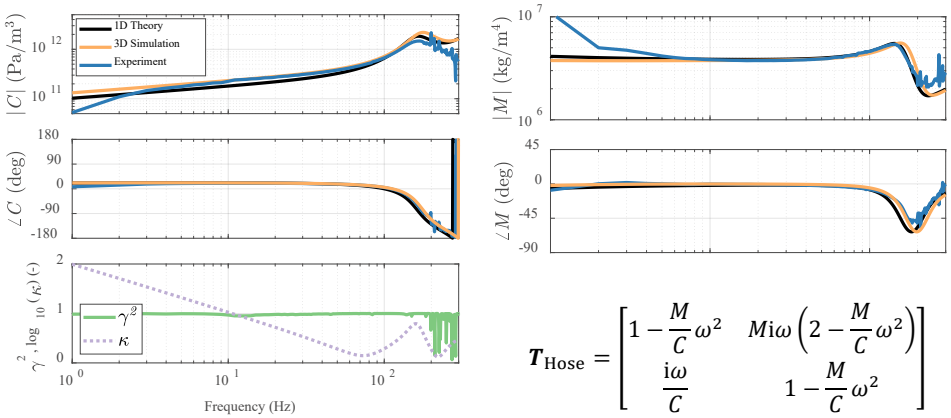

Figure 5: Comparison of various surrogate component models of the PVC hose.

3.2.3. Heat Exchanger Surrogate Model

As shown in Figure 6, the array of parallel narrow channels in the heat exchangers is connected via manifolds to the piping of the cooling circuit. Due to its highly branched and complex internal structure, a direct representation through a fully parametric TFM would be impractical and computationally inefficient. For this reason, the assembly of two heat exchangers and their respective manifolds is modelled through a surrogate model that extends from the "Inlet" to the "Outlet" port marked in Figure 6:

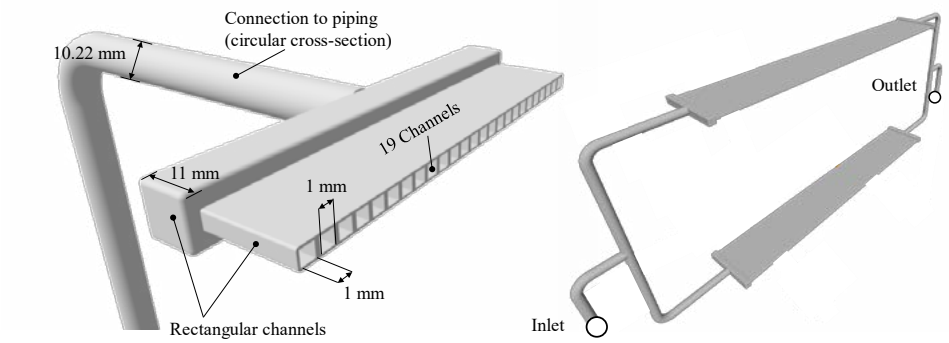

Figure 6: Heat exchanger cross-section with relevant dimensions.

The surrogate model is derived from a 3D vibro-acoustic simulation performed using commercially available FE software. Based on the calculated flow rates and pressures at the inlet and outlet of the heat exchanger assembly, the TFM elements of the surrogate model are determined using the same method as for experimental data (see section 2.4.1.).

3.3. Source Models

To obtain the pressures, flow rates and flow forces, the augmented 1D system model needs to be excited by source models. As outlined, several types of sources may excite liquid columns to oscillate. When modelling acoustic sources, a distinction is made between those of deterministic and those of stochastic nature. A typical example of a deterministic acoustic source is the flow ripple generated by the coolant pump.

3.3.1. Pump Flow Ripple

The coolant pump imposes a flow ripple phasor Q_{P}^{*} on the system boundary. For positive displacement pumps, the kinematic source flow ripple can often be reasonably approximated by a rectified sine wave with the amplitude Q_{P}' in the time domain. The sine amplitude is directly connected to the so-called degree of non-uniformity $\delta_{\mathrm{P}} = Q_{\mathrm{P}}'/\overline{Q}_{\mathrm{P}}$ commonly used in the pump industry [2]. The degree of non-uniformity δ_{P} can be reasonably approximated based on the number of pumping elements z (teeth per gear, pistons, etc.) by $\delta_{\mathrm{P}} = 2/z$ for $z \gg 1$. For the coolant pump at hand, $\delta_{\mathrm{P}} = 2/9 \approx 0.22$. Fourier decomposition of the assumed $Q_{\mathrm{P}}(t)$ shows that spectral contributions to the flow ripple amplitude spectrum (AS) only occur at integer multiples n of the fundamental pumping frequency $f_{\mathrm{P}} = f_{\mathrm{S}} \cdot z$ (with f_{S} denoting the pump shaft frequency), and that their amplitudes decay with the square of the order n as follows:

$$|Q_{\mathrm{P}}^{*}(n \cdot f_{\mathrm{P}})| = \frac{2}{\pi} \frac{\overline{Q}_{\mathrm{P}} \delta_{\mathrm{P}}}{4n^2 - 1} \tag{3.2}$$

3.3.2. Local Turbulence Sources

Even for nominally laminar flow throughout the system, strong deflections within a component may induce local turbulence (LT). These turbulent regions act as acoustic sources. In the investigated system, local turbulence occurs at the double bend and within the piping of the heat exchangers as depicted in Figure 1. The strength of local turbulence sources must be determined through CFD analysis or experimentally.

A common feature of sources due to local turbulence is their decay towards higher frequencies. Due to the randomness of the turbulent fluctuations, the corresponding sources show a stochastic behaviour, which is why they are characterised by a power spectral density (PSD) rather than an amplitude spectrum (AS). It is important to note that a PSD represents how the power of a signal is distributed across the frequency range. However, it *does not* represent a worst-case scenario that – for instance – can directly serve to calculate the maximum occurring pressure at a given location. Furthermore, it is not straightforward to combine deterministic and stochastic sources due to the different means of representation (amplitude and phase vs. PSD).

3.4. Pressures, Flow Rates & Forces

For the current model, one deterministic (pump) and two stochastic (local turbulence at the double bend and within the exchangers) sources are considered. Combining both deterministic and stochastic sources poses a particular challenge due to their different representations: Since a PSD does not contain any phase information anymore, a simple superposition of all sources is not guaranteed to provide the worst-case pressure and force amplitudes: Depending on the phase angle between the sources, superimposing them might result in constructive or destructive interference. To circumvent this issue, the relative phase angles of the stochastic sources with respect to the deterministic one are systematically varied which results in an envelope for the desired output quantities rather than single values.

This method is applied to the present system as well. The aim of the optimisation process is to minimise the axial reaction force amplitude $|F_{\mathrm{HE}}|$ at the heat exchangers which occurs primarily due to the pressure difference $\Delta p_{\mathrm{HE}} = p_{\mathrm{Inlet}} - p_{\mathrm{Outlet}}$ across them (see Figure 1 and Figure 6). Thus, the magnitude of the pressure difference $|\Delta p_{\mathrm{HE}}|$ at the heat exchanger is the hydraulic quantity of primary interest for the optimisation process. It is plotted as a function of the frequency in Figure 7. The dotted red curve shows the load case if only the pump source is active. The blue envelope band is obtained by adding the sources from local turbulence (heat exchangers and double bend) and varying their phase angles.

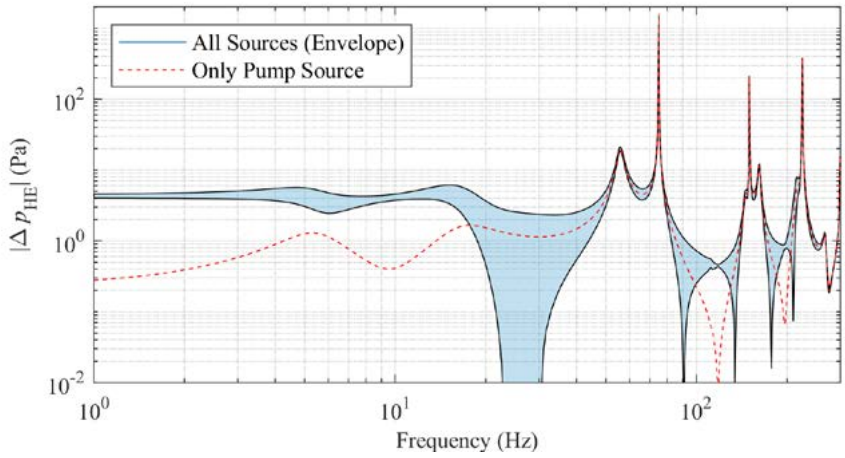

Figure 7: Baseline heat exchanger pressure difference $|\Delta p_{\mathrm{HE}}|$ as a function of the frequency.

As expected, the low-frequency range (below 20 Hz) is governed by the stochastic sources since these frequencies are well below the fundamental pumping frequency $f_{\mathrm{P}} = 75$ Hz. The distinct peaks due to pump excitation at 75 Hz and its harmonics (150 Hz, 225 Hz, …) are the most dominant contributions within the considered frequency range. When comparing the spectrum of the pressure difference (i.e. the forces on the laser source) with the characteristics of the control loop responsible for the laser beam orientation, the second-order peak at 150 Hz can be identified as the main driver of the precision loss of the prototype. Therefore, the goal of the following system optimisation will be the reduction of this peak.

4. OPTIMISATION WORKFLOW

Once the dominant force contributions and their causative sources are identified, targeted mitigation strategies can be derived. These measures are first evaluated virtually through surrogate-model enhanced 1D simulation. The innovative aspect of the proposed workflow is the ability to conduct rapid design iterations using a reduced-order system model while retaining the fidelity of full 3D simulations where necessary.

4.1. Hose Optimisation

A hose provides frequency-dependent compliance and damping through its viscoelastic material properties. Strategically positioning and sizing such a hose can attenuate pressure differences across sensitive components, thereby reducing the reaction force transmitted to the heat exchangers. This beneficial effect is to be maximised such that only minimal vibration affects the sensitive laser source. The optimisation problem possesses the following degrees of freedom:

- Hose length L_H.
- Hose position y_H, defined as the lateral distance of the bracket from the wall. The position affects local boundary conditions (e.g., support stiffness, damping) reflected in the section's transfer matrix.

The constraints are defined as follows:

- Box constraint on length of hose: 50 mm $\leq L_\mathrm{H} \leq$ 350 mm.
- Box constraint on position: 100 mm $\leq y_\mathrm{H} \leq$ 1900 mm.

The length of the viscoelastic hose is limited to prevent unwanted fluid-structure interaction. The limits for y_H are prescribed by layout rules and clearance envelopes (e.g., walls, frames, neighbouring equipment). In addition, the piping layout should be designed to route the flow directly to the heat exchanger, avoiding any detours or counterflow sections. Therefore, the axial constraint reads $L_\mathrm{H} + y_\mathrm{H} \leq 2100$ mm.

The optimisation problem of minimising the force magnitude at the heat exchangers is then given by $|F_\mathrm{HE}(f, L_\mathrm{H}, y_\mathrm{H})| \propto |\Delta p_\mathrm{HE}(f, L_\mathrm{H}, y_\mathrm{H})|$ and subject to the box constraints on L_H, y_H, and the non-linear routing constraint. For the optimisation, a global *surrogate-based optimisation* with *adaptive sampling* is employed. Each evaluation of $|\Delta p_\mathrm{HE}(f, L_\mathrm{H}, y_\mathrm{H})|$ requires a frequency-domain simulation using the full transfer-matrix chain, which is computationally expensive and involves nonlinear constraint interactions (via position-dependent boundary conditions). The chosen approach proceeds as follows:

1. Evaluation of objective function: A set of quasi-random points is generated, and the objective function is evaluated at these points.
2. Interpolation for surrogate: A radial basis function (RBF) is used to interpolate the objective function to set up the surrogate model [7]. The cheap-to-evaluate surrogate approximates the expensive objective function.
3. After building the surrogate, the algorithm generates a large set of candidate points across the domain. Each candidate is scored using a merit function that balances

the predicted objective value from the surrogate and the distance from existing sample points. The candidate minimising the merit function is selected for true evaluation [8][9], and the surrogate is updated with this new data point.

The algorithm is repeated until a certain budget of evaluations is exhausted. This particular method is used since it is well suited for problems involving expensive evaluations, nonlinear constraints and unknown gradients.

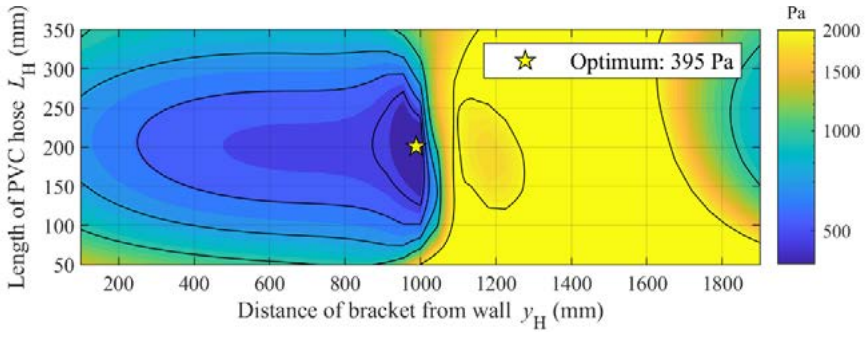

Figure 8: Contour plot of $|\Delta p_{\mathrm{HE}}|$ as a function of y_{H} and L_{H}, optimum marked with star.

The optimisation results are depicted in Figure 8. The minimal pressure difference (and thus force) is obtained for a hose length $y_{\mathrm{H}} = 200$ mm and a wall distance of $L_{\mathrm{H}} = 1000$ mm for the bracket. With the optimisation, a setup with only 3.8 % of the maximum pressure difference – and thus force – on the heat exchangers (baseline pressure difference $|\Delta p_{\mathrm{HE}}| = 10400$ Pa) could be identified.

Intuitively, one would expect the hose-related pressure suppression to monotonically increase with the hose length and provide minimal forces when the suppression is directly *before* the evaluated points. However, since the hoses not only act as dissipative but also as reflective elements, the maximal suppression is reached at different location and length.

Following virtual testing, the most promising mitigation measure undergoes detailed mechanical design. A detailed 3D vibro-acoustic analysis of the final hose design is then carried out, enabling an assessment of the stress distribution and – in a subsequent analysis – fatigue life under realistic operating conditions which are obtained from the augmented 1D system model. This phase ensures mechanical integrity and durability, considering factors such as vibrational loads and dynamic stress concentrations.

4.2. Engineering Framework for Development, Validation and Industrialisation

In addition to the mitigation measures described above, the development of other suppression devices such as chamber-based or membrane-type silencers, might be necessary for other systems to address acoustic, vibrational, or flow-induced disturbances. In such cases, a systematic and multidisciplinary development process is recommended, encompassing mechanical design, material science, and the application of appropriate computer-aided engineering (CAE) methods, including coupled thermal, thermo-

mechanical, and structural analyses, as well as reliability & lifetime assessment and industrialisation. Furthermore, the resulting components may need to be qualified and integrated for operation under non-standard environmental boundary conditions, including high- and low-temperature regimes, cleanroom environments, or vacuum conditions.

5. CONCLUSION & OUTLOOK

In this paper, a comprehensive workflow for identifying and mitigating flow-related disturbances in cooling circuits for high-precision applications via multidisciplinary simulation was presented. By employing surrogate models, the high fidelity of 3D simulations and experimental investigations could be carried over to a multidisciplinary augmented 1D system model. By optimising the length and location of PVC hoses, a substantial reduction of performance-degrading force disturbances could be achieved. Future research may focus on further refining surrogate modelling techniques and exploring adaptive or actively actuated mitigation strategies to dynamically counteract varying operational conditions.

Abstract: The hydraulic rock drill is a type of hydraulic impactor that relies on hydraulic power to deliver periodic impact forces externally. As a core piece of equipment in mining operations, the service life of its key internal moving components and supporting seals directly determines the overall operational efficiency of the equipment. This paper focuses on the cavitation erosion issue affecting the rear guide sleeve, which is a primary support component in the rock drill. Utilizing a rock drill impact test bench, experiments were conducted. The results indicate that the negative pressure zone generated during the outward movement of the impact piston from the rear braking chamber is the main cause of cavitation near the rear guide sleeve. By comparing the motion of the impact piston within the braking chamber and the corresponding pressure variations under different clearance conditions, it was found that the formation of the negative pressure zone primarily depends on the penetration depth of the piston into the braking chamber and the maximum pressure within the chamber. Furthermore, by comparing the variations in the impact performance of the rock drill under different clearance conditions, it is proposed that the optimal clearance for this type of rock drill should be within the range of 0.04 to 0.06 mm.

Keywords: Hydraulic rock drill, Cavitation, Clearance

1 Introduction

Hydraulic rock drills serve as critical equipment in modern mining and tunnel excavation [1,2], as shown in Fig 1.1. The stability and continuity of a rock drill's operation directly determine the overall working efficiency of mining equipment. Therefore, the service life of its core internal components is critical, primarily including the impact piston, guide sleeve, and sealing elements.

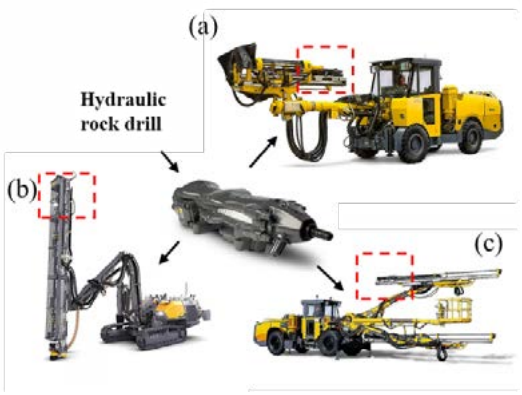

Fig 1.1 Mining machinery equipped with hydraulic rock drill
(a) Underground drilling rig, (b) Surface drilling rig, (c) Drill jumbo

Scholars have conducted in-depth research on the motion of the impact piston through mechanism analysis and hydraulic simulation techniques. Gorodilov [3] proposed a segmented modeling approach based on the assumption of constant inlet pressure and neglecting the impact and spool switching processes. To couple the motion of piston and spool, Hu [4] provided an AMESim-based model and based on this model Yang [5] added a plunger pump model to analyze the effect of inlet flow fluctuations on impact performance. Besides, Guo [6] employed the bond graph method to model the coupled motion, achieving lower complexity compared to AMESim.

Based on the motion analysis of the impact piston, the correlation between piston motion and internal cavitation has received some scholarly attention. For instance, Tian [7] and Jia [8] through experimental analysis, established a relationship between the service life of the front water seal and the impact piston's stroke in a rock drill, finding that seal life decreases

as the stroke increases. Separately, Geng [9,10] in a study on the cavitation mechanism in a dual-cushion rock drill, demonstrated that the piston's kinematic parameters upon entering the front cushioning chamber are a critical factor in the formation of cavitation in the front chamber.

While existing research has extensively addressed the front guide sleeve and seals, the rear guide sleeve has received limited attention. To bridge this gap, this study is dedicated to investigating the rear-side problem. By integrating laser displacement and pressure sensors, we capture the key parameters of piston motion and pressure dynamics at the rear cushioning chamber to elucidate the mechanism of cavitation erosion and develop a targeted solution.

2 Problem statement

2.1 Structure and working principle

Dual-control hydraulic rock drills (DHRD) have become the primary type of rock drill equipment in current mining machinery due to their high energy efficiency. Their basic structural composition is illustrated in Fig 2.1. The main body of DHRD contains impact piston (1), guide sleeve (2), and cylinder sleeve (3). It is used to perform the shock motion. The motion is controlled by the spool of direction valve (5), installed on the valve seat (4). There are four chambers formed by part 1 and 3, i.e., front chamber (FC), piston signal chamber (PSC), tank chamber (TC), and rear chamber (RC). Also, there is a signal chamber for direction valve (VSC). The pressure oil is input to power the whole system from the inlet port of direction valve.

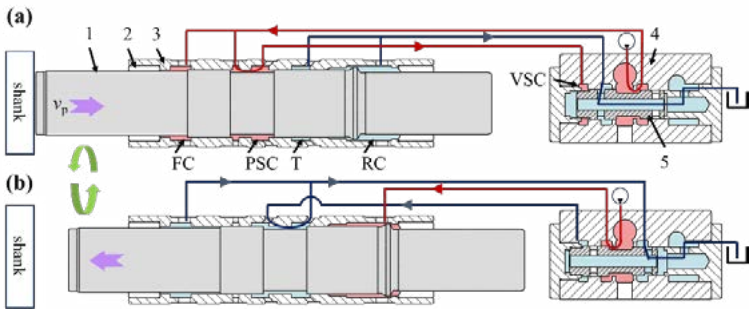

Fig 2.1 Working principle of DHRD

(a) Return stroke state, (b) Impact stroke state

The impact motion of DHRD contains two typical states, i.e., return stroke state (RSS) and impact stroke state (ISS), and the switching of these states above are shown in Fig 2.2. The working principle can be explained as follows: DHRD switches between RSS and ISS repeatedly by the coupling motion of part 1 and 5. The operating state during RSS and ISS can further be divided into acceleration and braking states according to the direction of movement of part 1.

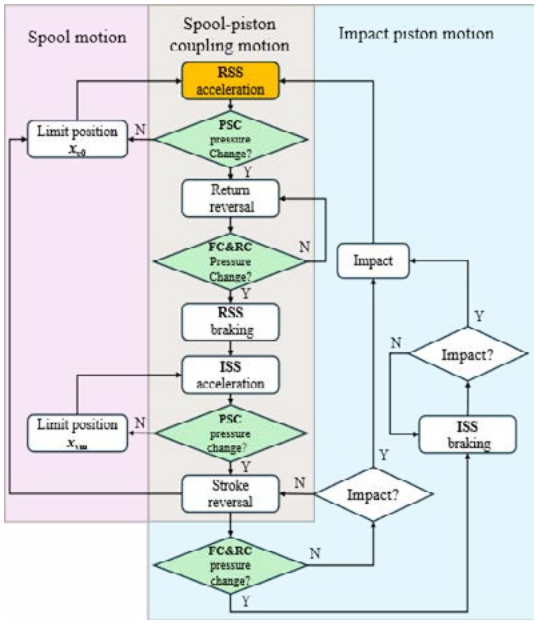

Fig 2.2 Flowchart of working principle of DHRD

2.2 Cavitation in the rear braking chamber

As illustrated in Fig 2.3, when the impact piston moves past a specific position in the cylinder, a sealed oil chamber forms between the piston, the cylinder, and the guide sleeve, and this chamber is the rear braking chamber. The chamber serves as an anti-impact mechanism to protect the piston from striking the rear guide sleeve in the period between RSS braking and ISS acceleration.

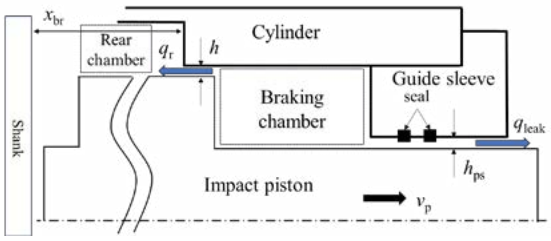

Fig 2.3 Structure of braking chamber

Damage progression in the rear guide sleeves of the same rock drill model reveals a clear time-dependent progression, as shown in Fig 2.4.

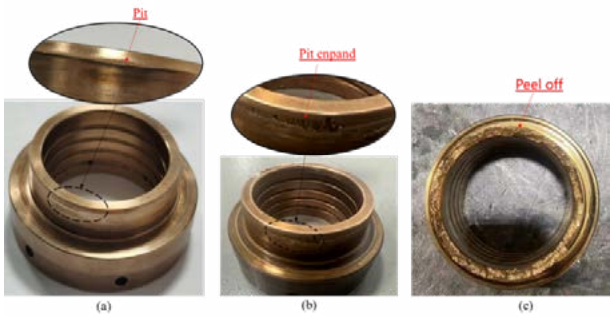

Fig 2.4 Cavitation phenomenon in different stages

(a) Early stage (less than 50 impact hours) (b) Intermediate stage (between 50 and 100 impact hours) (c) Late stage (over 100 impact hours)

Damage to the rear guide sleeve leads to hydraulic oil contamination. The resulting metallic debris poses a significant threat to both the rear seal and the piston surface, substantially reducing the service life of these components. Hence, determining how to optimize the rear braking chamber's structure to mitigate cavitation-induced damage to the rear guide sleeve is a critical issue for improving the service life of rock drills.

3 Method and materials

3.1 Hydraulic rock drill test bench

As shown in Fig 3.1, a hydraulic rock drill impact test bench (HRDITB) was established to acquire the pressure within the rear braking chamber and the motion of the impact piston.

The HRDITB is equipped with (A) an impacted system serving as the load, (B) pressure sensors mounted on the rock drill to record pressure variations in the rear braking chamber, and (C) a laser displacement sensor to track piston movement.

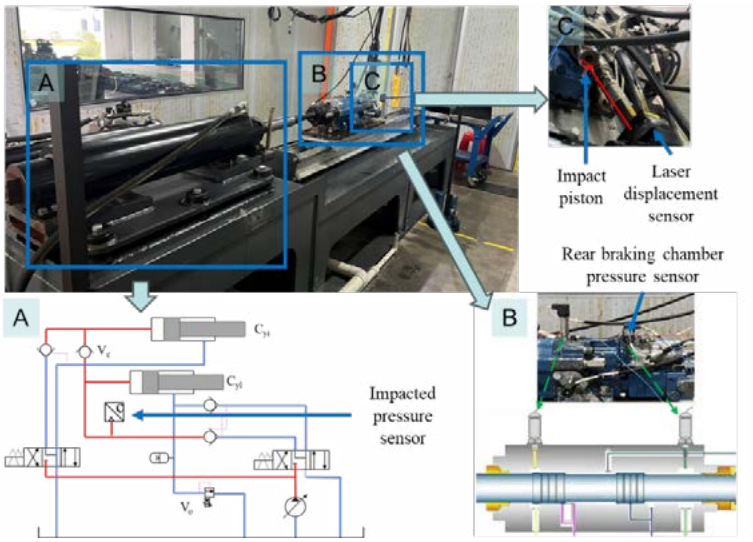

Fig 3.1 Hydraulic rock drill impact test bench

The load from the impacted system is generated by a hydraulic circuit where the impact cylinder (Cyi) is connected to a loading cylinder (Cyl). The pressure in the rodless chamber of Cyl is controlled by an overflow valve (Vo), thereby establishing a stable pressure differential across the intervening check valve. This differential pressure is the definitive load provided by the system. The sensors parameters are shown in Table. 3.1.

Sensor	Model	Range	Accuracy	Sample Rate
Laser displacement sensor	TS803-140/100	140~240 mm	± 0.05% FS	8192Hz
Pressure sensor	YN-63-IV-400	0~400 MPa	± 0.5% FS	8192Hz

Table. 3.1 Sensors used in the HRDITB

3.2 Motion and pressure variation characteristics of the impact piston in the rear braking chamber

Based on the mechanical structure, the position at which the impact piston enters the rear braking chamber is identified as x_{bl} = 58.5 mm. As shown in, the laser displacement data

confirm that the piston travels beyond this point. A calculation of the piston's velocity reveals that it decelerates abruptly within the braking chamber. Thus, the braking phase is defined by the piston's velocity.

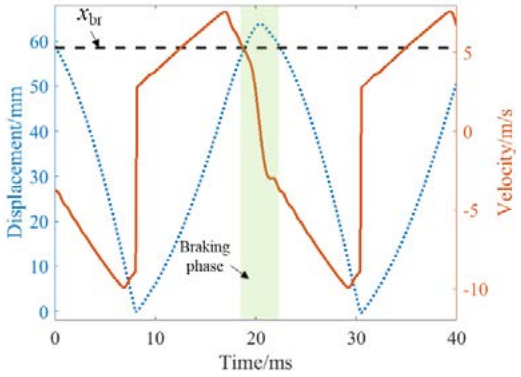

Fig 3.2 Braking phase in the motion of the impact piston

Based on Fig 3.2, the motion of the impact piston within the braking chamber (the braking phase) can be defined. To further analyze the relationship between piston motion and pressure changes during this process, the braking phase is subdivided according to the relative pressure relationship between the braking chamber and the rear chamber. The correlation between the piston's penetration distance into the braking chamber (x_{pb}), as well as the piston velocity, with the chamber pressure are separately shown in Fig 3.3.

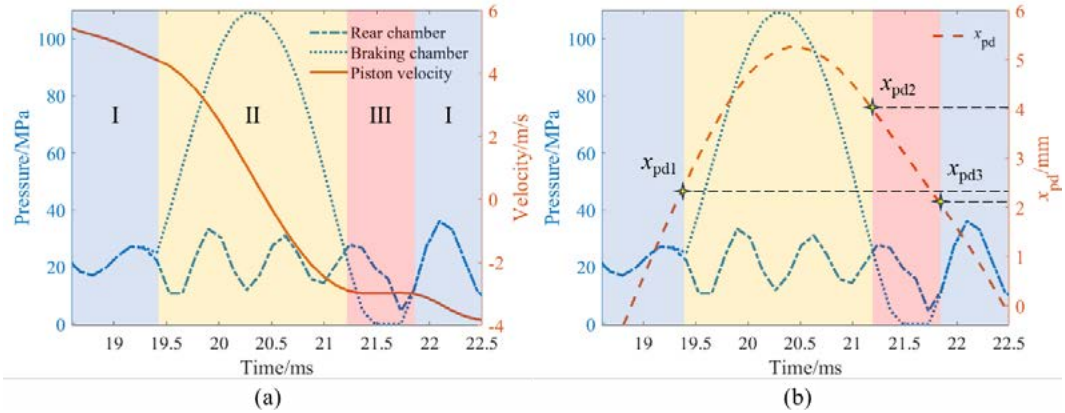

Fig 3.3 Motion and pressure variation in the rear braking chamber

As shown in Fig 3.3, the braking phase can be further divided into three states:

In part I, the braking chamber pressure equals the rear chamber pressure, the piston has entered the rear braking chamber less than 2 mm. During this state, the braking chamber does not form a sealed cavity. For most of the time, the pressure in the braking chamber equals that in the rear chamber. However, as the impact piston approaches the transition point x_{pd1} or x_{pd3}, a minor pressure difference arises between the braking chamber and the rear chamber due to localized throttling effects.

Then in part II, the braking chamber pressure exceeds the rear chamber pressure, the piston has entered the rear braking chamber between 2~5.3 mm. During this phase, the braking chamber is nearly fully sealed and functions approximately as a hydraulic spring on the impact piston, resulting in a linear change in piston velocity.

Part III occurs only when the impact piston exits the braking chamber, typically at a position about 4 mm within it. At this point, the braking chamber remains sealed, and the lack of fluid replenishment causes a sharp drop of the pressure in braking chamber as the piston moves. Consequently, the braking chamber no longer provides the outward thrust on the piston. Since the resistance from the front chamber pressure is relatively low, the piston exhibits a state of uniform motion during this phase.

Vapor cavitation is defined as the phase change resulting from a rapid drop in local pressure below the fluid's saturated vapor pressure. Hence the rapid pressure-drop in part II and the negative pressure in part III are the core elements of the appearance of the cavitation. Therefore, this study employs an experimental approach to investigate the influence of the clearance size on the pressure dynamics within the braking chamber, aiming to identify the optimal clearance value for mitigating cavitation in the current design.

4 Result analysis and discussion

Based on the analysis of the impact piston's motion within the braking chamber and the corresponding pressure variation in the chamber, it can be concluded that cavitation erosion on the rear guide sleeve is associated with the local negative pressure generated during the part III of the piston braking phase, as well as the piston's movement. During this state, the sealing length formed between the piston and the cylinder is insufficient to fully isolate the

braking chamber. As a result, high-pressure oil from the rear chamber flows into the braking chamber through this restricted passage via throttling. This flow, combined with the pressure drop induced by the piston's motion, ultimately leads to the occurrence of local cavitation.

To investigate the influence of different clearances on the pressure variation in the braking chamber and the motion of the piston within it, this study designed three sets of experiments with varying clearances for comparative analysis. In the experiment, the clearance between the braking chamber and the impact piston was controlled by adjusting the diameter tolerance of the cylinder's braking chamber. ISO VG 46 hydraulic oil was used in the tests, and the oil temperature was monitored via a temperature sensor installed in the tank. All experiments were conducted with an initial oil temperature of 60°C. Given the short duration of each test, it was assumed that the internal oil temperature of the rock drill remained consistent with the oil temperature in the tank.

The corresponding peak pressure (p_{brm}) in the braking chamber, the maximum penetration distance of the piston into the braking chamber (x_{pdm}), and time from piston entry into to exit from the braking chamber (t_{br}) for each clearance h are presented in Tab 4.1.

h /mm	p_{brm}/MPa	x_{brm}/mm	t_{br}/ms
0.02	114.1	1.6	1.7
0.04	120.5	5.25	3.8
0.083	108.6	5.17	3.3

Tab 4.1 Peak braking chamber pressure and critical impact piston motion parameters under different clearances

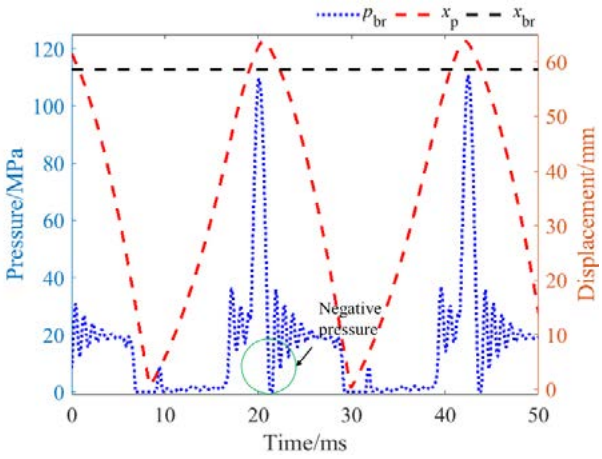

Fig 4.1 Clearance h = 0.083 mm, pressure and impact piston motion variations in the braking chamber

As shown in Fig 4.1, the original structural clearance h = 0.083 mm. Under this clearance, a high-pressure zone exceeding 100 MPa is formed in the braking chamber due to compression by the penetrating impact piston. Since the sealing length formed between the piston and the cylinder at this stage exceeds 5 mm, insufficient oil replenishment occurs in the braking chamber during the piston's outward movement, resulting in a negative pressure zone. This zone corresponds to the part III in Fig 3.3 and is the primary cause of cavitation in the braking chamber region.

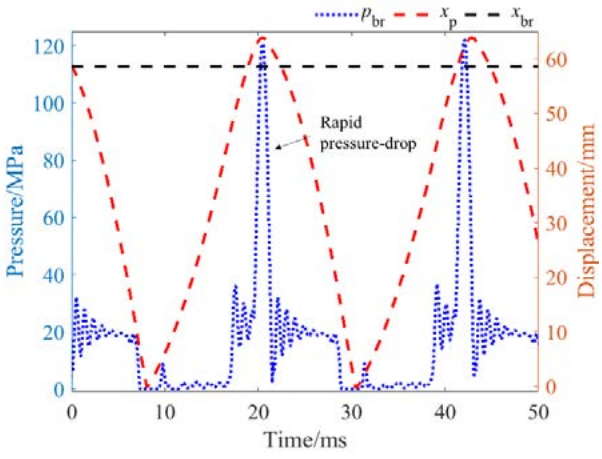

Fig 4.2 Clearance h = 0.04 mm, pressure and impact piston motion variations in the

braking chamber

As shown in Fig 4.2, the reduction in clearance accelerates the high-pressure buildup process in the

rear braking chamber, increase

ng the maximum peak pressure by approximately 12 MPa. However, the change in x_{brm} is minimal, so the pressure loss in the braking chamber caused by the outward motion of the impact piston remains essentially the same as when the h is 0.083 mm. Nonetheless, due to the increased p_{brm}, it does not enter a negative pressure state.

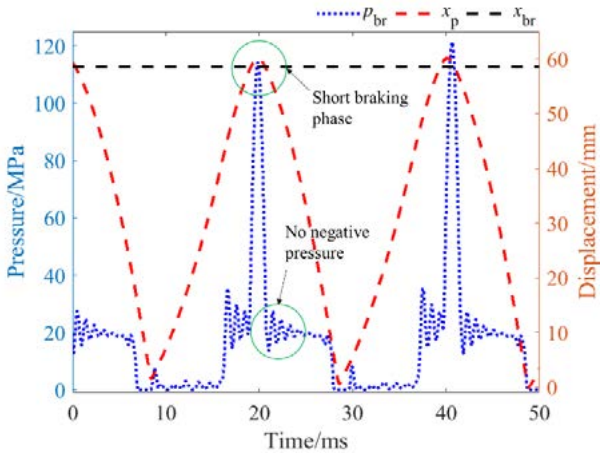

Fig 4.3 Clearance h = 0.02 mm, pressure and impact piston motion variations in the braking chamber

As shown in Fig 4.3, further reducing the clearance to 0.02 mm significantly decreases the sealing length required for the braking chamber to build high pressure. In this case, x_{brm} is only 1.6 mm, which is far smaller than the value under larger clearance conditions. Evidently, the increase in p_{brm} and the shortening of x_{brm} resulting from the reduced clearance jointly diminish the likelihood of the braking chamber entering a negative pressure range. Consequently, under this clearance condition, the rear braking chamber will be free from cavitation risk. However, as the tolerance for the guide sleeve is 0.015 mm, if the clearance h is set too close to this tolerance, it may impair the guiding function of the guide sleeve and significantly increase the probability of wear between the cylinder and the piston. Therefore,

the actual selected clearance value should be greater than twice this tolerance.

Based on the above analysis, it can be determined that the ideal clearance value should fall within the range of 0.03 to 0.083 mm. To explore the optimal parameters within this range, the impact performance of each group of rock drills was compared, and the results are presented in Tab 4.2 and Fig 4.4.

h	Stroke/mm	Impact energy/J	Impact frequency/Hz	Impact power/kW
0.04	60.1	361	49.4	17.8
0.06	63.5	327	46.8	15.3
0.083	63.6	331	46.3	15.3

Tab 4.2 Hydraulic rock drill impact performance under different clearances

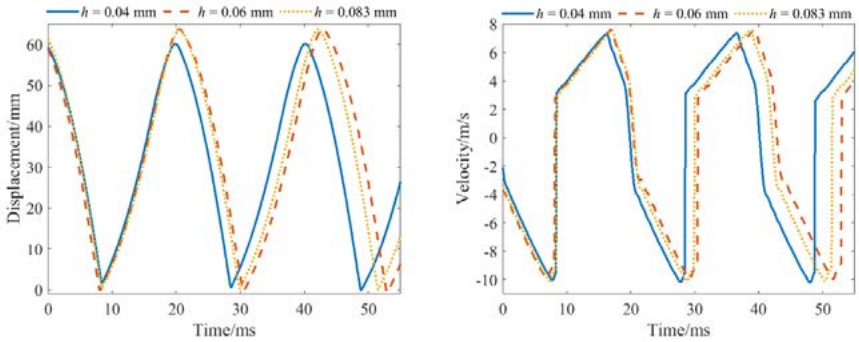

Fig 4.4 Hydraulic rock drill impact performance under different clearances

Based on Fig 4.1~Fig 4.4 and Tab 4.2, when the clearance value is between 0.06 and 0.08 mm, reducing the clearance only increases p_{brm} and lowers the risk of the braking chamber entering a negative pressure state during the piston's outward motion. However, when the clearance is reduced to 0.04 mm, this reduction significantly affects the sealing length required for the rear braking chamber to close, shortening x_{brm} and thereby reducing the total travel of the impact piston and increasing the impact frequency. At the same time, due to the reduction in energy loss within the braking chamber, the impact energy per piston stroke is also enhanced, leading to an overall improvement in the impact power of the rock drill.

5 Conclusion

This study, addressing the cavitation erosion issue in the rear braking chamber of a rock drill's cylinder, systematically investigated the influence of different clearance fits on the chamber's pressure dynamics in response to piston motion. The following principal conclusions were drawn:

(1) Cavitation in the braking chamber of a rock drill primarily occurs during the outward motion of the impact piston from the chamber. When the piston is approximately 4 mm away from exit the braking chamber, the braking chamber and the rear chamber gradually become connected. Due to the extremely low pressure in the braking chamber at this stage, the high-pressure oil from the rear chamber rushes into the braking chamber at high speed, leading to cavitation in the oil. This, in turn, causes vapor erosion on the adjacent guide sleeve.

(2) The clearance primarily influences the x_{brm} by affecting the rate of pressure buildup within the chamber. When the x_{brm} is less than 2 mm, the pressure drop in the braking chamber induced by the piston during the impact stroke is insufficient to create a negative pressure zone, thus preventing oil cavitation. However, if the clearance approaches the tolerance of the guide sleeve, it can impair the sleeve’s guiding function, leading to wear between the piston and the cylinder and reducing the piston's service life. Therefore, based on a comprehensive analysis of the experimental results, the optimal clearance for the model studied in this paper is approximately 0.04 mm.
