This volume constitutes a preprint edition of the conference proceedings and is intended solely for distribution to participants of the conference. The papers included herein have not yet undergone final editorial processing or formal publication. The final, citable versions of the contributions will be published subsequently by the designated publisher.

Germany, Aachen, 2026

WELCOME TO THE 15TH INTERNATIONAL CONFERENCE ON FLUID POWER (IFK)

The current economic and societal environments both present the fluid power community with significant challenges and important opportunities. The mechanical engineering sector faces economic uncertainty, volatile markets, geopolitical complexity, and a persistent shortage of skilled workers. At the same time, climate change and sustainability demands require focused and forward-looking action. Strengthening innovation, competitiveness, and technological progress is therefore essential.

Against this backdrop, the 15th International Fluid Power Conference operates under the motto "Fluid Power: Enabling Future Technologies." As a proven and robust technology, fluid power must be continuously advanced through creative and interdisciplinary approaches to remain a key enabler of future technologies. By bringing together science and industry, the IFK fosters exchange, collaboration, and innovation. In particular, artificial intelligence, machine learning, and digitalization are recognized as decisive drivers for the long-term competitiveness of fluid power in both research and industrial applications.

The IFK is one of the world's largest scientific conferences in fluid power. Since its first edition in 1974 in Aachen by Prof. Wolfgang Backé, it is now a leading forum for high-level scientific exchange and networking across the entire fluid power community. In 2026, the IFK is taking place again in Aachen and will be for the first time jointly organized with the GFPS Ph.D. Symposium, further strengthening international exchange and the integration of young researchers.

This year's program features 4 plenary lectures, 18 overview lectures, and 102 scientific presentations. Speakers from 21 countries underline the strong international character of the conference. Of the contributions, 52% originate from Germany, and 48% from international institutions and companies. In addition, 18 exhibitors will present their latest innovations in the accompanying exhibition.

The conference begins on Monday with the Symposium, focusing on scientific contributions from academia and industrial research. The day concludes with a networking get-together at the accompanying exhibition.

On Tuesday morning, the official opening ceremony will take place, with welcoming addresses and an international overview of current developments in academic fluid power research worldwide. To sharpen the technological look ahead, the following two plenary lectures focus on the role of artificial intelligence and digital twins in fluid power technology and applications. Tuesday's program places particular emphasis on industrial contributions and application-oriented topics, and concludes with a gala dinner in the Coronation Hall of Aachen City Hall, offering a distinguished setting for further exchange.
On Wednesday, the conference continues with additional technical sessions and concludes with a farewell event and the presentation of the Best Paper Awards for both the IFK and the GFPS Ph.D. Symposium.

Finally, we express our sincere gratitude to all committee members, speakers, authors, reviewers, session chairs, and exhibitors for their commitment and support. We wish all participants an inspiring and rewarding 15th IFK in Aachen and hope that this conference will provide valuable impulses for future research, innovation, and collaboration in fluid power technology.

Univ.-Prof. Dr.-Ing. Katharina Schmitz

PROGRAM COMMITTEE

Bauer, F.	Dr.-Ing., Hydac Technology GmbH, Sulzbach/Saar
Beck, M.	Dr.-Ing., Emerson Automation Solutions AVENTICS GmbH, Laatzen
Brahmer, B.	Dipl.-Ing., J.M. Voith SE & Co. KG I VTHL, Stuttgart
Brinkschulte, L.	Dr.-Ing., ARGO-HYTOS GmbH, Kraichtal
Boes, C.	Dr.-Ing., MOOG GmbH, Böblingen
Faß, U.	Dr.-Ing., Volvo Construction Equipment Germany GmbH, Konz
Fiedler, M.	Dr.-Ing., J. Schmalz GmbH, Glatten
Finzel, R.	Dr.-Ing., Wacker Neuson Linz GmbH, Hörsching, AT
Flaig, A.	Dr.-Ing., Bosch Rexroth AG, Lohr am Main
Fuchs, M.	Dipl.-Ing., Bürkert Werke GmbH, Ingelfingen
Gauchel, W.	Dr.-Ing., Festo SE & Co. KG, Esslingen
Geis, C.	Dr.-Ing., VDMA, Frankfurt a.M.
Hunger, J.	Dr.-Ing., Walter Hunger GmbH & Co. KG
Kohmäscher, T.	Dr.-Ing., Claas KGaA mbH, Harsewinkel
Krieg, M.	Dr.-Ing., Bosch Rexroth AG, Lohr am Main
Leifeld, R.	Dr.-Ing., Maschinenfabrik Bernard KRONE GmbH & Co. KG, Spelle
Lüüs, H.	Dipl.-Ing., Bucher Hydraulics GmbH, Klettgau
Merkelbach, S.	Dr.-Ing., Norgren GmbH, Alpen
Rahmfeld, R.	Dr.-Ing., Danfoss Power Solutions GmbH & Co. OHG, Hamburg
Roosen, K.	Dr.-Ing., Parker Hannifin GmbH, Kaarst
Schmitz, K.	Prof. Dr.-Ing., RWTH Aachen
Schultz, A.	Dr.-Ing., Magnet-Schultz GmbH & Co. KG, Memmingen
Schulze Schencking, D.	Dr.-Ing., Hauhinco Maschinenfabrik GmbH & Co. KG, Sprockhövel

PAPER OVERVIEW

DAY 1 09:30-10:30

SYMPOSIUM: OPENING SPEECH

Prof. Dr. Huayong Yang	Development of inspection and replacement robots for excavation tools of Tunnel Boring Machine (TBM)	19

M1 - SYMPOSIUM: MOBILE SYSTEMS

Zezhou Wang	Automated Steering Control for Articulated Off-Highway Machines	35
Dr. Matteo Bertoli	Design and Application of a Prediction Model of the Loads and Mission Profile for Hydraulic Steering System in Heavy-Duty Off-Road Vehicles	55
Jiaming Wu	Power optimization strategy design for electric wheel loader work function with variable speed and pump displacement control	75

M2 - SYMPOSIUM: CONTROLS

Simo Käki	A PID Controller Gain Adjustment Mechanism to Balance EHA Tracking and Health	93
Amy Rankka	Machine Learning Based Controller for Energy-Optimized Operation of Hydraulic Loader Cranes	110
Dr. Junjie Mi	Multidimensional Neural Networks Based RISE Control for Hydraulic Manipulators with Disturbances Compensation	128

M3 - SYMPOSIUM: TRIBOLOGY

Marius Hofmeister	Determination of Gas Solubility for Technical and Flammable fluids	145
Dr. Ana Trajkovski	Evaluating sliding properties of selective laser melted maraging steel against aluminium alloys in water and hydraulic oil	163
Pascal Moor	Performance evaluation of a wear test rig for positive displacement pumps	183

PAPER OVERVIEW

DAY 1 11:00-12:40

M4 - SYMPOSIUM: COMPONENTS PUMPS I

Roman Ivantysyn	Electrification-Ready Tribology:Experimental and Simulation Insights into Wear and Performance of Surface Optimized Valve Plates	197
Matthias Vogt	Analysis of Structure-Borne Noise Emissions of Axial Piston Pumps Using Blocked Forces and Virtual Point Transformation	225
Thomas Heeger	Review of Single-Sided and Double-Sided Axial Piston Machine Characteristics	240
Ishan Suvarna	Optimization of the Cylinder Block-Valve Plate Interface Considering Coupled Interaction from Piston Dynamics and Shaft Deformation	256
Dr. Rongfu Tang	New Prototype of High-Speed External Gear Pump with Filling Oil from Tooth Root	277

M5 - SYMPOSIUM: MOBILE APPLICATIONS

Dr. Lulu Gao	Duty-based Dumping Control for Underground Load-Haul-Dump Vehicle Based on Reinforcement Learning	295
Hongyun Mu	Energy efficiency evaluation of hybrid distributed-centralized load sensing system for electrified excavator	311
Paulo Leonel Teixeira	Innovative fan drive solution for mobile machines	327
Yihan Qiao	An Electro Hydraulic Hybrid System to Downsize Motor Power of Electric Wheel Loader Working Function	344
Yangxiu Xia	Motion Control of Multi-DOF Hydraulic Manipulator Driven by Independent Metering System with Friction Compensation	363

M6 - GFPS SYMPOSIUM: SYSTEMS & COMPONENTS

Marcel Steidle	Direct model reference adaptive control (MRAC) augmented frameworks for load pressure and position control of servo-valve controlled hydraulic cylinders	379
Seshan Calapatti Suresh	Design Overview and Performance Assessment of an Integrated Electro-Hydraulic Actuator (iEHA)	397
Lukas Boden	Non-destructive Detection of Fatigue Cracks in Hydraulic Components	415
Fabian Blatter	Investigation of Fatigue Crack Growth Under High Pressure Gradients with Fluid-Structure Interaction Model	433

PAPER OVERVIEW

DAY 1 13:40-15:00

M7 - SYMPOSIUM: SYSTEMS & ENERGY I

Vili Vironmäki	Feasibility of Electro-Hydrostatic Actuators in Wheel Loader Application: A Case Study Focusing on Energy Efficiency, Controllability and Thermal Behaviour	451
Dr. Bobo Helian	Automation Framework for Constrained Optimal Trajectory Planning and Adaptive Robust Motion Control of Electrohydraulic Mobile Machines	469
Artur Tozzi de Cantuaria Gama	Exploratory Analysis of Optimisation Results for the Multi-Pump System Using Data-Driven Methods	485
Ruiyao Tao	Analysis of High-Pressure Pneumatic Stage Separation System for Reusable Launch Vehicles Based on Real Gas Equation of State	499

M8 - SYMPOSIUM: COMPONENTS VALVES

Yuhang Zhang	Radial Flow Force Reduction for Hydraulic Spool Valve Core using Balanced Orifice Design	515
Krishna Bhaskar	Modelling and Analysis of the Performance for a Pressure Compensated Flow Control Valve	533
Junhao Chen	Thermal–fluid coupling analysis of the Deflector Jet Servo Valve: effects of internal air region, oil viscosity, and coil heat source	549
Timo Rothhardt	Model-Based Valve Design: Potential of CFD Simulations as a Database for Prediction Models	565

M9 - GFPS SYMPOSIUM: PUMPS & TRIBOLOGY

Felix Schlegel	Experimental Comparison of Polymer and Non-Ferrous Metal Slippers for Oil-Hydraulic Axial Piston Machines	583
Avae Béatrice Carla Berger	Modeling and Simulation of Oil Film Influence on Hydraulic Piston Pump Vibrations	601
Yuhan Song	Grain Microstructural Evolution of Friction Layers in Piston Pump Friction Pair	619
Dingchong Lyu	Physics-Informed Neural Network-Based Prediction of Mixed Lubrication Characteristics in Cylinder Block/Valve Plate Interfaces via Mechanism-Data Integration	635

PAPER OVERVIEW

DAY 1 15:30-17:30

M10 - SYMPOSIUM: SYSTEMS & ENERGY II

Harsh Kulkarni	Multi-Objective Optimization of Kfloid-Type Gerotor Pumps for High-Pressure Applications	653
Tobias Vonderbank	Beyond Pilot Control: A Prototype for Direct Actuation of Large Industrial Proportional Valves	669
Dr. Nejc Novak	Innovative Approach to Cleaning and Cleanliness Control of Newly Manufactured Hydraulic Assemblies	687
Christa Düsing	Automated Processing of FMEA-Induced Fault-Injection Simulation for Safety Functions in Dangerous Machinery	707
Dr. Qianpeng Chen	Hydraulic Spool Valve Contamination Susceptibility Test and Visualization Study of Clearance Particle Ingress-Aggregation Phenomenon	725

M11 - SYMPOSIUM: COMPONENTS PUMPS II

Prof. Dr. Gudrun Mikota	Performance analysis of rotary mechanical pulsation compensators for different types of pumps	741
Alfonso Rosario Apuzzo	Enhancing Volumetric Efficiency and Productivity of External Gear Pumps through Optimized Run-In Strategies.	757
Svenja Horn	Influence of surface structuring on the hydrostatic and hydrodynamic pressure distribution of slipper sealing lands	775
Liangyu Song	Effects of contamination on the wear process of piston/cylinder interface in axial piston machines considering three-body abrasive wear model	795
Dr. Komsan Ngamkham	Hydraulic Oil Temperature in Bridge Circuit and Hydraulic Bent Axis Piston as Load	811

M12 - GFPS SYMPOSIUM: MOBILE APPLICATIONS

Mohamed Allam	High-Resolution Force Control in a Multi-Pressure Hydraulic System for Excavator Work Functions	823
Dr. Zhixin Yan	Research on the Performance of a Heavy-Duty Robotic Arm Featuring Pump-Valve Coordination and Independent Metering Control with Hydraulic-Pneumatic Energy Storage	841
Bernhard Sender	Operator effect on the performance of a wheeled excavator	859
Róger Mateus Sehnem	Optimal preliminary design of electro-mechanical actuators over drive-cycle for mobile machinery	875
Daniel Kriegl	Universal and Highly Efficient Speed Control of the Hydraulic Motor in a Wire Saw Unit for a Hybrid Constant Flow and Constant Pressure System	891

PLENARY LECTURES

DAY 2 09:00 - 12:30

Prof. Dr. Katharina Schmitz (ifas), Dr. Ralf Otten (Mayor Aachen), Prof. Dr. Wolfgang Schröder (Dean RWTH), Dr. Christian Geis (VDMA)	Opening	
Prof. Dr. Huayong Yang (ZJU), Prof. Dr. Andrea Vacca (Purdue), Prof. Dr. Marcus Geimer (KIT)	Fluid Power Research Worldwide	
Dr. Steffen Haack (Bosch Rexroth)	AI in Fluid Power Technology	
Prof. Dr. Katharina Schmitz (ifas)	Digital Twins and AI in Fluid Power: Improving Systems by Connecting Real and Virtual Worlds	907

PAPER OVERVIEW

DAY 2 13:30-14:40

T1 - CONFERENCE: CONTROLS

Dr. Dirk Wroblewski	Next generation of intelligent electro-hydraulic control valve actuation	925
Filip Vlach	Push-pull electromagnet in hydraulics	939
Dr. Siegfried Rotthäuser	Recuperation on a transmission test bench	949

T2 - CONFERENCE: COMPONENTS PUMPS

Patrick Fischer	Next Generation Fixed Displacement Pumps for Electrified Mobile Applications	959
Alexandre Vucemilovic	Experimental study of the influence of the channel geometry of regenerative pumps on their internal flow	977
Nandakumar P S	Navigating Electrification Challenges: Low speed behavior of external gear units	995

T3 - CONFERENCE: ARTIFICIAL INTELLIGENCE

Faras Brumand-Poor	Geometry-Aware Physics-Informed Neural Network: A Framework for Solving the Reynolds Equation with Starvation for Lubricated Contacts	1013
Vaishnavi Kulkarni	Information Extraction from Various Formats for Engineering Decisions	1029
Maximilian Romeser	Enabling Vibroacoustic End-of-Line Testing of APUs Across Varying Fluid Temperatures through ML-based Conditional Anomaly Detection	1047

PAPER OVERVIEW

DAY 2 15:30-17:00

T4 - CONFERENCE: MOBILE SYSTEMS

Fabian Kreutmayr	Case Study on Independent Metering Hydraulics for Energy-Efficient Battery-Electric Telescopic Loaders	1065
Dr. Marcel Neu	Efficient holistic system simulation method for the analysis of thermal-management concepts for electrified construction machinery through inverse hydraulic modelling	1083
Prof. Dr. Lasse Schmidt	On Displacement Controlled Drive Networks	1099

T5 - CONFERENCE: COMPONENTS VALVES

Dr. Kristof Schlemmer	Development of a flow-optimised slip-in servo cartridge valve for high-performance applications	1115
Dr. Seiei Masuda	Modeling and Simulation of Damping Orifices for Pressure Control Valves (2nd Report)	1131
Keitaro Kamata	The optimal design of hydraulic pump performance and reliability through lubrication, mechanism, and structural coupling analysis	1149
Harsh Maniar	Performance Improvement of Pressure Compensated Flow Control Valve Using Virtual Engineering	1159

T6 - CONFERENCE: FLUIDS

Wolfgang Bock	Fluid Solutions (Innovative and sustainable hydraulic fluid concepts)	1171
Klaus Ellenrieder	Evaluating Hydraulic Fluids for Performance and Sustainability: Bosch Rexroth's Approach	1179
Sebastian Deuster	Influence of Fluid Mechanical Properties of Hydraulic Oils with Different Chemical Structur on the Efficiency of Hydraulic System Components	1189
Dr. Dmitriy Shakhvorostov	Advanced Hydraulic Fluids Make Mobile Machinery Not Only More Sustainable, but Also More Economical	1205

PAPER OVERVIEW

DAY 3 09:00-10:30

W1 - CONFERENCE: DIGITAL TRANSFORMATION

Dr. Mark Krieg	Digitalization & Standardization: Enablers for the Future of Industrial Hydraulics	1217
Dr. Vinay Partap Singh	Machine Learning- Based Health Monitoring of High-Power Electro-Mechanical Actuator for Non-Road Mobile Machinery Using Experimental Data	1225
Moritz Neltner	Digitaliztion in Sustainability for Fluid Power Components and Systems	1243
Simon Knoll	Predicting leakage and operating conditions in axial piston pumps using vibration-based machine learning	1257

W2 - CONFERENCE: MOBILE APPLICATIONS I

Thorsten Stiller	Improved System Efficiency thorugh Drained Case Operation of Axial Piston Units	1275
Dr. Fabio Scolari	Real time fault detection in hydraulic system for wheel loader application	1287
Sai Kishore Ayalasomayajula	Enhancing Energy Efficiency in Drilling: Innovative Pipe Handling with Hydraulic Energy Recovery	1305
Dr. Matteo Pellegri	Dextreme MAX: A Digital Displacement® Excavator System for Energy Recovery and Reduced Losses	1323

W3 - CONFERENCE: PNEUMATICS I

Dr. Wolfgang Gauchel	Environmental Sustainable Pneumatics	1341
Vladimir Boyko	Real-Time Fault Detection in Pneumatic Drive Applications Through Pattern Classification	1365
Prof. Dr. Olivier Reinertz	Quasi-Isobaric Compressed Air Reservoirs	1381
Prof. Dr. Zeljko Situm	Integration of Pneumatic Systems in Training Devices for Combat Sports	1399

PAPER OVERVIEW

DAY 3 11:00-12:30

W4 - CONFERENCE: NET ZERO

Prof. Dr. Lasse Schmidt	Estimating the Global Emissions by Fluid Power Machinery	1411
Dr. Andreas Schumacher	Decarbonization in mobile machinery – from reducing the carbon emissions to emission-free drive-trains	1427
Felix Ruthmann	Calculating use-phase greenhouse gas emissions of hydraulic components	1439
Heiko Steinbach	A Holistic Approach Towards Energy Efficient Excavators	1457

W5 - CONFERENCE: INDUSTRIAL

Dr. Johannes Gattinger	Innovative self-sufficient clamping system for machine tools	1469
Dr. Zhiqiang He	Digital Architecture Design and Implementation for Performance Optimization of Electromechanical-Hydraulic Systems: A Case Study on Injection Molding Machines	1479
Dr. Mark-Patrick Muehlhausen	Downsizing of hydraulic power units by accurate prediction of disperse flows	1497
Reiner Stammberger	Sensor-Efficient Health Monitoring for Brownfield Industrial Hydraulic Systems	1507

W6 - CONFERENCE: PNEUMATICS II

Dr. Harald Kuolt	Energy-efficient handling through passive vacuum generation and biomimetic functional principles	1525
Philipp Hüpper	Development and Experimental Validation of a Novel Origami-Inspired Pneumatic Actuator Concept with Progressive Force-Stroke Characteristics	1541
Micha Koebele	AAS-Orchestrated Production – End-to-End Digital Integration from Machine to Visualization	1557
Cong Liu	CFD-Based Optimization of a Supersonic Vacuum Ejector Using Combined 2D–3D Simulations and Latin Hypercube Sampling	1573

PAPER OVERVIEW

DAY 3 13:30-15:00

W7 - CONFERENCE: FLUID 4.0

Paul Remde	Digital fluid technology in the data space: From semantic component search to the development of mobile hydraulic systems using AAS	1591
Fabian Geibel	Vertical Integration of Energy Data - an Architectural Evaluation of Asset Administration Shell (AAS)	1613
Dr. Heiko Baum	System Simulation Meets Asset Administration Shell – Potentials and Challenges of a Standardized, Model-Based Development of Fluid Power Systems	1631
Barkha Sharma	Unlocking Semantic Interoperability in Industry with Large Language Models	1649

W8 - CONFERENCE: MOBILE APPLICATIONS II

Heiko Laffrenzen	Best of both worlds – load dependent and load independent hydrostatic driving switchable on-demand with innovative hybrid electro-proportional control	1667
Ralph Wassermann	High efficient Hydraulic Actuator Valve Sensor Unit without dedicated hydraulic supply	1683
Felix Figge	EHAs in mobile machinery: Experimental validation of a high-speed EHA with recuperation and load-holding capability	1699

W9 - CONFERENCE: SEALS

Dr. Niklas Bauer	Beyond PFAS: Challenges and Opportunities in Material Innovation for replacing PTFE in Hydraulic Seals	1717
Jiehao Wang	Percolation Analysis of Reciprocating Sealing Surfaces Based on the Statistical Evolution of HPD and PSD Induced by Wear	1735
Diego Manuel Chamorro	Wear modeling and sensitivity analysis for seals in hydraulic cylinders.	1753

PAPER OVERVIEW

DAY 3 15:30-17:00

W10 - CONFERENCE: DATA & SENSORS

Markus Fritton	Novel ultrasonic position sensor for hydraulic clamping cylinders	1771
Dr. Benedikt Müller	From Pressure Pulses to Noise Sources – NVH-Oriented Design of Hydraulic Systems	1783
Olaf Kissing	Current developments in magnetostrictive position sensors	1801

W11 - CONFERENCE: ADDITIVE MANUFACTURING & MATERIALS

Zita Tappeiner	Additive Manufacturing in Hydraulics: Design Methodologies for Manifolds	1811
Jan Bartolj	3D-Printed Polymer and Ceramic Spools as Alternatives to Steel for Hydraulic Valves	1829
Johannes Klotz	Hydraulic Substitute Base for Demolition Hammers	1847

W12 - CONFERENCE: SPECIAL APPLICATIONS

Prof. Dr. Mathias Niebergall	Hydraulic Artificial Muscles for Exoskeleton Actuation Solutions	1863
Dr. Christian Lessmeier	New hydrogen fuel lines from carbon steel tubes and their qualification for high-pressure hydrogen applications	1881
Dr. Enrico Pasquini	From Turbulence to Tranquillity: A Multidisciplinary Blueprint for Optimising Liquid Cooling in Precision Machinery	1891
Weihang Xi	Research of the cavitation in the rear brake chamber of hydraulic rock drill	1907

THE OPTIONAL PEER REVIEW

Many public institutions that support research projects require a regular publication of their results. To ensure that these results are in fact of scientific value, the assessment by a third party is often required. This process is known as peer-review and due to its demanding logistics is increasingly rare. The Institute for Fluid Power Drives and Systems (ifas) and organizers of the 15th IFK in Aachen wanted scientists to have the opportunity to have their work reviewed accordingly, so as to demonstrate its scientific value.
By tradition, the IFK unites scientists with industry in an international forum to exchange their knowledge. Therefore, a peer-review only makes sense for some of the authors. At this juncture, ifas would like to point out that the peer-review is intended in no way to classify the papers, but only to support the need for review.
The reviewed papers and the corresponding presentations are tagged with the sign below in the Scientific Programe.

Development of inspection and replacement robots for excavation tools of Tunnel Boring Machine (TBM)

Huayong Yang[1,2], *Cheng Wang*[1,2], *Haibo Xie*[1,2]

1 State Key Laboratory of Fluid Power and Mechatronic Systems, Zhejiang University, Hangzhou, China

2 Institute of Advanced Machines, Zhejiang University, Hangzhou, China

Abstract.

The cutterhead of a tunnel boring machine (TBM) operates in a confined, high-pressure, high-humidity environment where manual inspection and replacement of excavation tools is risky and time-consuming. To enable robotised maintenance, we developed a TBM inspection-and-replacement system composed of a snake-like inspection robot and a heavy-load disc-cutter replacement robot. For inspection, a compact cable-driven snake robot is designed to work at pressures up to 2 MPa and temperatures up to 65 C, integrating cleaning, lighting, and zoom imaging to achieve high-precision tool wear assessment. For replacement, a 6-DOF PRRPRR manipulator driven by electro-hydrostatic actuators (EHAs) is developed for heavy-load, constrained-space operation. A position-pressure feedback control (PPFC) method is proposed to improve the system response and position accuracy. Field deployment on the 'Pioneer II' TBM in the Shenzhen Airport metro project validates the robustness and effectiveness of the system.

Keywords. TBM maintenance robots; snake-like inspection robot; disc cutter replacement; electro-hydrostatic actuator; trajectory planning; adaptive control.

1. INTRODUCTION

Urban rail transit expansion and large-diameter tunnel construction have led to a sharp increase in TBM usage. Disc cutters on the cutterhead suffer severe wear and damage due to rock-breaking loads, and their condition directly affects excavation efficiency and safety.

In deep-buried and high-water-pressure projects, manual inspection and replacement require working under high pressure, poor visibility, and muddy conditions, which introduces significant safety risks and long downtime. Engineering statistics report that tool inspection and replacement can occupy a substantial fraction of the excavation schedule and a large share of project cost, while a large proportion of TBM-related accidents are associated with manual cutter maintenance.

Robotised maintenance is therefore essential to reduce human exposure and improve machine utilization. A complete system must provide reliable inspection, accurate wear assessment, and safe replacement in a confined environment, while coordinating with the TBM control architecture.

Recently, research institutes and companies worldwide have started to develop robotic systems for cutterhead inspection and tool replacement to overcome the limitations of manual in-chamber operations and to move toward robots instead of humans. Herrenknecht has developed an auxiliary cutter inspection robot [1]. The main body uses a folding arm, with lighting, a camera, and a high-pressure water device at the end, plus an industrial endoscope that can pass through the cutterhead to observe tools; the system is still under development. OC Robotics built a snake-like inspection prototype, JetSnake [2], and tested it in the Port of Miami and the Hong Kong International Airport projects. Public information indicates that their tests were performed only at atmospheric pressure, without reliability validation under high-pressure and high-humidity conditions [3]. The University of Tokyo designed a cutter inspection robot for a 5 m class TBM, WInBot [4], with a telescopic structure [5] that can extend 2.7x vertically and 1.5x horizontally, enabling operation in narrow spaces around the cutterhead. However, its limited DOF allows inspection in only one direction, and no field application has been reported. CREG invented a shield machine inspection robot system [6] using a telescopic design to wash and inspect cutters. CSIC Haiwei Zhengzhou High-Tech Co. proposed a snake robot for shield inspection [7] that remains at the proof-of-concept stage. Beijing Institute of Petrochemical Technology developed a folding-arm cutterhead cleaning robot [8] that can clean cutters with a high-pressure water gun and observe the excavation chamber, but it did not address the complex soil chamber environment and has limited obstacle avoidance, with no follow-up development. Shanghai Jiao Tong University studied a snake-arm inspection robot [9], but the work remains at simulation level and does not consider the high-pressure and high-humidity TBM soil chamber.

The earliest exploration of robotic cutter replacement was by Bouygues, which launched the TELEMACH project in 2007 with funding from the French National Research Agency. After years of development, TELEMACH was demonstrated in June 2015 during the Tuen Mun to Chek Lap Kok tunnel project in Hong Kong using a 17.6 m diameter Herrenknecht TBM. The TELEMACH replacement robot is based on a KUKA KR FORTEC industrial robot with 500 kg payload and a dedicated end effector for cutter replacement. The main contribution was a new cutter system for robotic replacement and supporting tooling for cutter assembly and disassembly. However, because a standard industrial robot was used, the system is large and poorly suited to confined spaces; it can only be installed on large-diameter TBMs and is not applicable to small-diameter machines [10-11]. Shanghai Hongrun Construction Co. and the Shanghai University Robotics Institute developed a multi-DOF manipulator in which a six-DOF arm is mounted on a three-DOF linear track. All joints are motor-driven and the end payload exceeds 200 kg [12-13].

This paper consolidates the design and validation of a complete inspection-and-replacement robot system for TBM cutterhead maintenance. The system integrates a snake-like inspection robot for cleaning and visual inspection, and a heavy-load replacement robot for cutter swapping. We present the mechanical design, workspace planning, kinematics and dynamics modeling, EHA-driven control strategies, and laboratory/field verification.

2. SYSTEM ARCHITECTURE

The TBM robotised maintenance system consists of: (1) a snake-like inspection robot responsible for cleaning and imaging cutter tools, and (2) a heavy-load replacement robot

for removal and installation of disc cutters. The inspection robot provides real-time assessment of cutter wear and damage, supporting maintenance decision-making, while the replacement robot executes planned trajectories to swap cutters through the access gate.

The workflow of the TBM robotised maintenance system is shown in Fig. 1. Embedded tool sensors monitor cutter condition online and provide preliminary fault locations. The supervisory computer decides whether in-chamber inspection is needed. If required, the inspection robot enters the chamber, moves near the target cutter, cleans it, and performs visual inspection. Based on the visual results, the system decides whether replacement is necessary; if damage is confirmed, the replacement robot enters the chamber to swap the cutter.

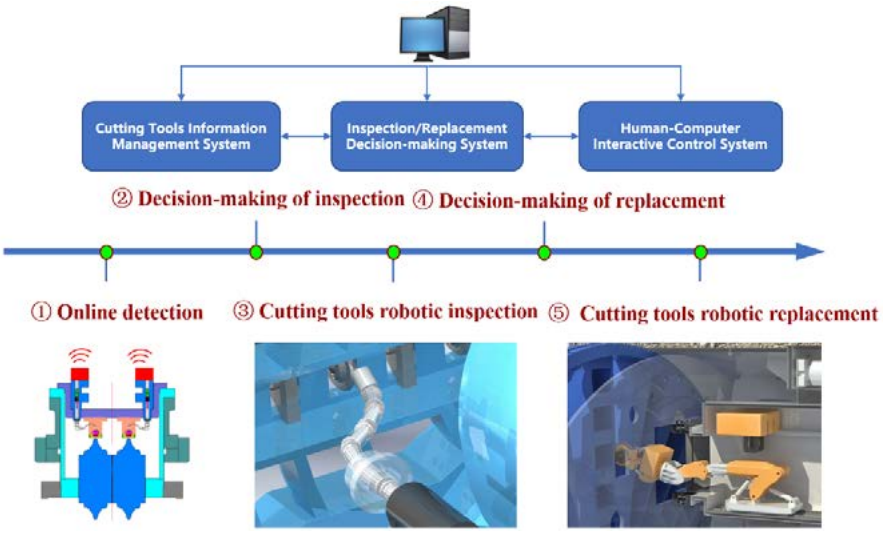

Fig. 1 Workflow for TBM cutter inspection and replacement

3. SNAKE-LIKE INSPECTION ROBOT

The snake-like inspection robot is cable-driven and segmented to enable long reach and high dexterity. Actuators are located in the rear module to avoid direct exposure to high pressure and water. The front section integrates a cleaning module, lighting, and an industrial zoom camera for in-situ inspection.

3.1. Inspection Coverage and Key Parameter Design

To support installation and testing on a TBM, we cooperated with CREG to design an inspection-robot prototype for a 6 m diameter EPB shield. Because various devices are installed behind the bulkhead of a typical 6 m EPB TBM, there is no extra space for a robot cabin. After discussions with CREG engineers, the available cabin space was determined to be a cylinder 600 mm in diameter and 2600 mm in length, as shown in Fig.2. The cabin center is 2207 mm from the TBM center, and the line connecting the two centers forms a 31 deg angle with the horizontal.

4

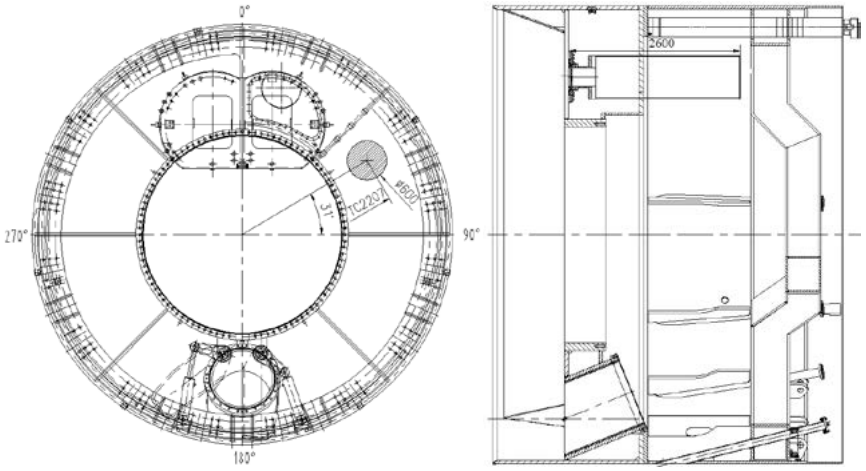

Fig. 2 Installation space of the inspection robot cabin in a 6 m class TBM

The snake-like inspection robot consists of a manipulator section and a drive module. The arm length determines the inspection reach, while the drive module length limits the maximum cable displacement and thus the joint angle range. To maximize inspection coverage within the limited installation space, we analyzed the robot's motion envelope inside the sealed chamber, obtained the maximum cable displacements in the drive space, and determined the screw stroke accordingly. This process finalized the key parameters of the snake robot.

Each joint of the snake robot has two degrees of freedom and can bend in arbitrary directions. Therefore, its workspace is symmetric. By analyzing planar motion, the maximum inspection range inside the TBM can be determined. Fig. 3 illustrates the workspace analysis of the snake robot in the XOY plane. The origin O is at the cabin door center and is 2207 mm from the TBM center. The Y-axis is aligned with the robot's centerline and points toward the cutterhead; the X-axis points to the cutterhead center. The distance from the cutter back edge to the bulkhead (along the X-axis) is 1300 mm. The wrist joint is denoted as a_n and the end link as a_{n+1}. The robot must pass through a narrow hatch between the robot cabin and the sealed chamber; this hatch is installed in the bulkhead and can be designed as an electric gate or replaced by a large-diameter ball valve. As shown in Fig. 3 the cabin outlet has a size D, and the robot must avoid interference with this opening during inspection. For cleaning and inspection, the robot should adopt a posture behind the cutterhead; an ideal pose is with the end link normal to the cutterhead and 300 mm from the cutter back edge. The inverse kinematics is solved to keep the end link horizontal (aligned with the Y-axis) while approaching edge and center cutters as close as possible to the 300 mm standoff. If a perpendicular end pose is infeasible, the end joint is tilted by a certain angle to observe the cutters. Using the optimal inverse-kinematics method, the maximum inspection range in the XOY plane is obtained.

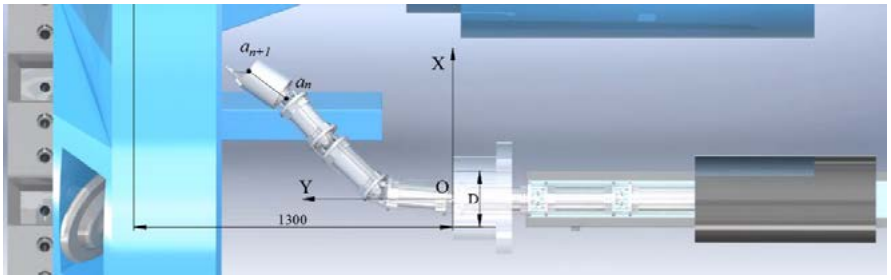

Fig. 3 Inspection range of the snake robot in the XOY plane

Equation (1) gives the inverse-kinematics model. The total length of the robot arm section is set to 1900 mm. The objective function drives the end-effector to stay as close as possible to the line Y = 1000, with constraints that prevent any link from interfering with the hatch during exit. The initial slope vector of the end link is set to k = [0 1 0]^T When the inverse-solution algorithm cannot continue, *k* is adjusted so that the end link adopts a tilted pose to observe the cutters.

$$\begin{aligned} \min \quad & \left\| y_{a_{n+1}} - 1000 \right\| \\ s.t. \quad & \begin{cases} q_i \le \max JointAngle, i = 1,...,n \\ x_{a_1} = 0 \,\&\, z_{a_i} = 0, i = 1,...,n+1 \\ -1030 \le x_{a_{n+1}} \le 2200 \\ \left\| a_i - a_{i+1} \right\| = L_i, i = 1,...,n \\ a_{n+1} = a_n + k \cdot L_n \\ if \;\; y'_{a_i} < 0, then \;\; \dfrac{x_{a_{i+1}} - x_{a_i}}{y_{a_{i+1}} - y_{a_i}} \cdot \left| y_{a_i} \right| + x_{a_i} \le \dfrac{D}{2}, i = 1,...,n \end{cases} \end{aligned} \tag{1}$$

Using the optimal inverse-kinematics method, the inspection range in the XOY plane is obtained as shown in Fig. 4 The robot can keep the end link perpendicular to the cutterhead and 300 mm from the cutter back edge within x = -1030 to x = 1300 mm,this is defined as the complete inspection range. When x > 1300 mm, the end link can be tilted by a certain angle for cleaning and inspection; this is defined as the tilted inspection range. At the limit, the distance between the end link and the back edge of the center cutter is 600 mm.

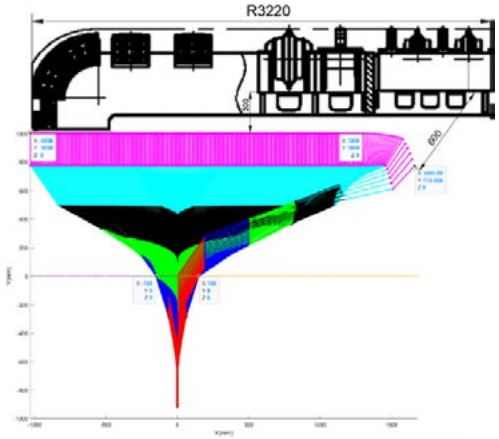

Fig. 4 Inspection range of the snake robot in the XOY plane for a 6 m class TBM

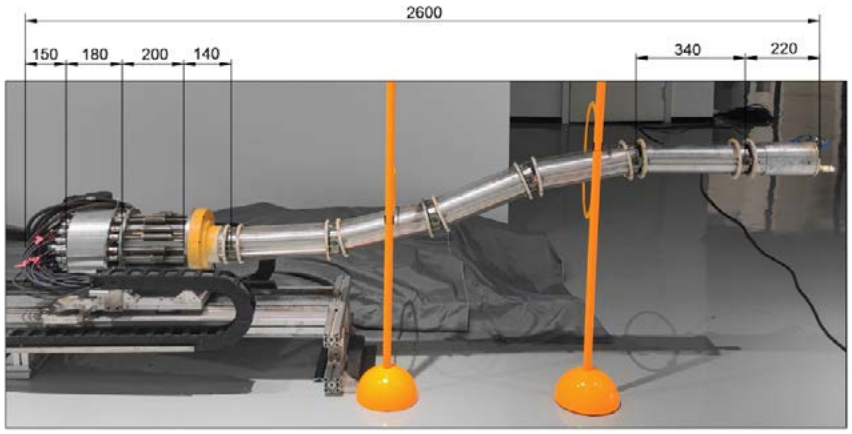
The maximum displacement of the drive cable is 150 mm. Considering a 30 mm slider length in the screw-nut pair and a safety margin, the screw length is set to 200 mm. The motor and coupling length is 180 mm; the fixed link length is 140 mm (equal to the hatch thickness); and a 150 mm cable space is reserved behind the robot. The total arm length is thus 1920 mm. The minimum end-link length is 220 mm, so the remaining five links are each 340 mm long. The overall dimensions are shown in Fig. 5.



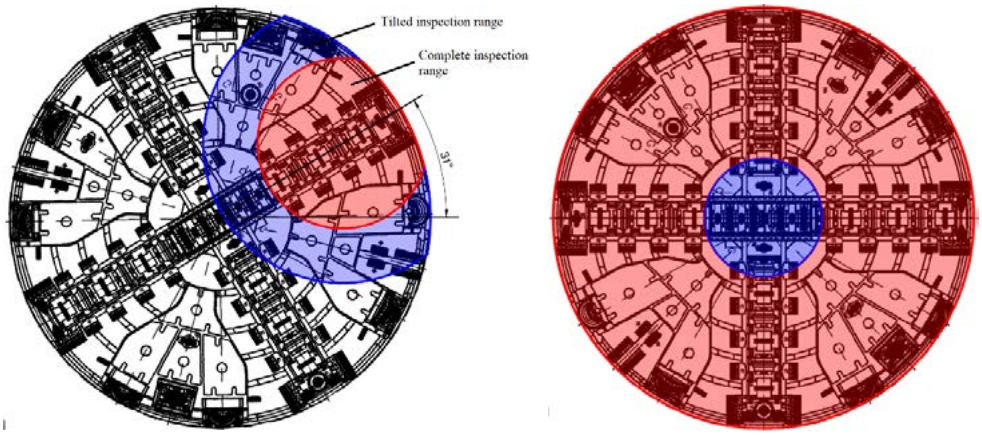


Fig. 5 Dimensions of the TBM snake-like inspection robot

After determining the design parameters, the cutterhead inspection coverage is calculated using this method, as shown in Fig. 6 (a), where the red area is the complete inspection range and the blue area is the tilted inspection range. In practice, cutterhead rotation can be coordinated with the robot to inspect more cutters; the resulting coverage is shown in Fig. 6 (b).By computing the ratio of the inspection area to the total cutterhead area under different conditions, Table 1 is obtained. The results show that full cutterhead coverage can be achieved when inspection is coordinated with cutterhead rotation.

(a) Inspection range with cutterhead stationary (b) Inspection range with cutterhead rotation

Fig. 6 Cutterhead inspection coverage of the snake robot

	Complete inspection range	Tilted inspection range	Total inspection range
Cutterhead stationary	15.11%	16.82%	31.93%
Cutterhead rotating	92.19%	7.81%	100%

Table 1 Cutterhead inspection coverage for a 6 m class TBM

3.2. End-effector cleaning and sensing

To ensure reliable inspection in muddy conditions, the end-effector integrates a self-balancing high-pressure nozzle (35 MPa) with one forward jet and three backward jets (120 deg spacing). The nozzle diameter is 1.0 mm with an orifice diameter of 0.68 mm, delivering about 30 L/min while keeping recoil below 10 N.

High-power lighting, a zoom industrial camera, and an air-knife/laser module are used to clean and illuminate the target area before image capture. The combined cleaning and imaging arrangement allows accurate detection of wear, cracks, and missing cutter components.

3.3. Protection Design in Harsh Environments

The harsh-environment protection design of the TBM snake inspection robot is shown in Fig. 7. The industrial camera at the end effector uses a pressure housing rated to 2 MPa so the camera operates at normal pressure and humidity. The magnetic rotary encoder boards inside the joints are potted, isolating them from high pressure and humidity without compromising measurement accuracy. In addition, the arm is enclosed by a pressure-resistant bellows that runs through the entire manipulator. A double-seal design is used at the base: the inner seal clamps the bellows root, and the outer seal connects to the base, further ensuring safe and reliable operation of precision joint components and magnetic rotary encoders.

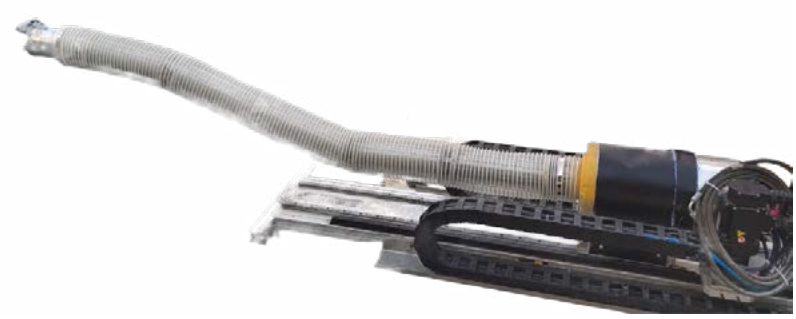

Fig. 7 Protective design of the snake robot for harsh environments

4. HEAVY-LOAD DISC CUTTER REPLACEMENT ROBOT

The replacement robot is a 6-DOF PRRPRR serial manipulator, as shown in Fig.8. Joint 1 is a linear slide for horizontal positioning; joint 4 is a telescopic arm for depth adjustment; joints 2 and 3 are hydraulic cylinders for boom angle and reach; and joints 5 and 6 are rotary swing cylinders for end-effector orientation. The design provides high payload capacity and sufficient stiffness for cutter handling.

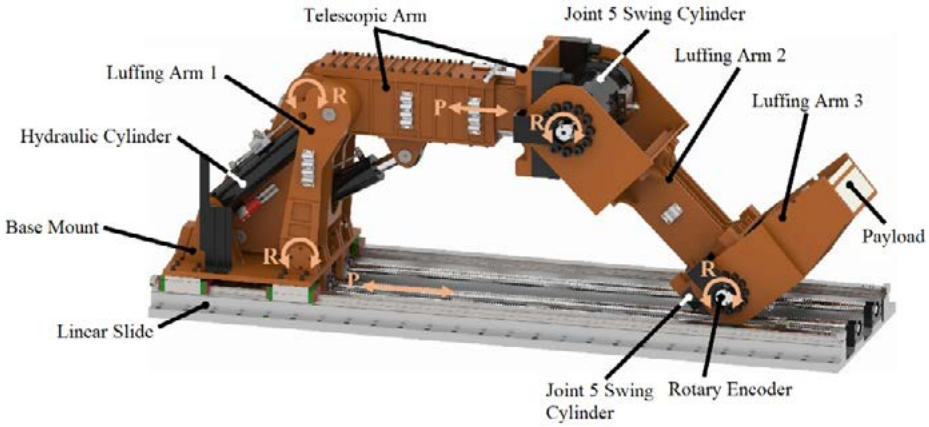

Fig. 8 Mechanical configuration of the replacement robot (joint layout)

4.1. Installation space and access

The robot is designed for an installation space of approximately 1 m x 1 m x 3 m and passes through a 0.65 m diameter, 0.39 m long access gate, as shown in Fig.9. The layout of the TBM chamber, partitions, and access door constrains robot motion. Manual maintenance under these conditions is hazardous, motivating robotised replacement.

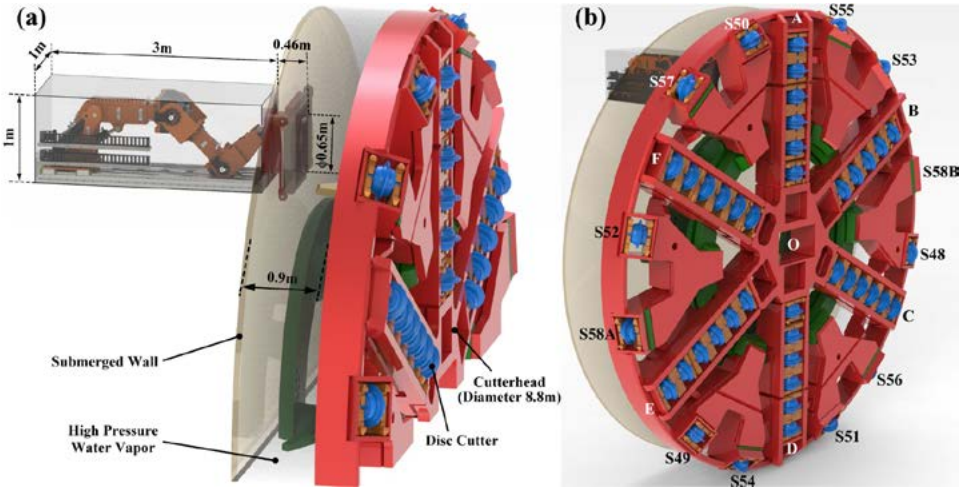

Fig. 9 TBM chamber layout and access positions for cutter replacement

4.2. Kinematics and dynamics modeling

A D-H based kinematic model is established to compute forward and inverse kinematics, as shown in Fig.10. And the D-H parameters table for the replacement robot is shown in Table 2. Redundancy is resolved by constraining joints 2 and 3 to reduce energy consumption and avoid collisions in the confined workspace. The cutterhead of an 8.8 m EPB TBM includes 35 radial cutters and 12 edge cutters, all of which must be reachable.

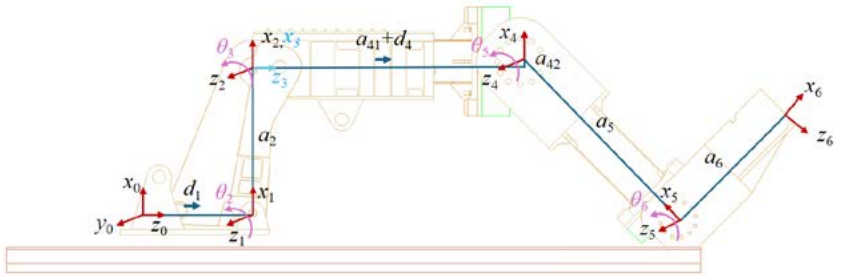

Fig. 10. Coordinate frames and kinematic parameters of the replacement robot

	θ_i	d_i	a_i	α_i
Joint 1	0	d_1	0	-90°
Joint 2	θ_2	0	a_2	0
Joint 3	θ_3	0	0	90°
Joint 4	0	$a_{41}+d_4$	a_{42}	-90°
Joint 5	45°+θ_5	0	-a_5	0
Joint 6	-90°+θ_6	0	a_6	90°

Table 2. D-H parameters table for the replacement robot

4.3. Constrained-space trajectory planning

A region-based joint-space planning strategy is proposed. Cutters are divided into middle, lower, and upper regions. For each region, a small number of key poses (initial, one or two intermediate poses, and target pose) are selected to minimize joint reversals, especially for joints 2 and 3. Trajectories are generated using cubic spline interpolation to ensure smooth velocity and acceleration profiles. Fig.11 shows cutter replacement process for multiple tool locations.

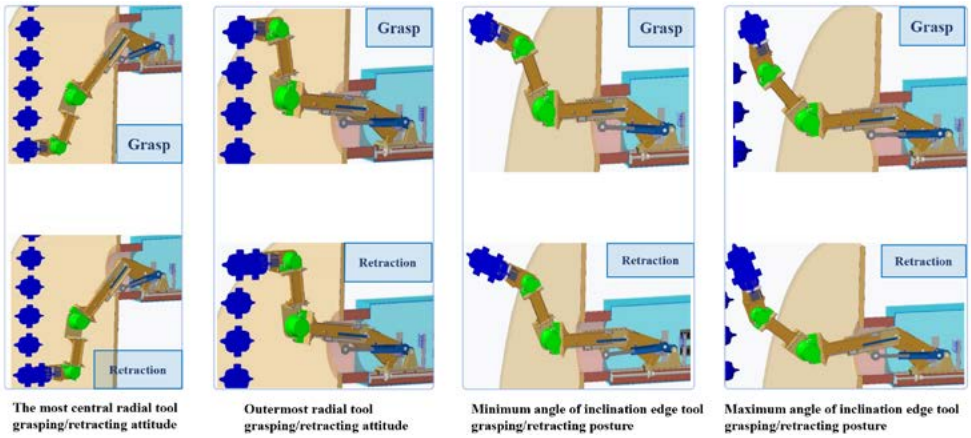

Fig. 11 Demonstration of cutter replacement process for multiple tool locations

4.4. EHA Modeling and Control

Electro-hydrostatic actuators (EHAs) drive joints 2 to 6. As shown in Fig. 12，it includes two major parts, the first part is mainly comprised of a servomotor, an EHA pump, a pressurized tank and a series of cartridge valves, mounted on the manifold block. And the second part is an integrated cylinder, which includes an internal magnetostrictive displacement sensor and an external dual pilot operated check valve. The position control strategy using both position feedback and pressure feedback is proposed. Here, the high gain pressure loop only comes into effect at the beginning of reversing. Hence the pressure in the contained volumes can be raised as soon as possible, which is beneficial for increasing the response speed of the actuator.

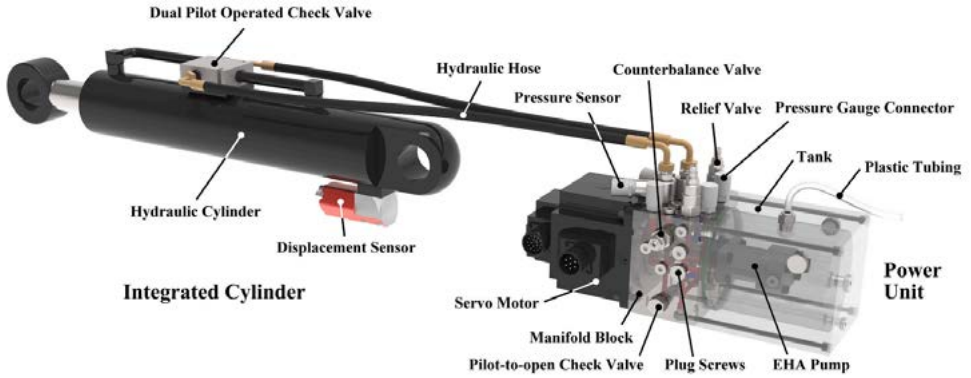

Fig. 12 Global 3D view of the electro-hydrostatic actuator (EHA)

Fig. 13 is the schematic diagram of the presented EHA system, and the corresponding 3D structure diagram is shown in Fig. 12. In this paper, the integrated cylinder is separated from the power unit, which is connected by hydraulic hoses. The integrated hydraulic cylinder is installed on the manipulator and is located in its installation space, while the power unit of the EHA is installed outside the manipulator's installation space.

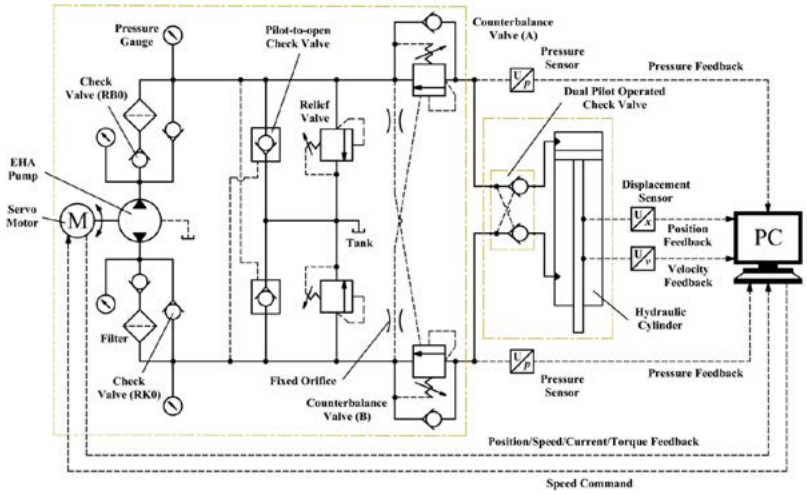

Fig. 13 Schematic diagram of the EHA

The control strategy combines two control loops, a high-gain pres-sure loop and a traditional position loop, as shown in Fig. 14. The goal of the high-gain pressure loop is to increase the speed of system response by increasing the pressure build-up speed of the working chamber when the piston rod moves in reverse, where the pressure controller is a high gain P controller. The position loop is used to realize the precise position control of the actuator, where the position controller is a PD controller. Adopting position-pressure feedback control (PPFC) strategy is to achieve both high positioning accuracy and high dynamic response of the pump control system.

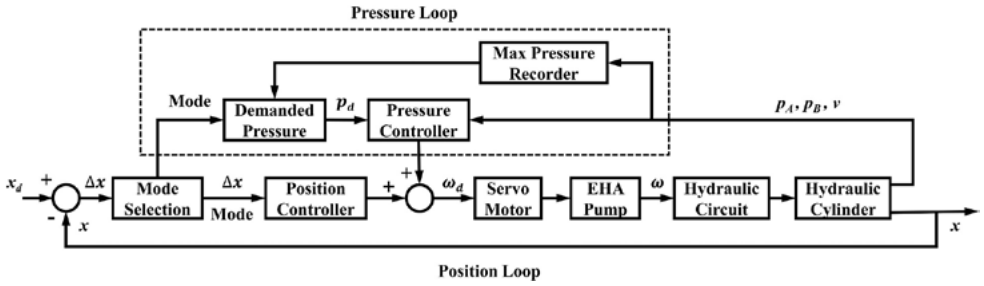

Fig. 14 Block diagram of the control strategy for the EHA

5. FIELD APPLICATION

The inspection-and-replacement system was deployed on the 'Pioneer II' TBM in the Shenzhen Airport metro tunnel project. The TBM operated in mixed geology. The overburden depth along the interval tunnel ranged from 10.13 to 265.81 m, with a maximum longitudinal gradient of 28%. The minimum horizontal curve radius was 568 m. The tunnel section passed through 3965 m of moderately to slightly weathered granite (87% of the alignment), while the remaining sections were gravelly cohesive soil and completely to strongly weathered granite, crossing seven fault zones and four densely jointed zones.

The engineering application of the inspection/replacement robots was first evaluated at the Foshan assembly plant to verify installation inside the TBM and to conduct cutter inspection tests, shown in Fig.15.

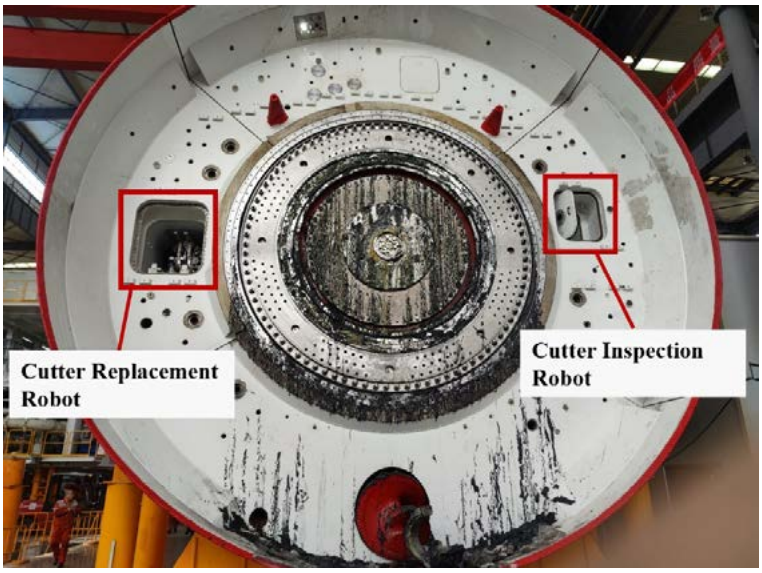

Fig. 15 The inspection-and-replacement system deployed on the 'Pioneer II' TBM

After installation, the snake robot was controlled via a virtual-environment human-machine interaction platform to conduct cutter inspection tests shown in Fig. 16. The platform includes a 3D cutterhead model; the cutterhead status displayed in software together with the robot's real-time posture was used to determine the relative position between the robot and the cutter. A serpentine motion-control method combined with end-camera images enabled cutter inspection.

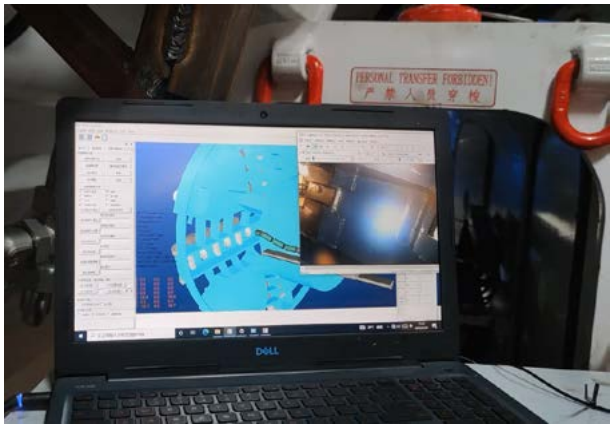

Fig. 16 Cutter inspection using the virtual-environment human-machine interaction platform

During installation and commissioning, the in-TBM installation issue of the snake robot was resolved. As shown in Fig. 17, a complete out-of-cabin inspection and retraction test was performed, preliminarily verifying the robot's operational capability inside the TBM.

Fig. 17 The snake robot exiting the cabin for cutter inspection.

During field operation, the snake robot completed cleaning and inspection of front cutters, and the replacement robot validated safe access for disc-cutter replacement. Fig. 18 shows the snake robot performing cutter cleaning at the tunneling site.

Fig. 18 The snake robot performing cutter cleaning at the tunneling site

6. DISCUSSION AND FUTURE WORK

While the proposed system demonstrates reliable inspection and replacement in harsh environments, several challenges remain: (1) current work is limited to visual image examination, future work should integrate specialized equipment such as depth-sensing cameras and laser profilometers to achieve precise wear measurement of the cutters, (2) the intense vibrations during TBM tunneling can easily cause failures in the cutter inspection and replacement robot, future work should consider implementing vibration-resistant design

to enhance the robot's reliability. Future work will address these issues and extend the system to larger TBM diameters and deeper burial depths.

7. CONCLUSION

A TBM robotised maintenance system combining a snake-like inspection robot and a heavy-load cutter replacement robot has been developed and validated. The inspection robot integrates cleaning and visual sensing for high-precision wear assessment under extreme conditions, while the replacement robot employs region-based trajectory planning and EHA control to achieve safe, accurate cutter swapping. Field application confirm reliability of the inspection robot in harsh environments, as well as its effectiveness in cutter cleaning and inspection.

Abstract.

Automated steering control is a more and more important function for Articulated Off-Highway Machines (AOHMs) operating in construction, mining, and forestry. Their articulation-based kinematics enable high maneuverability but also introduce challenges for lateral control, particularly when tracking paths with large curvature or frequent directional changes. In the forestry industry, AOHMs must achieve precise and stable path tracking in unstructured environments, where disturbances and dynamic path updates are common. This paper investigates a combined control approach that combines a Pure Pursuit (PP) and a Stanley (ST) controller into a feedforward–feedback framework tailored to AOHMs. As an example application in an AOHM, a forwarder is used in simulations on four representative paths—circular, sinusoidal, straight, and real-world trajectories—in both forward and backward driving. The results show that the PP-ST controller consistently outperforms the individual controllers, achieving maximum lateral errors below 0.2 m across all test paths. Robustness analysis under dynamic steering and velocity noise, payload variation, and initial offsets demonstrates convergence in all cases, with steady-state lateral errors remaining within 0.1 m. Even for extreme orientation deviations at the initial position, the controller eventually corrects the trajectory and returns to the reference path. Overall, the PP–ST controller provides accurate, stable, and robust lateral control for articulated off-highway machines in representative forestry scenarios.

Keywords. Assistance systems, articulated vehicle, lateral control, mobile machine, Pure Pursuit, Stanley.

1. INTRODUCTION

Nowadays, off-highway mobile working machines play a critical role in industries such as construction, mining, and forestry, where operations are performed in unstructured and often challenging environments [1]. Automated driving technology for these machines has the potential to enhance safety, reduce operator fatigue, and improve overall productivity [2]. By enabling precise navigation and efficient task execution, these systems can also help optimize fuel usage and minimize environmental impact [3].

All Open Access articles are peer-reviewed, distributed under the Creative Commons Attribution-Non Commercial 4.0 International

Within this category, Articulated Off-Highway Machines (AOHMs)—comprising multiple rigid units connected via articulation joints—are widely adopted due to their exceptional maneuverability in confined spaces [4]. The articulated steering mechanism enables tight turning radii and improved mobility on complex terrain. However, the kinematic complexity introduced by articulation makes lateral control more challenging than for rigid-frame vehicles, requiring control strategies capable of handling large steering angles and rapid changes in path curvature.

AOHMs are frequently deployed in the forestry industry, in machines like forwarders and harvesters, where precise lateral control is essential for safe and efficient operation. Reliable environmental perception—such as detecting and parameterizing individual trees—is a prerequisite for navigating the narrow and irregular lanes found in forest environments, often on uneven and unstructured terrain [5]. In such conditions, the planned path is continuously updated in response to changes in the surrounding environment and operational demands. Consequently, the lateral control system must not only achieve high tracking accuracy on paths with large curvature and frequent directional changes but also adapt in real time to sudden adjustments while maintaining vehicle stability.

In addition to the single-joint configuration that dominates current forestry machines, multi-articulated vehicle architectures have been investigated in the broader field of heavy-duty vehicle dynamics and control. Examples include multi-unit articulated systems comprising dual multi-axle trailers with coordinated steering for motion control [6]. Further studies have analyzed articulated multi-body vehicle systems that combine articulated joints and other joint types to capture complex interactions between interconnected units [7]. This paper focuses on AOHMs with a single articulation joint between the front and rear units, which remains the prevailing design in forestry applications such as forwarders and harvesters.

Among the existing lateral control methods, geometric approaches such as the Pure Pursuit (PP) and Stanley (ST) controllers are well known for their robustness, simplicity, and suitability for real-time implementation [8]. This work adapts and integrates these two controllers into a feedforward–feedback framework tailored to the kinematics of articulated off-highway machines, aiming to achieve robust and precise path tracking under diverse and dynamic operating conditions, including those encountered in forestry operations.

2. Lateral Control Methods for All-Wheel-Driven Articulated Off-Highway Machines

In this section, the kinematics of AOHMs are described, followed by the introduction of two lateral control methods: The Pure Pursuit and the Stanley controller.

Advanced control approaches such as Model Predictive Control (MPC) and nonlinear MPC require accurate dynamic vehicle models, reliable state estimation and considerable real-time computational resources. For articulated vehicles, tube-based robust MPC for tracking control explicitly relies on a detailed vehicle model and online optimization of the control sequence [9]. Nonlinear MPC for underground articulated vehicles is based on a high-fidelity dynamic model and nonlinear optimization at each control step [10], and multi-time-scale predictive control for underground articulated vehicles further illustrates the

computational effort associated with predictive control in this class of machines [11]. Robust path-following control for articulated heavy-duty vehicles addresses model uncertainty but still requires substantial tuning and validation effort to guarantee performance across the operating range [12]. In contrast, geometric controllers such as PP and ST controller operate with a kinematic model and low computational cost, which makes them suitable for real-time implementation on AOHMs. These characteristics motivate the use of the combined PP and ST controller in this work.

2.1. Kinematics of the Articulated Off-Highway Machine

Figure 2.1 illustrates the geometry of an AOHM. The steering angle δ can be derived from the orientation angles θ_i of the vehicle units [13]:

$$\delta = \theta_2 - \theta_1 \qquad (2.1)$$

A (virtual) axle can be defined between the two wheels of each vehicle unit. From the midpoint of this axle to the articulation joint, the lengths l_i and the corresponding radii r_i to a virtual center of rotation center o— about which the AOHM moves during a steering maneuver — can be determined. The radii are given by [13]:

$$r_1 = \frac{l_1 \cdot cos(\delta) + l_2}{sin(\delta)} \qquad (2.2)$$

$$r_2 = \frac{l_2 \cdot cos(\delta) + l_1}{sin(\delta)} \qquad (2.3)$$

To standardize the motion orientation of the AOHM, a quasi-static planar kinematic model is considered. When the machine moves forward, the pose reference point is defined at the front axle center; when moving backward, it is defined at the rear axle center. Under this kinematic assumption (negligible tire slip and compliance), r_1 and r_2 in Eq. (2.2) and Eq. (2.3) denote the instantaneous curvature radii of the chosen reference point. These radii are geometric quantities only and do not represent the actual turning radius, which in practice is influenced by payload, tire–soil interaction, velocity, and vehicle dynamics.

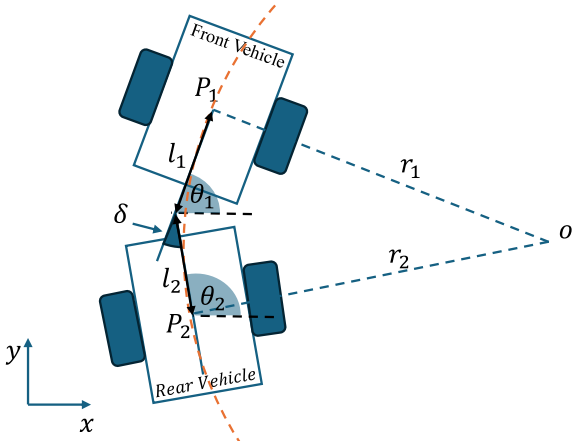

Figure 2.1. Geometry of an Articulated Off-Highway Machine

2.2. *Pure Pursuit Controller for AOHM*

The Pure Pursuit controller steers the vehicle toward a target point located at a specified lookahead distance l_d along the planned path [14, 15]. The lookahead distance is

$$l_d = max\left(l_{d,min}, min\left(k_{PP} \cdot |v|, l_{d,max}\right)\right) \qquad (2.4)$$

where v is the current vehicle speed, k_{PP} is the speed gain, and $l_{d,min}$, $l_{d,max}$ are the allowable bounds. This distance is smoothed to prevent abrupt steering changes.

As illustrated in Figure 2.2, l_d is measured along the reference path from the vehicle's current projected position to the lookahead point. The angle α is the heading from the vehicle to the lookahead point, while $\Delta\psi_1$ and $\Delta\psi_2$ are orientation differences between the Pure Pursuit arc and the reference path at the first and second candidate lookahead points, respectively. An orientation difference check reduces l_d in highly curved segments until $|\Delta\psi|$ falls below a predefined threshold, improving stability in dynamic paths.

Once the lookahead point is determined, the turning radius R can be calculated [16]:

$$R = \frac{l_d}{2 \cdot sin\alpha} \qquad (2.5)$$

By applying the tangent half-angle substitution, where $t = \tan\frac{\delta_{PP}}{2}$, and considering the forward motion case in which the turning radius $R = r_1$, Eq. (2.2) can be transformed into:

$$(l_1 - l_2) \cdot t^2 + 2\, r_1\, t - l_1 - l_2 = 0 \qquad (2.6)$$

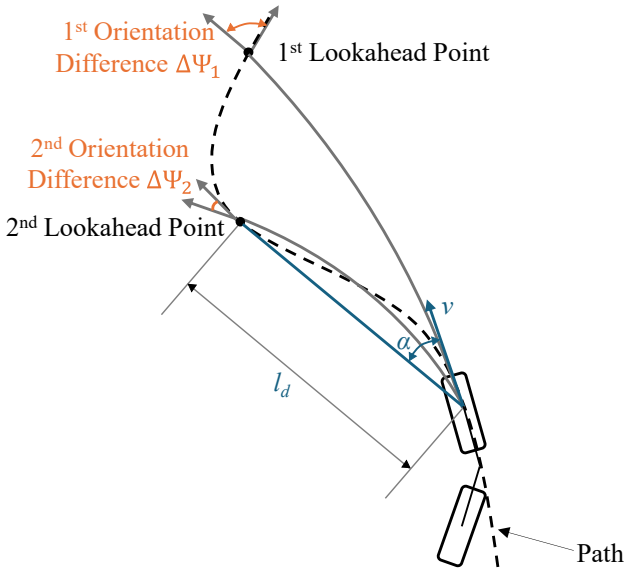

Figure 2.2. Selection of Lookahead Point for Pure Pursuit Controller

The steering angle of the Pure Pursuit controller for AOHM can then be obtained by applying the quadratic formula:

$$\delta_{PP} = 2\left(\tan^{-1}\left(\frac{-r_1 \pm \sqrt{l_1^2 - l_2^2 + r_1^2}}{l_1 - l_2}\right) + \pi n\right), \quad n \in Z \tag{2.7}$$

The same applies to the backward motion case, where r_1 in Eq. (2.6) and Eq. (2.7) is replaced by r_2 from Eq. (2.3), and n denotes the periodicity of the tangent function.

2.3. Stanley Controller for AOHM

The Stanley controller, similar to the Pure Pursuit controller, is employed for the lateral control of vehicles. However, instead of relying on a fixed lookahead point as in the Pure Pursuit controller, the Stanley controller determines the steering command based on the path point that is closest to the vehicle along its heading direction. To prevent oscillatory steering behavior when the reference point is too close, a lookahead distance is introduced in practice. Compared to the Pure Pursuit controller, the Stanley controller is generally more effective in suppressing lateral errors and achieving higher path-tracking accuracy, particularly in low-speed or sharp-turn scenarios [17].

The Stanley controller is a geometric method for lateral vehicle control that simultaneously corrects the heading error and the lateral position error to align the vehicle with the planned path. As shown in Figure 2.3, (c_x, c_y) denotes the closest point on the path to the AOHM's current reference point, e_l is the signed lateral error measured perpendicularly from this closest point to the vehicle reference point, and θ_h is the heading error between the longitudinal axis of AOHM's front vehicle and the tangent direction of the path at (c_x, c_y). The front vehicle's longitudinal speed at the reference point is denoted by v, and δ_{ST} is the steering command generated by the controller.

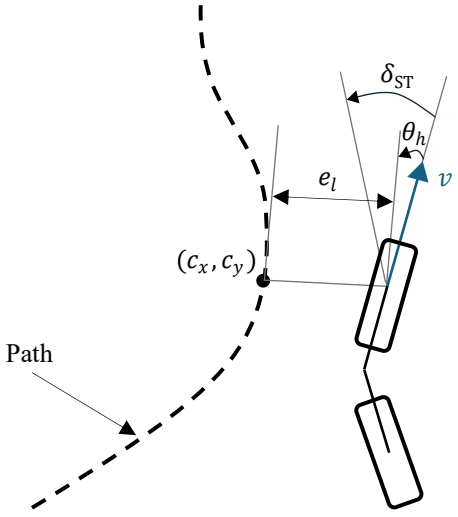

Figure 2.3. Stanley Controller for AOHM

In this work , based on the original Stanley controller, as proposed by Hoffmann et al. [18], a small positive constant k_v is integrated in the denominator to suppress excessive steering

at very low speeds and to avoid division by zero. The Stanley steering angle can be computed as

$$\delta_{ST} = \theta_h + \arctan\left(\frac{k_l e_l}{v + k_v}\right) \tag{2.8}$$

where the lateral correction term scales inversely with the vehicle's speed v, and k_l is the lateral error gain that scales the correction based on the magnitude of e_l. The first term in the equation corrects the heading to match the path's tangent direction, while the second term drives the lateral error toward zero. This combination allows the controller to achieve accurate path tracking across a wide range of speeds and curvature conditions.

3. Overall Framework of Automated Steering Control for Articulated Off-Highway Machines

The feasibility of combining the Pure Pursuit (PP) and Stanley (ST) controllers has been proved for robust lateral path tracking of indoor mobile robots [19]. Building upon this concept, the PP–ST combination will be adapted to the lateral control of AOHMs.

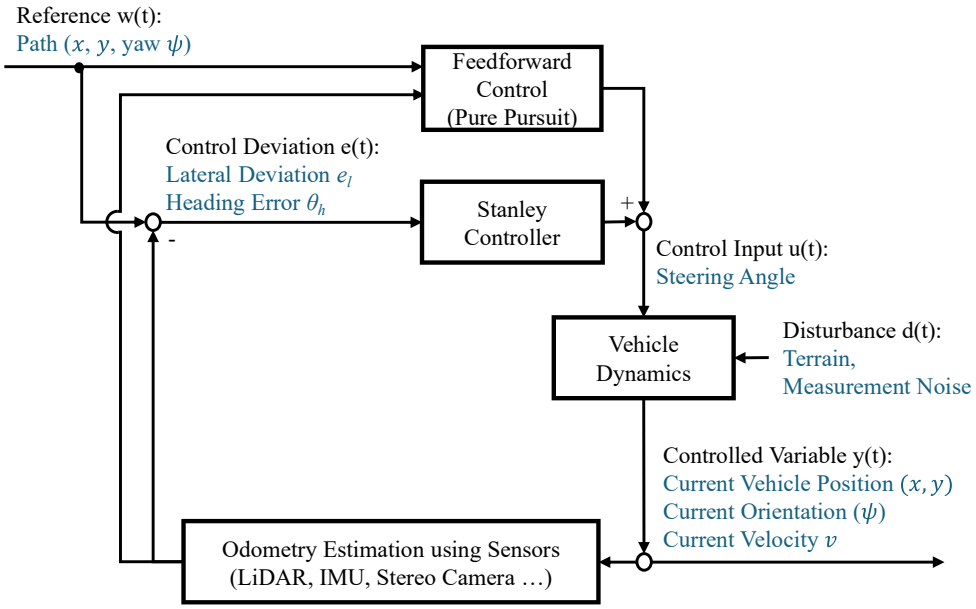

Figure 3.1. Overall Framework of Automated Steering Control for AOHMs

The overall framework is illustrated in Figure 3.1. In this framework, the planned path is available from a higher-level planning module, which generates a sequence of target poses (x, y, ψ) based on environmental perception and task objectives. At each control step, the vehicle's current pose and velocity are obtained from the odometry estimation module. A feedforward–feedback strategy is applied to generate the steering command: the PP module

determines the curvature required to reach a look-ahead point on the planned path, while the ST controller compensates for both lateral displacement and heading misalignment relative to the nearest path point. The outputs of both controllers are summed to form the steering angle command, which is sent to the articulated steering joint via the vehicle's actuation interface. The resulting vehicle motion is continuously monitored, closing the control loop and enabling precise path tracking under the kinematic constraints of articulated steering.

4. SIMULATION SETUPS

In this paper, a Forwarder is used as an exemplary application of the proposed control schematics.

Table 1: Technical Specifications of the Test Vehicle

Technical Specifications			
Total length (m)	10.96	Curb Weight (kg)	18,500
Width (m)	3.0	Maximum Payload (t)	14
Height (m)	3.79	Weight Distribution	60/40 (Front/Rear)
Front Axle Length l_1 (m)	1.799	Tire Diameter (m)	1.312
Rear Axle Length l_2 (m)	3.480	Tire Width (m)	1.42
Maximum Articulation Angle δ_{max} (°)	30	Ground Friction (rolling / static)	0.35 / 0.45

The Forwarder will be simulated in MATLAB Simulink with Simscape Multibody, where the forwarder is represented as a multi-body system including the articulated steering joint and axle constraints listed in Table 1. Tire–ground interaction is modeled with constant rolling and static friction coefficients (0.35 / 0.45). A variable-step solver with adaptive step sizes is applied to ensure numerical stability of multi-body dynamics. The simulation horizon is adjusted to allow traversal of each path. Outputs such as pose, steering angle, and lateral error are sampled at every time step.

In the simulations, the vehicle pose and velocity are provided as ideal ground-truth states from the multibody model without sensor noise. This assumption isolates the controller performance from perception uncertainties and allows a focused evaluation of the lateral control scheme. The initial forward velocity is set to a baseline value of 2 m/s, which corresponds to typical low-speed operation of forestry machinery and is used as the nominal input for all simulated scenarios.

The Forwarder will be tested on four paths: a circular path, a sinusoidal path, a straight line, and a real-world path collected from the Forwarder in the forest.

The formulas of the first three paths are defined in Table 2, where x starts from 0 m and path points are sampled every 0.5 m, resulting in a total of 150 points forming the final path. On each path, the Forwarder is tested once in forward and once in backward direction, i.e.,

evaluating the lateral control performance when either the front or the rear vehicle is leading. In addition, to investigate the robustness of the lateral controllers, further simulations are conducted on the sinusoidal path by introducing various disturbances, including dynamic steering and velocity noise, payload variations, and initial offsets.

Table 2: Equations of the Test Path

Path	Equation
Circular Path	$y_{circular}(x) = -12 \pm \sqrt{12^2 - x^2}$
Sinusoidal Path	$y_{sin}(x) = 5 \cdot \sin(x/10)$
Straight Line	$y_{straight}(x) = 0$

For the PP and ST controllers, the relevant parameters in Eq. (2.4) and Eq. (2.8) are listed in Table 3. These parameters are determined based on a sinusoidal path defined by $f_{\sin 2}(x) = 20 \cdot \sin(x/20)$, which will be detailed in subsequent sections.

Table 3: Parameters of Lateral Controllers

Parameter	Value
Maximum Lookahead Distance $l_{d,max}$ (m)	15.0
Minimum Lookahead Distance $l_{d,min}$ (m)	2.0
Speed Gain of PP controller k_{pp} (s)	3.0
Orientation Difference $\Delta\Psi$ (°)	20
Step Size for Orientation-Difference $\Delta\Psi$ Adaptation (m)	0.5
Velocity Offset k_v (m/s)	0.1
Lateral Error Gain k_l (s^{-1})	5.0

5. RESULTS AND ANALYSIS

In the following sections, simulations based on the setups described in Section 4 are conducted to evaluate the performance of the PP-ST controller introduced in Section 3. First, the optimal ST controller parameters, such as lateral error gain k_l, are determined through parameter variation. Next, the path-tracking performance of the PP-ST controller is compared with that of the standalone PP and ST controllers. Finally, different disturbance scenarios are introduced in the simulations to investigate the robustness of the PP-ST controller.

5.1. Parameter Tuning of the PP–ST Controller

In this paper, the controller parameters are tuned using a trial-and-error–based, simulation-driven approach. To illustrate the tuning procedure, the lateral error gain k_l of the ST controller is selected as a representative example.

As shown in Eq. (2.8), the lateral error gain k_l is a key parameter influencing the performance of the ST controller. The following simulations are conducted on the previously defined $f_{sin2}(x)$ path using different values of k_l to determine the optimal setting.

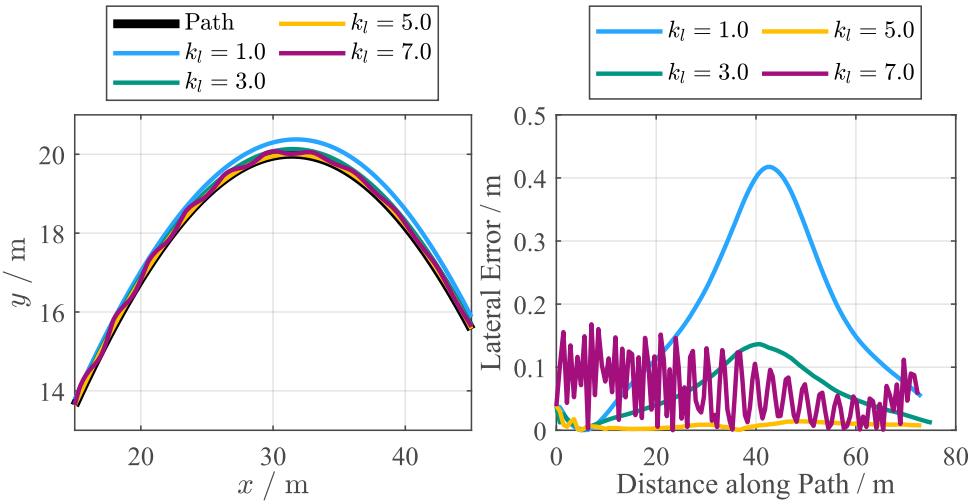

Figure 5.1. Optimization of Stanley Controller's Lateral Error Gain

As illustrated in Figure 5.1, four cases are compared: $k_l = 1.0$, $k_l = 3.0$, $k_l = 5.0$, and $k_l = 7.0$. The left-hand side of the figure presents the path-tracking results of the ST controller under different k_l values, while the right-hand side shows the corresponding lateral errors relative to the reference path. It can be observed that when $k_l = 1.0$, the lateral error is relatively large, particularly in sections with higher curvature. As k_l increases, for example to 3.0, the overall lateral error decreases. However, when $k_l = 7.0$, the lateral error exhibits strong oscillations. Consequently, a compromise value of 5.0, achieves relatively low and stable lateral errors without noticeable oscillations.

Table 4: Performance of ST Controller's Lateral Error Gains on Lateral Error

Lateral Error Gain k_l (s^{-1})	Mean / m	Max / m	Median / m
1.0	0.192	0.418	0.167
3.0	0.063	0.137	0.063
5.0	**0.008**	**0.038**	**0.008**
7.0	0.062	0.168	0.062

The lateral error metrics in Table 4, namely the mean, maximum, and median values, further confirm that the ST controller with $k_l = 5.0$ achieves the best performance across all

indicators. Based on this tuning procedure, the value of k_l is fixed to 5.0 in the subsequent simulations. Following the same trial-and-error–based tuning strategy, the remaining PP–ST controller parameters listed in Table 3 are determined analogously.

5.2. Comparison of Lateral Controllers

Subsequently, the PP, ST, and the PP-ST controller are tested and compared on the four paths described in Section 4. The first scenario considers driving forward.

As shown in Figure 5.1, all three controllers achieve close adherence to the reference circular path in terms of path tracking, as show on the left. However, the lateral error plots on the right indicate that, although the errors of the PP and ST controllers are not large and tend to stabilize after initial oscillations, they still exceed those of the PP-ST controller.

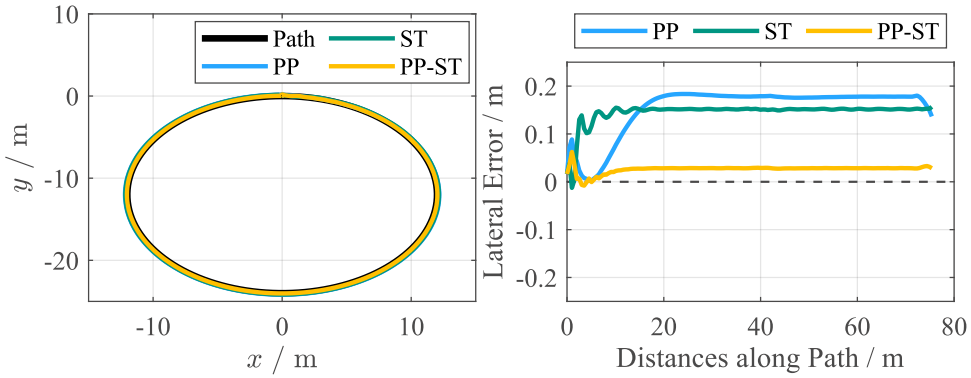

Figure 5.1. Lateral Controller Comparison during Forward Driving on a Circular Path

For the sinusoidal path in Figure 5.2, all three controllers exhibit noticeable sinusoidal oscillations in lateral error. However, the PP-ST controller shows the smallest amplitude, whereas the PP controller produces the largest. Nevertheless, the maximum absolute lateral error of all three controllers remains below 0.2 m.

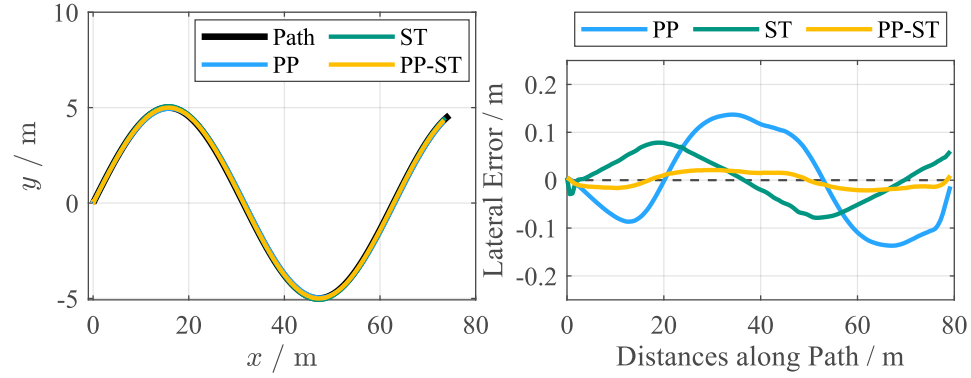

Figure 5.2. Lateral Controller Comparison during Forward Driving on a Sinusoidal Path

In the straight-line simulation shown in Figure 5.3, all three controllers exhibit strong oscillations at the beginning, with the ST controller even showing lateral swaying. However, in the later stage, all three converge to stable behavior and achieve a high degree of accuracy in straight-line tracking, with their lateral errors approaching 0 m.

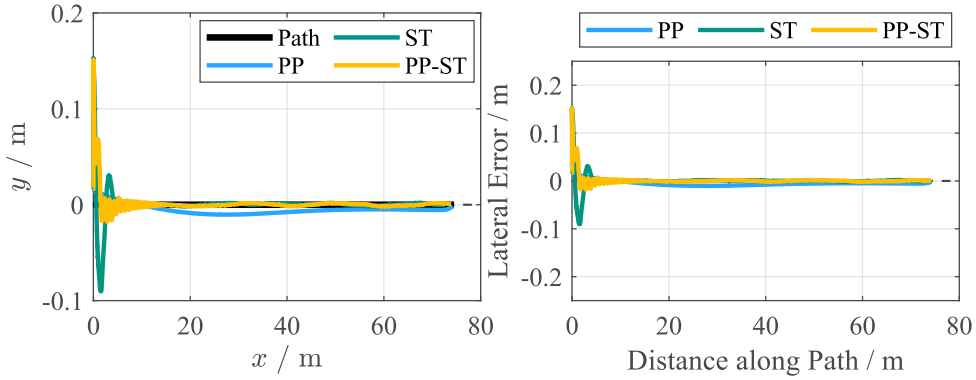

Figure 5.3. Lateral Controller Comparison during Forward Driving on a Straight Line

Figure 5.4 illustrates a real-world path. As a result, all three controllers exhibit high oscillation frequencies. Nevertheless, their overall performance remains satisfactory, with the PP-ST controller once again demonstrating the best results.

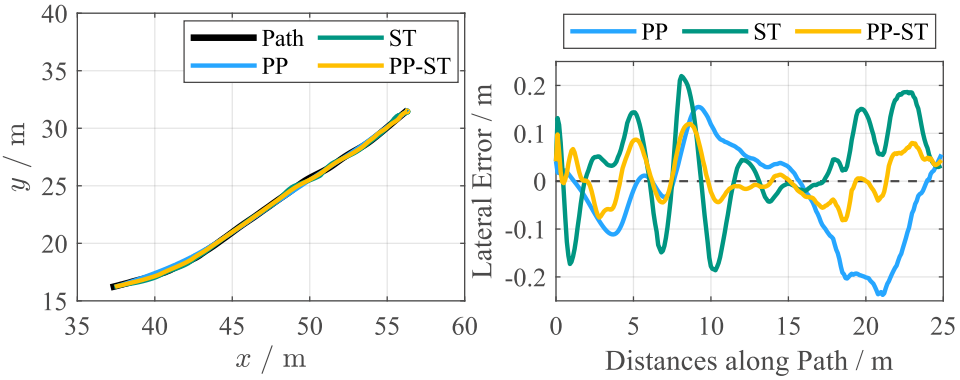

Figure 5.4. Lateral Controller Comparison during Forward Driving on a Real Path

Table 4 summarizes the controller performance in forward and backward driving across the four paths, based on identical simulation settings to ensure comparability. Although in certain cases, such as the straight-line scenario, the ST controller achieves marginally lower mean and median errors (e.g., 0.005 m and 0.001 m, respectively), the PP-ST controller introduced in this paper consistently delivers superior results in most test cases.

For forward circular and sinusoidal paths, the PP-ST controller reduces the mean error by more than 70% compared to PP and ST individually. Specifically, the mean error is 0.027 m compared to 0.153 m and 0.145 m for the circular path, and 0.014 m compared to 0.084 m and 0.042 m for the sinusoidal path. On the real path, it again halves the error (0.039 m) compared to PP and ST. This demonstrates its strong ability to track curved trajectories with high precision.

Table 4: Controller Performance on Absolute Lateral Error

Scenario Path	Lateral Controller	Mean / m	Max / m	Median / m
Driving Forward Circular Path	PP	0.153	0.184	0.178
	ST	0.145	0.157	0.152
	PP-ST	**0.027**	**0.063**	**0.028**
Driving Forward Sinusoidal Path	PP	0.084	0.137	0.087
	ST	0.042	0.078	0.041
	PP-ST	**0.014**	**0.040**	**0.015**
Driving Forward Straight Line	PP	0.007	**0.023**	0.006
	ST	**0.005**	0.153	**0.001**
	PP-ST	**0.005**	0.151	**0.001**
Driving Forward Real Path	PP	0.080	0.239	0.059
	ST	0.078	0.221	0.053
	PP-ST	**0.039**	**0.120**	**0.037**
Driving Backward Circular Path	PP	0.286	0.365	0.318
	ST	0.182	0.442	0.187
	PP-ST	**0.064**	**0.202**	**0.071**
Driving Backward Sinusoidal Path	PP	0.101	0.192	0.114
	ST	0.053	0.130	0.051
	PP-ST	**0.022**	**0.110**	**0.020**
Driving Backward Straight Line	PP	0.024	0.030	0.026
	ST	**0.004**	**0.191**	**0.001**
	PP-ST	0.005	0.201	0.003
Driving Backward Real Path	PP	0.035	0.127	**0.010**
	ST	0.028	0.127	0.013
	PP-ST	**0.021**	**0.109**	0.011

The backward driving cases further highlight the robustness of PP-ST. In the circular and sinusoidal paths, its mean error is reduced to 0.064 m and 0.022 m, respectively, significantly lower than the pure PP or ST controllers. Even in the more challenging real-path scenario, PP-ST achieves the smallest mean error (0.021 m) while maintaining stable maximum and median errors, underscoring its ability to generalize across both motion directions.

Overall, despite isolated cases where ST exhibits competitive performance, particularly in straight-line driving, the PP-ST controller demonstrates superior accuracy and stability across diverse paths and driving directions, validating its effectiveness as a more reliable solution for articulated off-highway machine lateral control.

Figure 5.5 presents boxplots of the lateral errors for all cases. The PP-ST controller achieves a maximum lateral error of less than 0.2 m, which is clearly lower than that of the other two controllers, whose performances are relatively similar to each other.

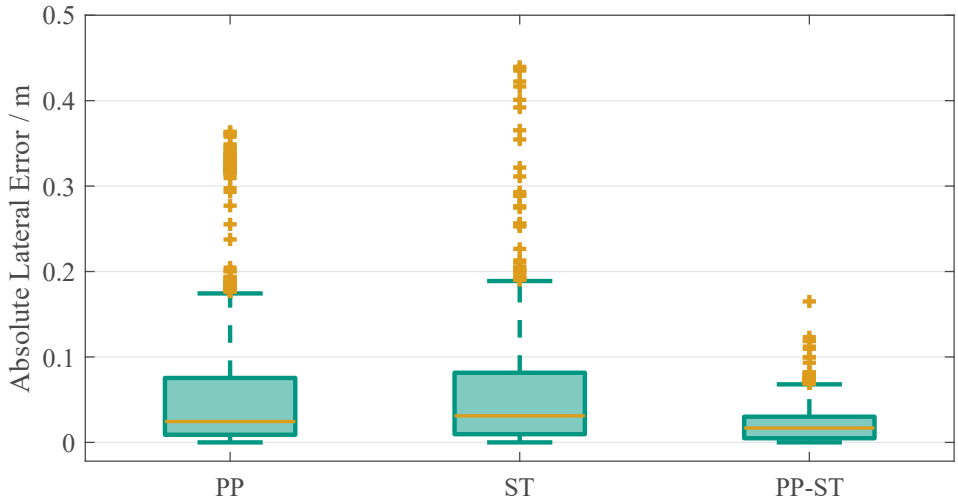

Figure 5.5. Overall Lateral Error Distributions of Absolute Lateral Controllers

5.3. Robustness Analysis of PP-ST Controller

Next, different disturbances are introduced on the sinusoidal path in Figure 5.2 to evaluate the robustness of the PP-ST controller. These disturbances include adding a noise term $2\sin(3t)$ to both the steering angle $\delta(t)$ and the velocity $v(t)$, where t denotes time; applying an additional load of 14 t to the rear vehicle of the forwarder; introducing an extra orientation offset of 45° at the initial position; and starting path tracking from a location 2 m away from the initial position.

Figure 5.6 illustrates the path-tracking performance and the corresponding signed lateral errors of the PP-ST controller under different disturbance scenarios. In the upper plot, the trajectories remain close to the reference path in most cases, with only the scenario starting with an additional orientation offset of 45° showing a visible deviation at the beginning before converging.

The lower plot shows the lateral error. When sinusoidal noise $2\sin(3t)$ is added to either the steering angle $\delta(t)$ or the velocity $v(t)$, the error exhibits oscillations but remains within 0.1 m. The additional rear-vehicle load of 14 t and the initial orientation offset of 45° cause slightly larger fluctuations than the normal case, yet the errors converge to near zero. The initial position offset of 2 m has only a minor transient effect. Overall, the controller demonstrates strong robustness under all disturbances.

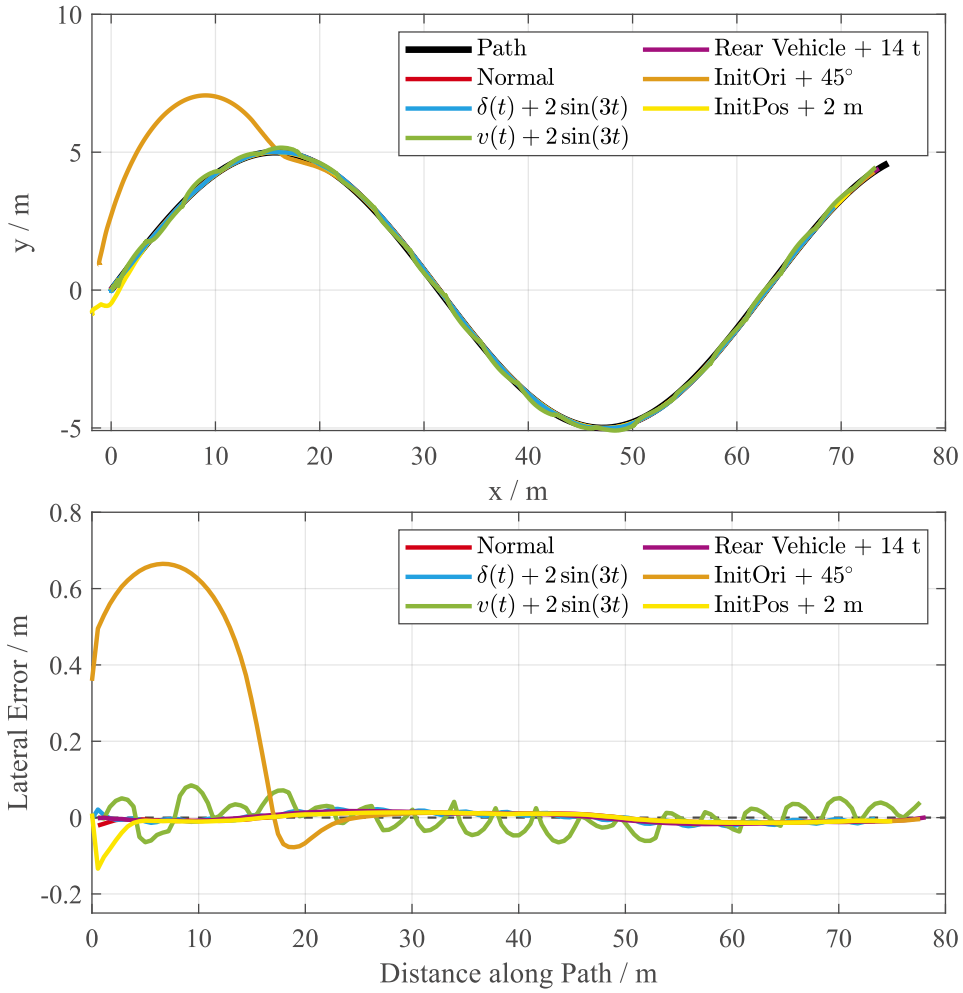

Figure 5.6. Performance of the PP-ST Controller under Different Disturbance Scenarios

The quantitative metrics in Table 5 confirm the observations in Figure 5.6. Under normal conditions (with no noise), the mean, maximum, and median lateral errors are 0.023 m, 0.049 m, and 0.024 m. Adding sinusoidal noise to the steering angle $\delta(t)$ causes only a marginal increase, with errors nearly identical to the baseline. Velocity disturbance results in higher values, with a mean of 0.068 m and a maximum error of 0.215 m. An additional rear-vehicle load of 14 t has almost no effect on the controller's performance. By contrast, the initial orientation offset of 45° produces the most significant degradation, with the maximum error rising to 3.622 m, while the mean remains relatively moderate at 0.588 m due to eventual recovery. Starting from an initial position offset of 2 m leads to a transient maximum error of 0.361 m, but the mean and median remain close to the normal case, indicating fast convergence.

Overall, both the trajectory plots and the error metrics demonstrate that the PP-ST controller is robust against most dynamic and static disturbances. Only the extreme initial orientation

offset leads to a substantial temporary degradation, while in all other cases the steady-state lateral errors remain within 0.1 m.

Table 5: Metrics of PP-ST Controller's Absolute Lateral Error under Disturbance

Scenario	Mean / m	Max / m	Median / m
Normal	0.023	0.049	0.024
$\delta(t) + 2sin(3t)$	0.024	0.054	0.024
$v(t) + 2sin(3t)$	0.068	0.215	0.060
Rear Vehicle + 14 t	0.024	0.040	0.025
InitOri + 45°	0.588	3.622	0.027
InitPos + 2 m	0.029	0.361	0.023

6. CONCLUSIONS

This paper presented a lateral control framework for Articulated Off-Highway Machines (AOHMs) by combining Pure Pursuit (PP) and Stanley (ST) controllers. The lateral error gain of the ST controller for a typical AOHM, a Forwarder, is first simulated on circular, sinusoidal, straight, and real paths demonstrated that the proposed PP–ST controller consistently outperformed standalone PP and ST controllers, achieving maximum lateral errors below 0.2 m in most cases. Robustness analysis under disturbances such as dynamic steering and velocity noise, payload variations, and initial offsets confirmed stable convergence, with steady-state lateral errors remaining within 0.1 m except for extreme orientation offsets, which caused only transient degradation. Overall, the results show that the PP–ST controller combines the complementary strengths of both methods, providing accurate, stable, and robust automated steering control for AOHMs.

Abstract.

Centralized hydraulic circuits are typically employed to actuate the steering system and other different users in off-road vehicles, particularly in agricultural tractors. These solutions, while robust and widely adopted, lead to high energy demands and significant contributions to overall fuel consumption and greenhouse gas emissions. This study forms part of a wider academic research project aimed at developing an experimental platform integrated with virtual models to study alternative architectures, with the objective of improving energy efficiency and sustainability of heavy-duty off-road vehicles. In particular, this work is dedicated to developing a mathematical model that predicts the loads acting on the hydraulic steering actuator during working cycles. Indeed, measuring the loads acting on a tractor's steering system during real-world operation is challenging and costly. Field tests require the vehicle to be equipped with sensors and to undergo controlled work cycles on different terrains, which demand considerable time, resources and logistical complexity. Predictive models thus offer a clear advantage, addressing the lack of experimental data by generating virtual but realistic steering loads. The novel contribution of this paper is a simulation framework that, accounting for the vehicle's front axle load, soil type, and tire sinkage, creates realistic duty cycles to feed a hardware-in-the-loop test bench. These parameters, in fact, critically affect the forces transmitted to the hydraulic actuator. The model is based on a detailed kinematic study of the front axle with core terramechanics concepts to define the tire–soil interaction. The mathematical model was corroborated by comparing the results with those of a multibody simulation model of the front axle. The virtual assembly includes the main rigid bodies and a double-rod hydraulic steering cylinder. This simulation shows the mechanical behavior under both static and dynamic loads, providing force estimates across different realistic operating scenarios. We derived the modeling assumptions and boundary conditions from relevant literature on heavy-duty vehicle dynamics. As a future application, the results obtained from this validated model will be employed to actuate the solenoid valves of a load generating system in a test bench, thereby exerting the desired working conditions on the hydraulic power steering system.

1. INTRODUCTION

Hydraulic steering systems in heavy-duty off-road vehicles are typically driven by centralized load sensing circuits. While robust and widely adopted, these architectures result in high energy demands and significant hydraulic losses. Recent studies highlight the impact of these systems on fuel consumption and greenhouse gas emissions, especially during multi-actuator operations where overload pressure and compensator-induced dissipation are prevalent [1, 2]. Driven by growing industrial interest in sustainability and energy efficiency in the agricultural sector, research focuses on alternative hydraulic layouts. These include independent metering valve systems, electronically controlled variable displacement pumps and electro-hydraulic power steering systems with solenoid valves [3, 4, 5, 6]. Such configurations improve control flexibility and decrease power losses, particularly when integrated with digital control strategies that interact with mechanical models [7, 8].

However, the performance evaluation of hydraulic steering systems in realistic operating conditions is still a complicated and resource-intensive process. Field testing requires advanced instrumentation, controlled cycles on different terrains and considerable logistical effort [9, 10, 11]. In this context, predictive modeling proves to be an effective method for estimating steering loads, thereby avoiding the necessity for extensive experimental testing. Prior research validated the effectiveness of multibody simulations and terramechanics-based models for tire–soil interactions [12, 13, 14, 15, 16]. Angelucci et al. [17] explore the applicability of terra-mechanical models to optimize soil-tire interaction and highlight a gain on performance. Analytical foundations for predictive models are based on multidisciplinary contributions: Hegendus introduces dimensional analysis and plate penetration techniques to derive soil parameters [18], while Bekker's model estimates ground deformation, sinking and shear stresses induced by vehicular loads [19]. Thus, Taborek provided the theory for studying kinematic behavior on vehicle steering mechanics, while Terzaghi's theoretical soil mechanics further clarified the role of cohesion, internal friction, and effective stress in soil failure [20, 21]. These cross-disciplinary notions are used in several engineering fields, e.g. robotics: Jia et al. [22] and Ishigami et al. [23] built a predictive model for a rover focused on tire-soil interaction, which can be integrated into multibody simulations. Instead, Patel et al. [24] applied Hegendus terramechanics to shovel-ground interaction in excavators. In conclusion, Cao et al. [25] pointed out the importance of axle friction and alignment forces, during pivot steering alongside terra-mechanical contributions. Despite the extensive literature on terramechanics and vehicle dynamics, a significant research gap remains in the availability of reliable, experimental-like load data for the validation of steering systems without relying on costly field campaigns. Drawing inspiration from rover studies, this research adapts the methodology to the agricultural sector. The novelty lies in the integration of these analytical foundations into a comprehensive multibody co-simulation approach. The result is a 'virtual sensor' capable of generating reliable duty cycles for hardware-in-the-loop validation.

2. EXPERIMENTAL TEST BENCH LAYOUT

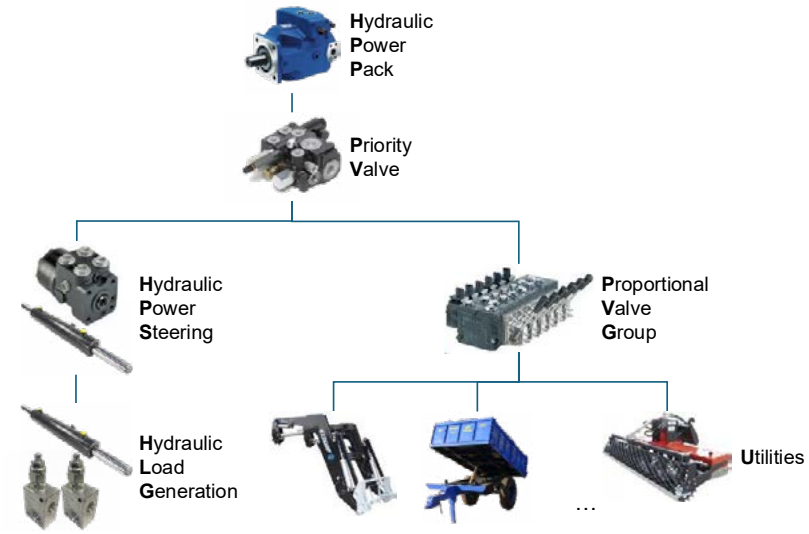

Figure 2.1. Baseline configuration layout

The design of an experimental bench for testing hydraulic and electro-hydraulic components, typically used in heavy duty vehicles, needs a method to replicate a duty cycle on the primary user, i.e. the steering system. Therefore, the primary purpose of the platform is to exert on the hydraulic power steering (HPS) system the same forces and displacements that would be observed during actual field operation. Although the platform does not include a physical front axle, this apparent hardware limitation is in fact advantageous: the platform core is a digital twin that replicates the front axle and its kinematics through the hydraulic load generation (HLG) system. Different axle geometries, kinematics or tractor dimensions can be simulated by updating the model, without mechanical reconfiguration.

The layout also includes secondary users, such as lifting actuators and orbital motors, or in general users that can be mounted on a tractor. Hydraulic power distribution is managed by a priority valve. The described layout is known as the baseline configuration and is illustrated in Figure 2.1. Obviously, the platform's modular design allows for the configuration of alternative hydraulic architectures. For example, it can operate without a priority valve and with users powered independently. Nevertheless, the focus of this work is the steering function. Therefore, alternative circuit configurations and secondary users, including the priority valve, are not considered in this context. The analysis addresses HPS and HLG subsystems.

2.1. HPS Main Components

Figure 2.2 illustrates the hydraulic layout of the steering branch of the experimental platform. HPS replicates the steering architecture typically utilized in utility tractor. We chose two representative components:

- Danfoss OSPC80LS steering unit (4 in Fig. 2.2) [26]

- Ognibene 57/35 × 190 mm double acting steering cylinder with through rod (3A) [27]

The OSPC80LS is connected to the steering wheel and adjusts the flow to the cylinder based on the pilot's manual input. The cylinder is selected with a through rod, similar to many of those installed on front axles.

2.2. HLG Main Components

The innovative core of the test bench is the HLG system. This unit provides an autonomous short-circuited load system, unlike conventional rigs, which include safety valves to release oil in case of unexpected pressure spikes. This represents an effective solution for avoiding power saturation of the bench control unit. The main components of the HLG are:

- Ognibene 57/35 × 190 mm double-acting steering cylinder with through rod (3B) [27]
- Hydraforce TS12-27 two-way proportional solenoid valves (5A and 5B) [28]
- Anti-cavitation and anti-shock safety valves (6)

Note that we chose the same actuator as the steering one, as it provides the same area ratios on both sides. However, the platform is not limited to this configuration. In fact, if different cylinders are used, a correction factor derived from the chamber area ratio could be considered. The proportional pressure relief valves operate alternately depending on the steering direction. Their opening is controlled by a PWM signal generated by the data acquisition and control system (DAQ). However, a key consideration for this configuration is the need for high-frequency acquisition to quickly control valve opening, thus ensuring stability within the simulated duty cycle.

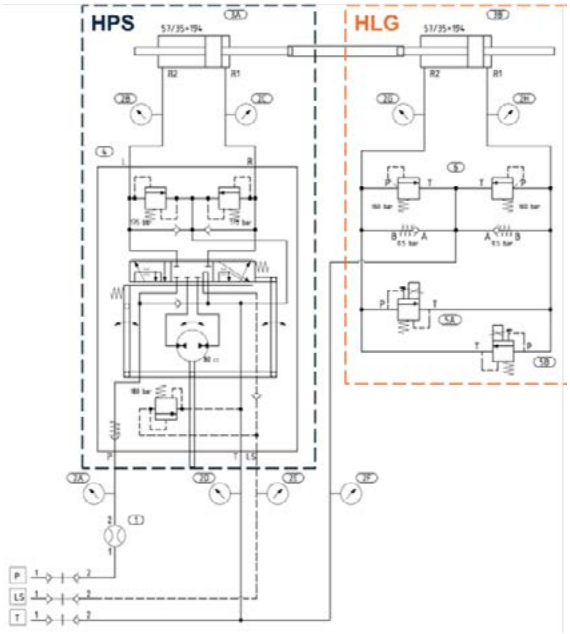

Figure 2.2. Hydraulic circuit of power steering (HPS) and load generation (HLG) systems

2.3. DAQ Design

The platform's data acquisition and control system is implemented on a National Instruments CompactRIO (cRIO), a real-time embedded controller integrating a real-time processor, an FPGA, and modular I/O. Acquisition is handled by the NI Scan Engine, which performs a deterministic I/O scan cycle over a user-defined scan period (typically 1 ms, up to ~1 kHz), ensuring synchronous sampling of multiple signals, such as hydraulic pressures, flow rates, angular steering position, linear displacement, and load cell measurements. Scan Engine logic is easier to program because you can access I/O variables directly in LabVIEW Real-Time as shared variables, but the maximum cycle speed is limited by the scan speed. PWM signals for Hydraforce T12-27 are also generated through the Scan Engine. High-frequency FPGA acquisition is not required in this context.

Based on this hardware setup, three operating scenarios are supported. The first uses fixed pressure thresholds on proportional valves, simplifying the identification of steady-state behavior. This mode is used for preliminary hardware calibration and does not rely on the simulation model. The second scenario uses a look-up table that correlates predefined steering resistances with wheel angular positions. The validated model presented in this paper is specifically aimed at generating the data for this second scenario. The last scenario, representing the next step of the research work, provides continuous co-simulation during the experimental test. In this setup, the DAQ integrates real-time simulation outputs to dynamically adjust the valve opening, effectively connecting the physical steering system with the digital twin.

3. ANALYTIC APPROACH

This chapter presents the analytical approach used to validate the virtual model of the front steering axle and to estimate the soil-induced resistance on the vehicle. Modeling is broken down into two problems: the kinematics and dynamics of the steering axle, which provides how steering inputs turn into wheel motion and reaction forces; and the terra-mechanical model, which estimates ground-tire forces in relation to terrain characteristics and tire/load conditions. The aims of the analytical formulation are to obtain a reduced-order dynamic system of the front axle and to define a mathematical model that correlates the lateral forces on the tire surface to the steering cylinder based on the steering angle.

3.1. Assumptions and Reference Frames

The steering axle and components are modeled as rigid bodies, the vehicle is considered stationary, and friction in the kinematics is assumed negligible due to lack of literature data. Furthermore, a limiting scenario is considered in which the minimal imprint that the tire can create in the soil corresponds to the square of its thickness.

We considered both a fixed O_{xyz} and a rotating $O_{x'y'z'}$ reference system. The O_{xyz} frame is located along the cylindrical joint connecting the hub and the axle, and it is aligned perpendicularly to the ground plane. The mobile reference system $O_{x'y'z'}$ is obtained from the former by a γ-rotation around the z-axis, which is the steering angle, and a δ-rotation around the x-axis, which is the kingpin angle. Naming O the fixed frame O_{xyz} and O' the rotating frame $O_{x'y'z'}$, Equation 3.1 provides the rotation matrix to pass from O to O'.

$$R_{O\to O'} = R_z(\gamma)R_x(\delta) = \begin{bmatrix} \cos\gamma & -\sin\gamma\cos\delta & \sin\gamma\sin\delta \\ \sin\gamma & \cos\gamma\cos\delta & -\cos\gamma\sin\delta \\ 0 & \sin\delta & \cos\delta \end{bmatrix} \quad (3.1)$$

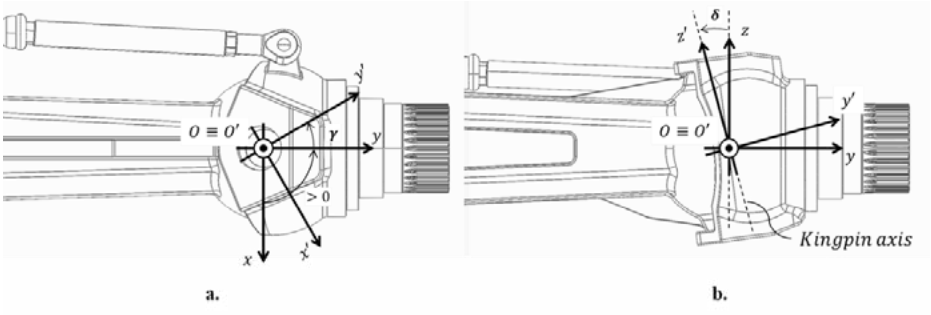

Figure 3.1. Fixed reference frame O_{xyz} and mobile $O_{x'y'z'}$ on xy-plane (a) and yz-plane (b)

3.2. Front Axle Analysis: Kinematics and Dynamics

The steering axle is approximated as a crank mechanism with deflected thrust, as Figure 3.2 depicts. For the sake of clarity, we use the same reference systems as common methods. Note that α, named the crank angle, can be written as $\alpha(\gamma)$ if $\widehat{AOG} = \pi/2$, where G is the tire center of gravity. Furthermore, the domain of $\alpha \notin [0; 2\pi]$ but is limited due to the kinematics of the axis. Eq. 3.2 represents the OAB vector closing triangle in terms of its coordinates.

$$A = \begin{cases} a\cos\alpha \\ a\sin\alpha \end{cases} \quad B = \begin{cases} s \\ h \end{cases} \quad (3.2)$$

where h is a fixed dimension that depends on the axle geometries, s is the cylinder stroke. Using Eq. 3.3 we obtain the length of the rod AB.

$$b = \sqrt{(s - a\cos\alpha)^2 + (h - a\sin\alpha)^2} \quad (3.3)$$

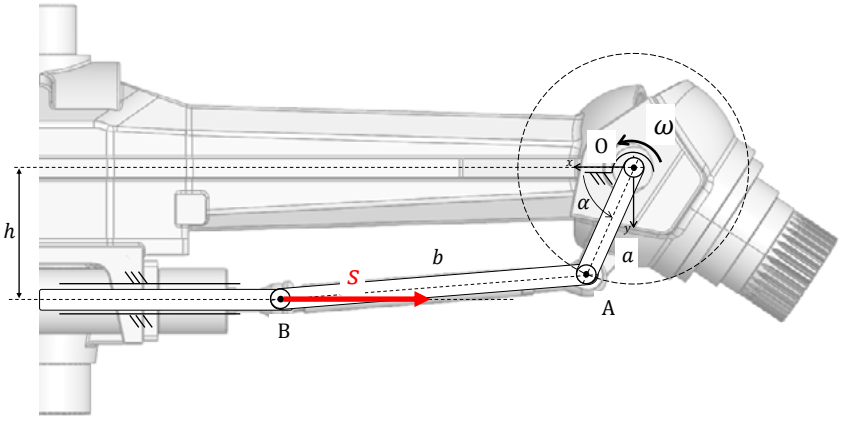

Figure 3.2. Kinematics right steered analysis

This condition results in a quadratic equation in s from which the solution, described in Eq. 3.4, is obtained.

$$s(\alpha) = a\cos\alpha + \sqrt{b^2 - (h - a\sin\alpha)^2} \tag{3.4}$$

It is now possible to derive Eq. 3.4 to obtain the speed of the steering actuator. Similarly, acceleration can be obtained by deriving the velocity.

Subsequently, we focus on dynamic analysis, with the system being modeled again as a crank mechanism with deflected thrust. The aim of this formulation is to guarantee that M_{res}, denoting the torque at hub, is balanced from the cylinder force. We present the right steering scenario, illustrated in Figure 3.3a.

However, this approach can also be applied to left steering. Therefore, the rod angle β can be expressed in Eq. 3.5.

$$\beta(\alpha) = \cos^{-1}\left(\frac{h - a\sin\alpha}{b}\right) \tag{3.5}$$

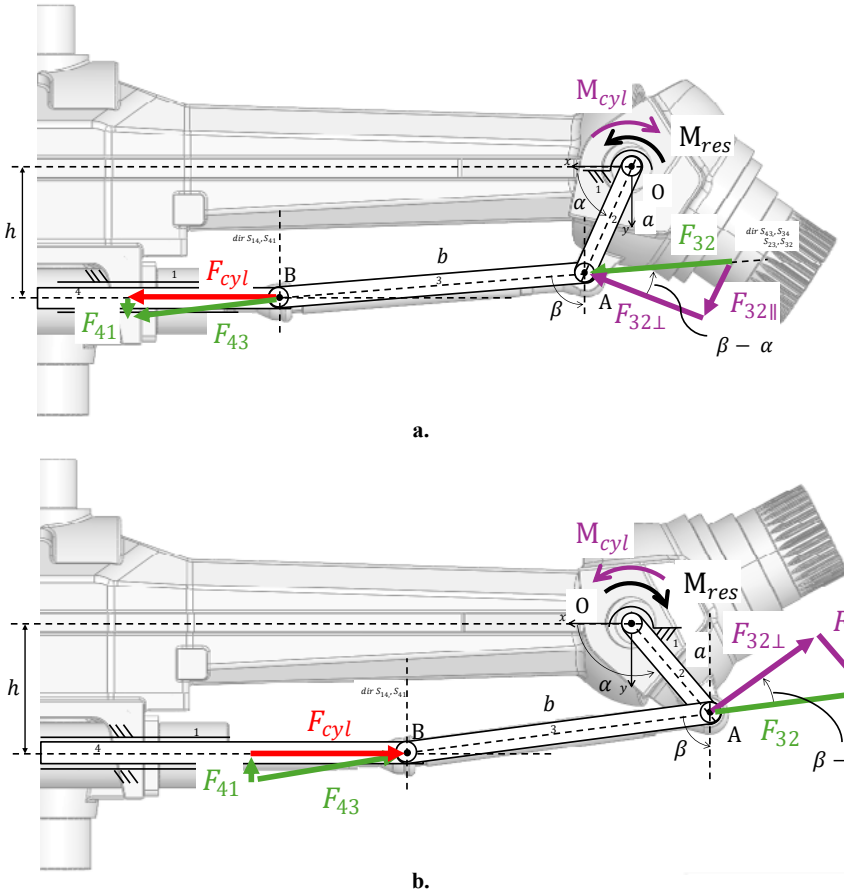

Figure 3.3. Dynamic right (a) and left (b) steered analysis

F_{cyl} represents the force applied by the cylinder in the direction of the guide. The axial force acting on the connecting rod AB is obtained by projecting it along the slider's axis, while the perpendicular component to the crank AO produces the resisting torque at the hub M_{res} around point O. Equation 3.6 illustrates the computation of M_{res}.

$$M_{res} = aF_{32,\perp} = aF_{32}\cos(\beta - \alpha) = a\frac{F_{cyl}}{\sin\beta}\cos(\beta - \alpha) \tag{3.6}$$

In conclusion, M_{res} is moved from the fixed frame to the mobile frame $O_{x'y'z'}$ by means of the rotation matrix $R_{O\to O'}$, to represent the hub torque on kingpin axis. Note that this model refers to a specific axle configuration and, in the future, with a library of axles available, the same method can be applied to other configurations.

3.3. Kingpin Torque Calculation and Terramechanics Analysis

In this subchapter, the resistance torque acting on the steering hub is estimated by combining different theoretical frameworks from kingpin analysis to terramechanics-based tire–soil interaction models. We chose a customized analytical approach rather than commercial "black-box" models in order to ensure flexibility and explicit control over critical variables, particularly tire sinkage (h). This allows for rapid reconfiguration of soil-vehicle parameters and direct definition of sinking levels, which are the main determinants of lateral loads on the steering. The current approach assumes a stationary vehicle and a pivot steering; therefore, future developments will extend the model to include vehicle motion, allowing the simulation of dynamic efforts.

3.3.1. Normal Contact Pressure and Sinkage

According to Bekker's pressure–sinkage relationship, the normal contact pressure $\sigma(h)$ between tire and soil is expressed as Eq. 3.7.

$$\sigma(h) = \left(\frac{k_c}{b} + k_\varphi\right)h^n \tag{3.7}$$

where k_c, k_φ, n are soil parameters, h is sinkage, and b is the tire width. The wheel sinkage $h(\theta)$ at arbitrary angular position θ is given geometrically by Eq. 3.8.

$$h(\theta) = r\,(\cos\theta - \cos\theta_s) \tag{3.8}$$

The contact angle θ_s is derived from the vertical load balance,

$$W = \int_{-\theta_s}^{\theta_s} \sigma(\theta)\, br\, \cos\theta\, d\theta \tag{3.9}$$

as W is the known tractor load on the wheel. The static sinkage is then evaluated using the geometric relation described in Eq. 3.10.

$$h_s = r(1 - \cos\theta_s) \tag{3.10}$$

where r is the tire radius and θ_s is the contact angle. Finally, the local pressure distribution can be represented as a function of θ, as shown in Eq. 3.11.

$$\sigma(\theta) = \left(\frac{k_c}{b} + k_\varphi\right)[r\,(\cos\theta - \cos\theta_s)]^n \tag{3.11}$$

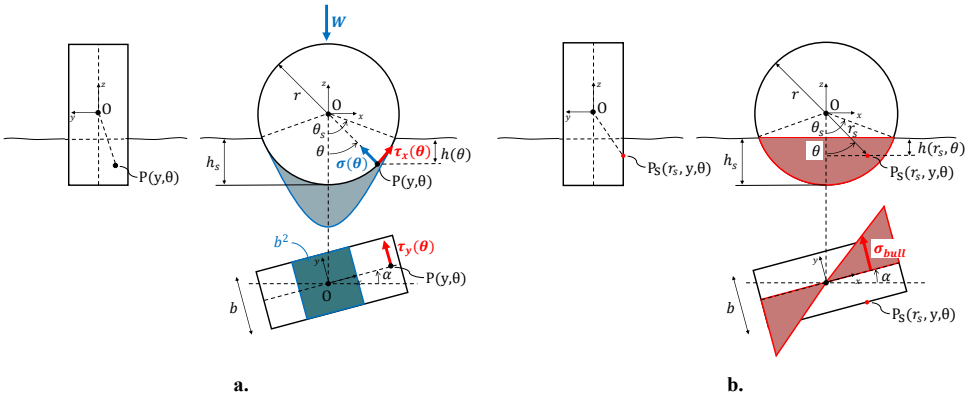

Figure 3.4. Representation of the contributions of normal pressure in $P(y,\theta)$ (a) and bulldozing in $P_s(r_s,y,\theta)$ (b) on the wheel

3.3.2. Shear Stress

The maximum shear stress that can be transferred between the ground and the tire is limited by the weakest contact, determined by the tire-to-ground friction and the internal cut resistance of the ground (Mohr-Coulomb). This relation is described in Eq. 3.12.

$$\tau_{max} = min\ (\mu_s\sigma, c + \sigma \tan\phi) \tag{3.12}$$

where μ_s is the sliding friction coefficient, c is the soil cohesion, and φ is the soil internal friction angle. For the integration of this contribution, we consider the point $P(y,\theta)$ as

$$P(y,\theta) = [r\ \sin\theta \quad y \quad -r\cos\theta]^T \tag{3.13}$$

In the stationary vehicle assumption ($v_x = 0$), slip ratio and slip angle lose physical meaning, so the Janosi–Hanamoto formulation is excluded. It will be introduced in future model extensions to account for longitudinal motion.

3.3.3. Bulldozing Resistance

In addition to shear stress, the soil exerts resistance on the lateral sinkage tire surface. We consider the point $P_s(r_s,y,\theta)$ as Figure 3.4 (a) depicts.

$$P_s(r_s,\ y,\theta) = [r_s\ \sin\theta \quad y \quad -r_s\cos\theta]^T \tag{3.14}$$

Thus, the relative sinkage is evaluated using Eq. 3.15.

$$h(r_s,\theta) = r_s\ \cos\theta - r\ \cos\theta_s \tag{3.15}$$

Following Hegedus model, the stress per unit width is evaluated using Eq. 3.16.

$$\sigma_{bull}(r_s,y,\theta) = D_1\left[c\ h(r_s,\theta) + D_2\frac{\rho_d h(r_s,\theta)^2}{2}\right] \tag{3.16}$$

In the equation above $D_1$and D_2 represent geometric coefficients derived from the soil internal friction angle, while ρ_d is the soil density.

3.3.4. Steering Aligning Torque

Due to kingpin inclination, steering must overcome soil resistance and generates a restoring torque. The steering aligning torque is evaluated using Eq. 3.17.

$$M_\theta = -W[e + (r - h_s)\tan\delta]\sin(2\delta)\sin\left(\frac{\gamma}{2}\right) \tag{3.17}$$

where e is the kingpin offset and δ the kingpin angle. This torque tends to realign the wheel toward the neutral position.

3.3.5. Resulting Force and Moments

Lateral (Y-direction) friction forces are computed by integrating over the cylindrical surface element $rd\theta dy$, which characterizes the interface between the wheel and soil (Figure 3.5).

$$F_y = \int_{-b/2}^{b/2}\int_{-\theta_s}^{\theta_s}\left(r\cdot\tau_y(\theta)\right)dyd\theta \tag{3.18}$$

An additional contribution from soil bulldozing must be considered, integrated over the lateral surface increment $r_s\ d\theta dr_s$ within the sink region of the tire.

$$F_{bull} = \int_{r-h(\theta)}^{r}\int_{-\theta_s}^{\theta_s}\sigma_{bull}(\theta)dr_s d\theta \tag{3.19}$$

The corresponding resisting torque is then evaluated using Eq. 3.20.

$$M_{res} = M_z = \int r\ sin\theta\ dF_y + \int r_s\ sin\theta\ dF_{bull} + M_\theta \tag{3.20}$$

In conclusion, M_{res} is moved from the fixed frame to the mobile frame $O_{x'y'z'}$ by means of the rotation matrix $R_{O\to O'}$ (Eq. 3.1).

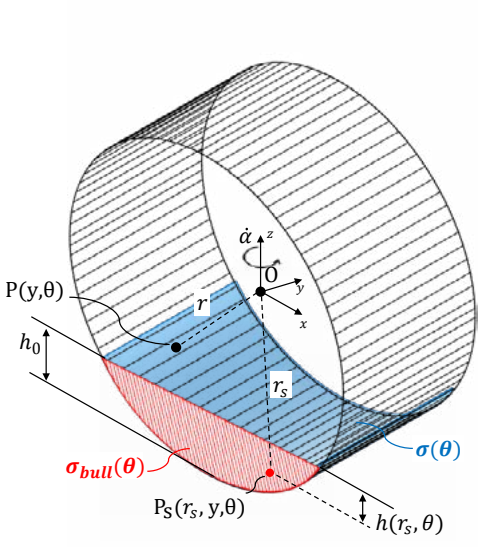

Figure 3.5. Integrals graphical representation of sigma and shear stresses on a tire

4. MULTIBODY APPROACH

The analytical formulation is then translated into a virtual prototype developed in a multi-body environment. In the present work, the modeling strategy is divided into two parts: the development of the steering axle model in ADAMS [29] and the implementation of the control logic in Simulink [30], which together forms the basis for co-simulating the complete steering system.

4.1. Front Axle Analysis: ADAMS model

The steering geometry was first designed in CAD and then imported into ADAMS for the definition of kinematic constraints and dynamic interactions. Some rigid components were merged according to their relative motion to maintain computational efficiency. For instance, the steering knuckle and hub were combined into one unit, while the cylinder of the hydraulic tie-rod assembly was incorporated into the housing.

Kinematic constraints were implemented to replicate the physical linkages, such as revolute joints at the kingpins, translation motion for the actuator rods, and spherical joints at the ball connections between the hubs and brackets.

The model dynamic behavior is introduced by applying a torque on the hubs joint aligned with the kingpin axis. This resistant torque, calculated in Simulink according to the selected operating scenario (for example clay soil with the New Holland T4.75 vehicle without cabin), reproduces the terra-mechanical resistance on the steering system. At the same time, the force exerted by the hydraulic actuator along its sliding axis is measured as the fundamental output of the multi-body model.

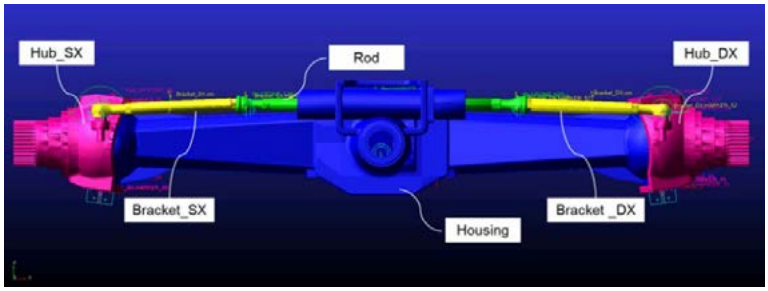

Figure 4.1. CAD model imported to ADAMS and creating constraints

4.2. Simulink Control Loop

The control subsystem was implemented in MATLAB/Simulink to drive the multibody model developed in ADAMS. The Simulink model is structured around different functional blocks, which together reproduce the dynamics of the steering bench and the input control to the hydraulic actuator.

The key parameters for the selected vehicle–ground configuration are read from .csv files, based on the user choices provided through the drop-down menu selections (1 in Fig. 4.2). In Tables 4.1 and 4.2, we provide parameters that characterize respectively soils and tractors, which relate to the results of the simulations discussed in the following chapter. It is important to note that we have assumed a vehicle weight distribution of 45% front and 55% rear. Also, the vehicle was evaluated without ballast and tools.

The control input of the system is the steering wheel angular position. Currently, a lock-to-lock maneuver is simulated; however, this signal will be logged in real-time concerning the angular position of the platform's steering wheel (2). These data and the geometric properties of the bench components are used to derive the displacement of the steering cylinder.

Blocks (3) and (4) contain MATLAB functions for computing the wheel hub-resistant torque $M(\gamma, k_{tractor}, k_{soil})$ and the actuator position $s(\theta_w, V_c)$, derived from the analytical model described in the previous sections.

The interface between Simulink and ADAMS was created using Adams Control/Plants (5), which exports the multibody model to a block that can be directly used in Simulink. Furthermore, a closed-loop is implemented to dynamically use the actual steering angle in the terramechanics function (3).

T6.180	27755	480	670	225	7.5

4.3. Co-simulation Setup

To realize the interfacing between the multibody model in ADAMS and the control model in Simulink, the ADAMS/Controls plugin is used. This tool allows the export of the ADAMS model as a block "plant", i.e. a template that defines the co-simulation inputs and outputs, into Simulink model. This block is a dynamic system that receives commands and returns kinematic/dynamic measurements to the control loop. From Simulink to ADAMS, the following state variables are provided:

- Torque corrections derived from the feedback law, M_{res}.
- Actuator rod displacement, s.

From ADAMS to Simulink, the following state variables are provided:

- Actual steering angle of the hubs, γ.
- Actuator force, F_{cyl}.

ADAMS simulates one time step while maintaining the received inputs constant. Then, Simulink simulates for the step, keeping the ADAMS outputs constant. The new values are then exchanged, and this loop continues.

5. RESULTS

The first set of results, shown in Figure 5.1 (a–b), presents a comparison between the analytical formulation and the multibody simulation. A lock-to-lock maneuver was simulated that corresponded to four complete turns of the steering wheel. In this manner, the steering actuator executes its complete stroke within the bench configuration.

Note that, due to the modeled mechanism, the full stroke of the actuator corresponds to a steering sweep of approximately 60° on the hub. Therefore, the steering angle asymmetry shown in Figure 5.1b is inherent to the steering axle kinematics. Future developments may include testing different CAD configurations. Finally Figure 5.1 (c–d) illustrates the steering cylinder force and the resisting hub torque, respectively, throughout the simulated duty cycle. The clear overlap between the curves indicates a strong correlation between the analytical and multibody models, with negligible deviations, confirming the accuracy of the kinematic and dynamic implementation of the virtual model.

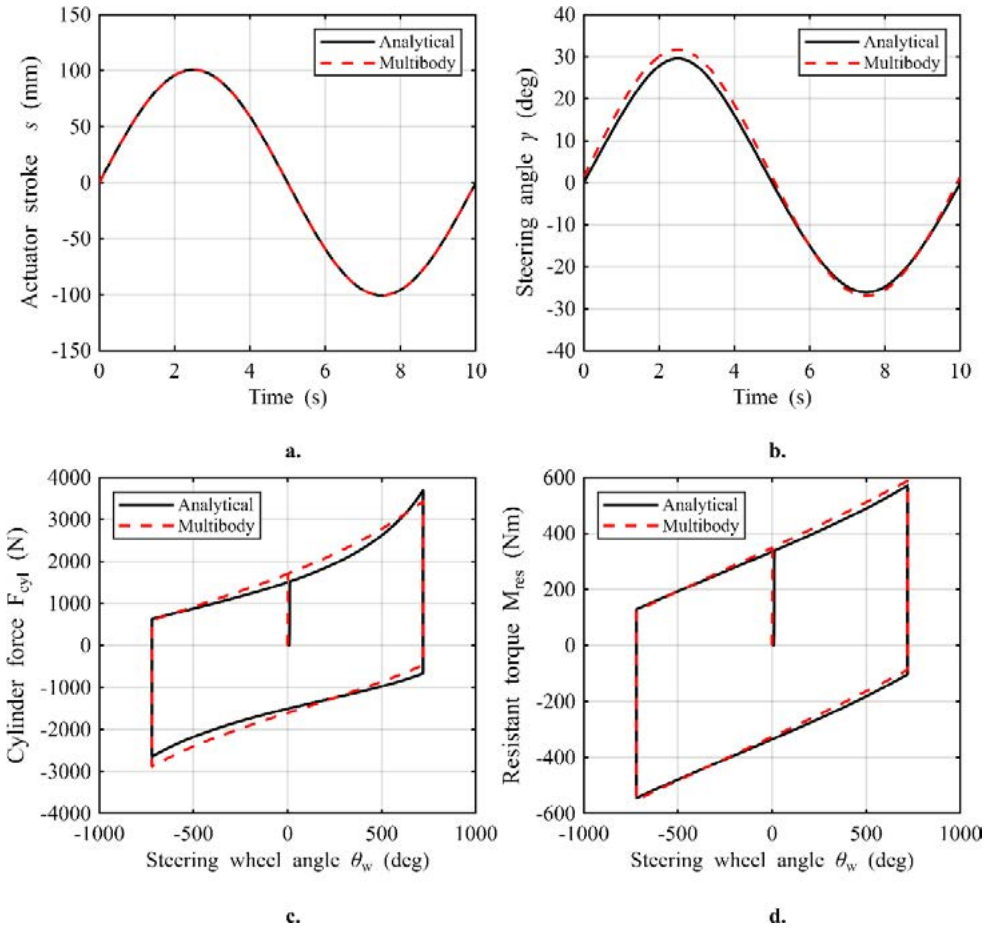

Figure 5.1. Simulation results for T4.75.4RM on Fertile Loam

Figure 5.2 illustrates a comparative analysis between the lighter New Holland T4.75 and the heavier T6.180 across four simulated soil conditions: Asphalt (A), Standard Sandy Loam (SSL), Fertile Loam (FL), and Moist Heavy Clay (MHC). For the New Holland T4.75.4RM (Figure 5.2 a-b), the impact of soil type on steering loads is minimal: the resulting resistance torques is similar in different scenarios. In fact, with a low vertical load, the deformation of the contact area and the corresponding soil shear stress are minimal, thereby reducing the variability of the steering resistance.

In contrast, in the case of the heavier vehicle (Figure 5.2 c-d), the influence of soil characteristics becomes significant. The heavier load on the front axle increases the tire-soil contact pressure, resulting in greater static sinkage (approximately 10 cm). As a result, more cohesive or compact soils generate the strongest torques, while softer soils allow easier lateral movement of tires. A distinct behavior can be observed on clayey soil (MHC): this soil provides low surface resistance, which is at most balanced by the self-aligning torque due to the kingpin's geometry during the rod's return movement. It is important to highlight that this kind of soil provided the greatest resistance when the tire sinkage is severe (for instance, during overload or "stuck" scenarios).

6. CONCLUSIONS

This work supports the performance evaluation of hydraulic steering systems in heavy vehicles, highlighting the role of digitalization in laboratory reproduction of operational scenarios through a digital twin approach. The proposed layout represents modular and scalable architecture, facilitating the acquisition of hydraulic and mechanical data that are often estimated during vehicle tests. This model represents the preliminary step of a forward-looking Hardware-in-the-Loop (HIL) approach. Despite the simplifying hypotheses adopted, the results appear robust and physically consistent, supported by the tuning of the terra-mechanical parameters according to the analytic approach.

Driven by growing industrial interest in improving the efficiency of on-board hydraulic systems, especially steering, future research will aim to simulate different front axle configurations. In addition, future developments will extend the model to include vehicle dynamics, influence of tire inflation pressure and non-stationary steering maneuvers.

Finally, the implementation of a Digital Twin, characterized by real-time bidirectional data exchange and synchronization between the digital model and the physical platform, represents the goal of this research project. Future works will focus on this final integration step and on the experimental validation of the complete co-simulation loop. This approach lays the groundwork for future advancements in virtual testing methodologies, contributing to more sustainable and efficient development of off-road vehicle systems.

Abstract.

Powertrain electrification is key to decarbonizing mobile machinery like wheel loaders. However, their work functions still rely on centralized valve control, causing significant energy losses. Electro-hydrostatic actuators (EHA) offer a decentralized, efficient alternative but often use fixed-displacement pumps, leading to poor efficiency under high-torque, low-speed conditions. Existing cooperative speed and displacement control are rule-based and neglect system dynamics, limiting optimal effect. This paper proposes a power optimization strategy for electric wheel loader work function with variable speed and pump displacement cooperative control. Offline dynamic programming (DP) first determines globally optimal operating points under typical conditions. Then a real-time optimization strategy is proposed based on the optimal results from DP algorithm. Results show the proposed system achieves a 9.12% reduction in energy consumption compared with the EHA system under the familiar cycle (9.76% for DP system). Under another unfamiliar cycle, the proposed system still has a 4.9% energy consumption reduction, demonstrating its energy-saving potential across various operating conditions.

Keywords. Electro-hydraulic actuator, variable speed and pump displacement control, dynamic programming, distributed hydraulic system, mobile machine.

1. INTRODUCTION

Powertrain electrification has emerged as a pivotal technological pathway for reducing carbon emissions in mobile machinery and represents a major focus of current research [1]. Among various types of electric mobile equipment, wheel loaders have achieved the highest market penetration [2]. Conventional electric wheel loaders typically utilize two electric motors—one for wheel drive and another for the working functions, and the latter consumes a substantial portion of the total battery energy. Although these systems employ high-efficiency electric motors, the working functions often continue to rely on centralized

All Open Access articles are peer-reviewed, distributed under the Creative Commons Attribution-Non Commercial 4.0 International

hydraulic valve control systems [3]. This results in significant throttling losses, reduced overall system efficiency, and limited operational duration per charge [4].

Decentralized hydraulic systems have gained increasing attention due to their potential for higher energy efficiency and superior control performance compared to centralized configurations [5, 6]. A prominent solution in this category is the electro-hydrostatic actuator (EHA), which uses a variable-speed electric motor as the prime mover for each hydraulic actuator. Many studies have been conducted on that solution. Qu applied an electro-hydrostatic variable speed drive system in a skid steer loader, achieving a steady-state energy efficiency of up to 59.9% [7]. Ge proposed a EHA driving by an asymmetric pump and the energy consumption during the entire boom cylinder loading cycle can be reduced by 75.0 % [8]. Guo proposed a variable speed drive steering system for wheel loaders, which reduced energy consumption by 22.8% compared with centralized systems [9].

However, in most EHA implementations, the hydraulic pump displacement remains fixed. This limitation forces the electric motor's operating points to be dictated directly by the external load, leading to relatively low system efficiency—particularly under high-torque, low-speed conditions. To address this challenge, several cooperative control strategies for simultaneous speed and displacement adjustment have been proposed. Huang proposed an active load-sensitive EHA with a dual control variable system. The output flow of the pump is implemented by adjusting the motor speed and the pump displacement based on the load-sensitive principle. The system efficiency is optimized in real time and the system dynamic performance is improved [10, 11]. Lin developed a combined motor speed and hydraulic pump displacement control strategy, achieving hierarchical system pressure control, reducing energy consumption by up to 70% [12].

Nevertheless, existing methods predominantly rely on simplified rule-based approaches, which fail to achieve optimal system energy efficiency. Moreover, these strategies often neglect system dynamic characteristics, thereby limiting their practical effectiveness. The dynamic programming (DP) algorithm is a well-established method for solving global optimization problems in dynamic systems [13, 14]. However, its high computational burden renders it unsuitable for real-time implementation.

In this context, this paper proposes an energy-optimized control strategy for the work function of electric wheel loaders, based on cooperative variable speed and displacement control. The DP algorithm is first applied offline to derive efficiency-optimal operating parameters under typical working cycles. These results then guide the design of a real-time optimization strategy that incorporates system dynamics. The rest of the paper is organized as follows. Section II presents system mathematical modelling, section III shows DP algorithm and real-time optimization strategy, section IV presents simulation study and section V gives conclusions.

2. MATHEMATICAL MODELLING OF ELECTRO-HYDRAULIC ACTUATOR SYSTEM

2.1. System Overview

The schematic of EHA system with variable speed and pump displacement control for wheel loaders is shown in Figure 2.1. It uses an electric motor (EM) as a primary mover for each

hydraulic working function and is able to optimize the working points of both electric motor and hydraulic pump (HP). The working hydraulic system consists of lift and tilt functions. The hydraulic variable displacement pumps can work in four quadrants. Two 4/3 directional valves (DV) allow for load holding capability. An on-off valve works as a bypass valve (BPV) parallel to the tilt cylinder (TC). The accumulators (ACC) compensate for the differential flow of the cylinders during extension phase and intake excess flow during retraction phase. Two sets of pilot check valves (PCV) control the charging and discharging process of the accumulator.

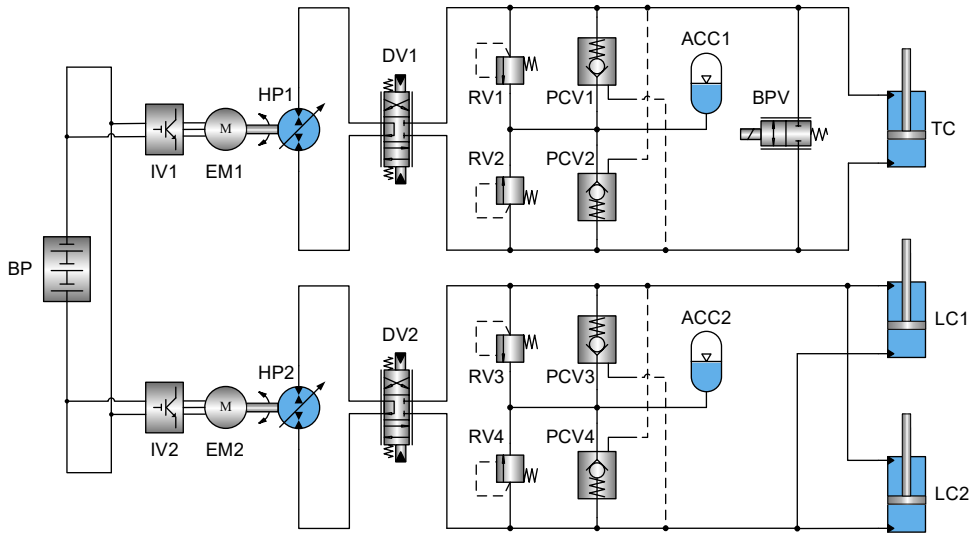

Figure 2.1. Schematic of electro-hydraulic actuator system with variable speed and pump displacement control

2.2. System Modelling

The physical-based mathematic models are established in this study for the following power optimization strategy design, including the models of battery pack, electric motors, hydraulic pumps, and so on. The SI unit is used in the mathematic models.

Battery Pack

A widely used equivalent circuit model composed of a voltage source, U_{oc}, and a resistance, R_b, is used for battery modelling [15,16]. The battery charge/discharge current, I_b, is given by:

$$I_b = \frac{U_{oc} - \sqrt{U_{oc}^2 - 4R_b P_{bout}}}{2R_b} \tag{2.1}$$

where P_{bout} is the output power (electric load power) of battery and can be expressed as:

$$P_{bout} = P_{iv1} + P_{iv2} \tag{2.2}$$

where P_{iv1}, and P_{iv2} are the input power of two inverters respectively.

Electric Motor

The electric motors in this study are permanent magnet synchronous motors (PMSM) that can work either as motors or as generators. A commonly used mathematical model of PMSM is to present electromagnetic vectors in an orthogonal d-q coordinate with d axis coinciding rotor flux linkage direction [17]. The winding stator voltage components in the d-q axis, u_d, u_q are:

$$\begin{cases} u_d = R_s i_d + \frac{d\psi_d}{dt} - \omega_{em}\psi_d \\ u_q = R_s i_q + \frac{d\psi_q}{dt} + \omega_{em}\psi_q \end{cases} \quad (2.3)$$

where R_s is stator winding's equivalent resistance, ω_{em} is the shaft speed of electric motor, i_d and i_q are equivalent currents in the d-q axis, ψ_d and ψ_q are d-q components flux linkage.

The electric motor output shaft torque T_{em} is:

$$T_{em} = \frac{3}{2} n_p i_q \left[\psi_f + (L_d - L_q) i_d\right] \quad (2.4)$$

where n_p is the number of pole pairs of motor stator.

The dynamics of electric motor shaft speed is:

$$(J_{em} + J_{hp})\dot{\omega}_{em} = T_{em} - T_{hp} - k_{vf}\omega_{em} \quad (2.5)$$

where J_{em} and J_{hp} are shaft inertia of electric motor and hydraulic pump, T_{hp} is hydraulic pump torque, k_{vf} is rotary friction coefficient.

Hydraulic Pump

The shaft torque of hydraulic pump, T_{hp}, is:

$$T_{hp} = \frac{D\Delta p}{\eta_{mech}{}^{\beta}} \quad (2.6)$$

where D is pump displacement, Δp is pressure difference between pump outlet and inlet pressure, η_{mech} is pump mechanical efficiency, β is mode factor ($\beta = 1$ in pumping mode and $\beta = -1$ in motoring mode).

The pump output flow rate, q_{hp} is:

$$q_{hp} = D\omega_{em}\eta_{vol}{}^{\beta} \quad (2.7)$$

where η_{vol} is pump volumetric efficiency.

3. DYNAMIC PROGRAMMING ALGORITHM AND REAL-TIME STRATEGY

3.1. Dynamic Programming Algorithm

The Dynamic Programming is a powerful algorithmic technique for solving complex optimization problems by breaking them down into simpler, overlapping subproblems. Its core principle is to solve each subproblem only once, store the solution, and reuse it when needed, thereby avoiding redundant calculations and improving efficiency, as shown in Figure 3.1. This "divide-and-conquer-with-memorization" approach is particularly effective for sequential decision-making processes. The method relies on Bellman's principle of

optimality, which states that an optimal policy consists of optimal sub-policies. By recursively defining the value of a state based on subsequent states, DP constructs an optimal solution from back to front, making it ideal for applications like pathfinding, resource allocation, and optimal control strategies.

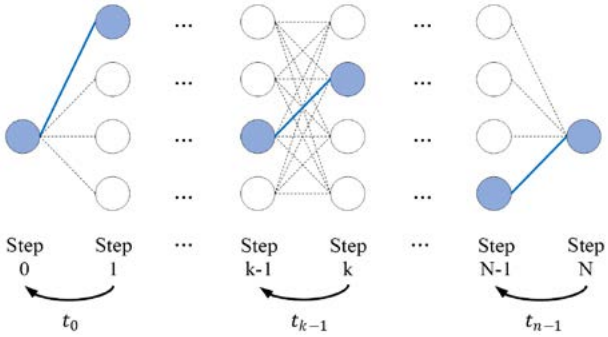

Figure 3.1. Schematic of dynamic programming algorithm

DP is adopted in this paper to obtain the efficiency-optimal operating parameters (rotary speed of electric motor and pump displacement) under typical working conditions of wheel loaders. Considering that the calculation complexity of DP algorithm increases exponentially with the dimensions of state variables and control variables, the pressure dynamics in the pipelines are neglected for simplicity and feasibility.

The flow chat of dynamic programming algorithm is shown in Figure 3.2. After getting the piston velocity and load force from loading cycle, the system operating mode is classified. The operating mode of wheel loaders normally includes two quadrants since the load force direction remains the same.

During extension mode ($v > 0$), the system power losses are given by:

$$P_{pvl} = \Delta p \omega_{em} D(1-\eta_{vol}) = \Delta p \frac{A_{head}}{\eta_{vol}}(1-\eta_{vol})v \quad (2.8)$$

$$P_{pml} = \Delta p \omega_{em} D \frac{1-\eta_{mech}}{\eta_{mech}} = \Delta p \frac{A_{head}}{\eta_{vol}} \frac{1-\eta_{mech}}{\eta_{mech}} v \quad (2.9)$$

$$P_{ml} = \omega_{em} T_{hp} \frac{1-\eta_{em}}{\eta_{em}} = \Delta p \frac{A_{head}}{\eta_{vol}\eta_{mech}} \frac{1-\eta_{em}}{\eta_{em}} v \quad (2.10)$$

$$P_{bl} = I_b^2 R_b \quad (2.11)$$

where P_{pvl} and P_{pml} are volumetric and mechanical power losses of hydraulic pump, P_{ml} is power loss of electric motor and inverter, P_{bl} is power loss of battery.

During retraction mode ($v < 0$), the system operations between lift and tilt functions are different. The lift function recoveries gravitational potential energy of loader working device and its hydraulic pump works in motoring mode. The system power losses are given by:

$$P_{pvl} = \Delta p A_{head}(1-\eta_{vol})v \quad (2.12)$$

$$P_{pml} = \Delta p A_{head}(1-\eta_{mech})\eta_{vol} v \quad (2.13)$$

$$P_{ml} = \Delta p A_{head}\eta_{vol}\eta_{mech}(1-\eta_{em})v \quad (2.14)$$

$$P_{bl} = I_b^2 R_b \tag{2.15}$$

For the tilt function, the bypass valve placed in parallel to the tilt cylinder is open during retraction mode to accelerate the motion process. Since the pressure difference between pump outlet and inlet pressure equals to zero, the system power losses during the bucket retracting are neglected.

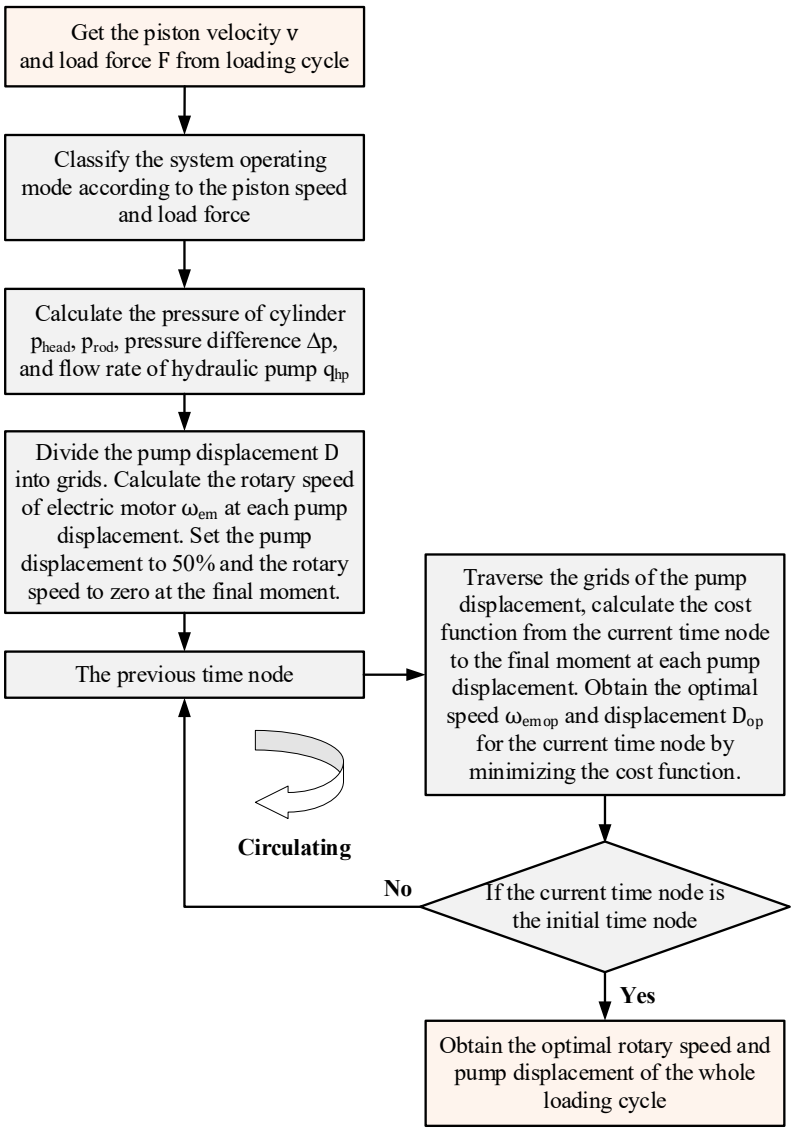

Figure 3.2. Flow chat of dynamic programming algorithm

After calculating the system states, a set of pump displacement is selected from 2.5 cc/rev to 250 cc/rev (100% maximum displacement) with an interval of 2.5 cc/rev. Then the rotary speed of electric motor at each pump displacement is calculated according to Eq. (2.7). To

facilitate the DP algorithm to find the optimal displacement more quickly, the pump displacement at the final moment is set to 50%. The rotary speed at the final moment is set to zero.

During the dynamic programming process, the rotary speed, acceleration of electric motor and the rate of change of the pump displacement should be restricted within proper range according to the real dynamics of electric motor and hydraulic pump. Therefore, a penalty function is added to the optimization problem to discard the state exceeding physical limitations in the optimization process, since a larger value from penalty function will be added besides cost function.

By setting the weight coefficient of all constraints. The expression of the penalty function is given by:

$$\begin{aligned} f_{pen} = k_{penalty}\big[&H(\omega_{em} - \omega_{emmax}) + H(\omega_{em} - \omega_{emmin}) + H(\dot{\omega}_{em} - \dot{\omega}_{emmax}) + \\ &H(\dot{\omega}_{em} - \dot{\omega}_{emmin}) + H\big(\dot{D} - \dot{D}_{max}\big) + H\big(\dot{D} - \dot{D}_{min}\big)\big] \end{aligned} \tag{2.16}$$

$$\dot{\omega}_{emmax} = \frac{T_{emmax}\text{-}T_{hp}\text{-}k_{vf}\omega_{em}}{J_{em}+J_{hp}} \tag{2.17}$$

$$\dot{\omega}_{emmin} = \frac{T_{emmin}\text{-}T_{hp}\text{-}k_{vf}\omega_{em}}{J_{em}+J_{hp}} \tag{2.18}$$

where $k_{penalty}$ is weight coefficient of penalty function, ω_{emmax} and ω_{emmin} are the maximum and minimum rotary speed of electric motor, $\dot{\omega}_{emmax}$ and $\dot{\omega}_{emmin}$ are the maximum and minimum rotary acceleration of electric motor, T_{emmax} and T_{emmin} (reverse) are the maximum and minimum output shaft torque of electric motor, $\dot{D}_{max}$ and $\dot{D}_{min}$ are the maximum and minimum rate of change of the pump displacement obtained from test results.

The cost function from the current time node to the final moment at each pump displacement is given by:

$$J_k = \int_{kT_s}^{(k+1)T_s} P_{pvl} + P_{pml} + P_{ml} + P_{bl}dt + f_{pen,k} + J_{k+1} \tag{2.19}$$

where J_k, J_{k+1} are cost functions of time nodes k and $k+1$, T_s is discrete-time timestep.

By traversing the grids of the pump displacement, the optimal pump displacement for the current time node is obtained by minimizing the cost function:

$$D_{op,k} = \underset{D \in \Omega}{\operatorname{argmin}}\, J_k \tag{2.20}$$

The nested loops are used that start at the end and the optimal pump displacement is computed for every node recursively.

3.2. Real-Time Rotary Speed and Pump Displacement Optimization Strategy

Although DP is an effective method to solve global optimization problems, its substantial computational demands make real-time optimization infeasible. Therefore, in this paper, a real-time rotary speed and pump displacement optimization strategy is designed based on the optimized results from dynamic programming algorithm.

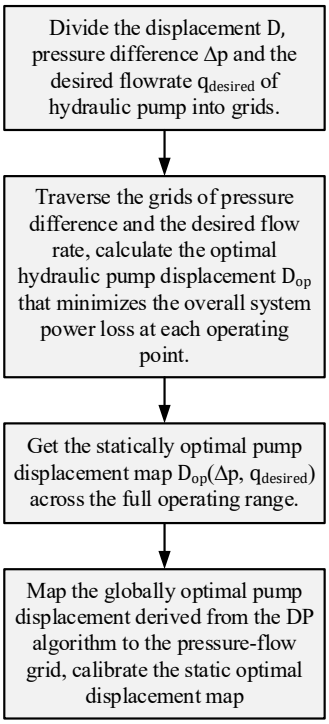

Figure 3.3. Flow chat of real-time optimization strategy

The flow chat of real-time optimization strategy is shown in Figure 3.3. The real-time optimization strategy is a two-stage methodology for determining the globally optimal displacement of a hydraulic pump. The first stage is to obtain the statically optimal pump displacement map $D_{op}(\Delta p, q_{desired})$ across the full operating range. Key operational parameters (displacement D, pressure difference Δp, and desired flow rate $q_{desired}$ of hydraulic pump) are discretized into grids in the beginning. For each discrete operating point within this grid, it calculates the specific pump displacement that minimizes the overall system power loss. This exhaustive search yields a preliminary, statically optimal displacement map, which defines the most efficient pump setting for any given pressure and flow requirement within the predefined operating range.

In the final and crucial step, the results from DP algorithm, which computes a sequence of optimal decisions over time, are mapped onto the same pressure-flow grid. This integration allows the static map to be calibrated and refined with the globally optimal trajectory from the DP solution, thereby enhancing its accuracy and ensuring system-wide optimality.

4. SIMULATION STUDY

4.1. Simulation Parameters

The dynamic simulation model of the proposed system is developed in Amesim. The simulation models target a 12 tons electric wheel loader. The major parameters are shown in Table 4.1. The nominal voltage of battery is 648 V. The accumulator volume is calculated to compensate for the differential volume of the cylinders during extension phase. The

displacement of the hydraulic pumps determines the shaft speed limits of electric motors. In the simulation, two 22 L accumulators are selected for the tilt and lift functions.

The efficiency map of electric motor is obtained from the experimental data as shown in Figure 4.1. The flowrate and shaft torque of hydraulic pump/motor is shown in Figure 4.2 and Figure 4.3. The first loading cycle used in this study is 60 s long and includes six phases: preparing, bucket filling, load holding, boom lifting, dumping and boom lowering.

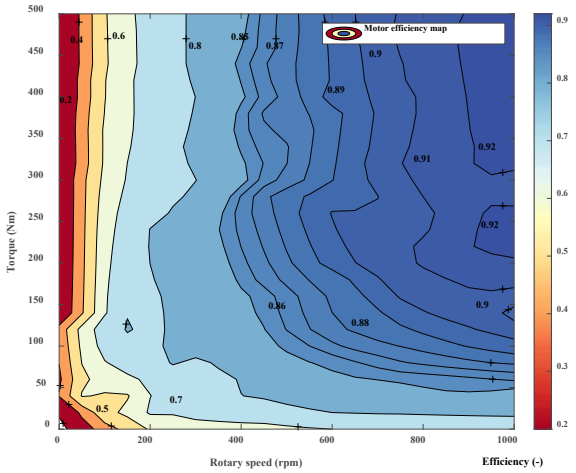

Figure 4.1. Efficiency map of the electric motor

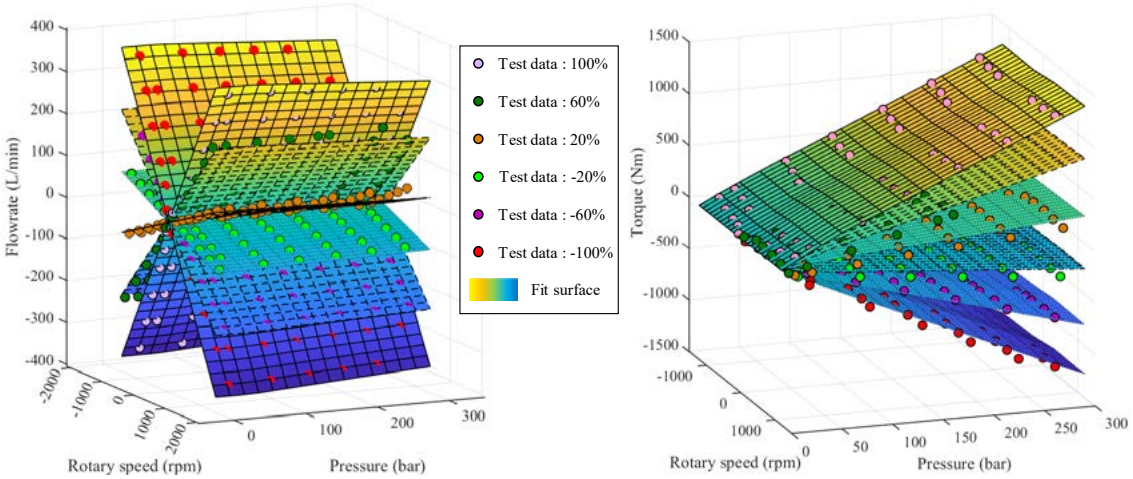

Figure 4.2. Flowrate and shaft torque of hydraulic pump/motor

Table 4.1. Main simulation parameters

Property		**Value**	**Unit**
Battery	Nominal voltage	648	V
Electric motor	Maximum rotary speed	2000	rpm
	Maximum torque	648	Nm
Hydraulic pump	Geometric displacement	250	cc/rev

Accumulator	Volume	22.0	L
	Precharge pressure	8	bar
Direction valve	Maximum throttling area	256.12	mm2
	Natural frequency	20.0	Hz
	Damping ratio	1.2	-
Tilt/Lift cylinder	Piston stroke	350.0/450.0	mm
	Piston diameter	180.0/150.0	mm
	Rod diameter	80.0/90.0	mm

4.2. Simulation Results

There are three hydraulic system configurations considered in the simulation study: normal EHA system, variable speed and pump displacement control system with DP algorithm (VSVD-DP), variable speed and pump displacement control system with real-time optimization strategy (VSVD-RT).

In the EHA system, each actuator is driven by a stand-alone electric motor with a fixed displacement hydraulic pump and the actuator speed is controlled through variable speed drive of electric motor. The 4/3 directional valve is fully open when the actuator moves and closes in standby mode. The comparison of piston displacement between three systems is shown in Figure 4.3. The piston displacements of the three systems are essentially consistent, except for the discrepancy during the bucket lowering phase. This is due to the drastic changes in piston velocity during the bucket lowering phase, which poses challenges to the control accuracy of variable speed and displacement system.

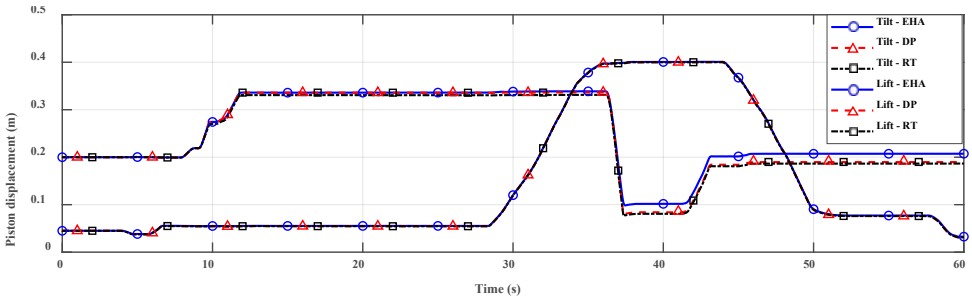

Figure 4.3. Comparison of piston displacement between three systems

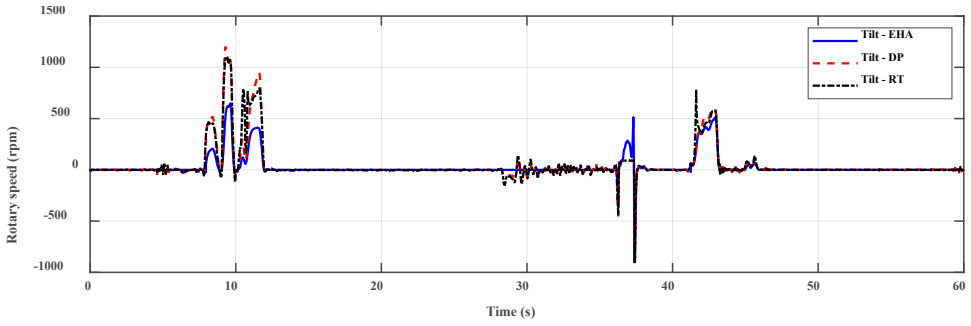

Figure 4.4. Comparison of tilt rotary speed between three systems

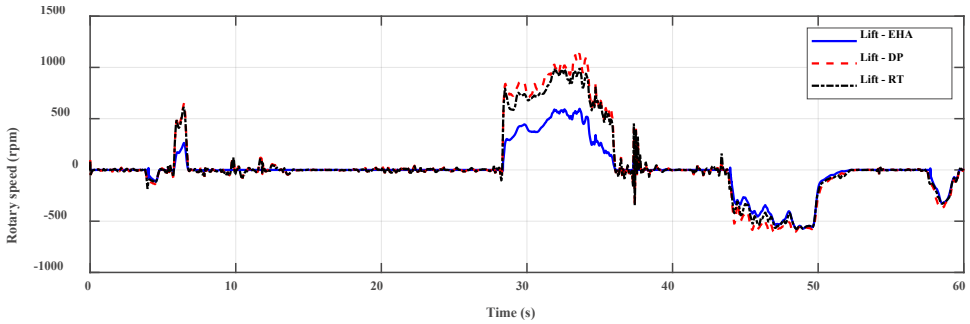

Figure 4.5. Comparison of lift rotary speed between three systems

The comparison of rotary speed between three systems is shown in Figure 4.4 and Figure 4.5. As the 4/3 directional valve opens and closes during system status switching process, there are some pressure shocks leading to the peak fluctuations of motor shaft torque in the EHA system. Compared with the EHA system, the shaft speeds of DP and RT systems are much higher during bucket filling and boom lifting phase.

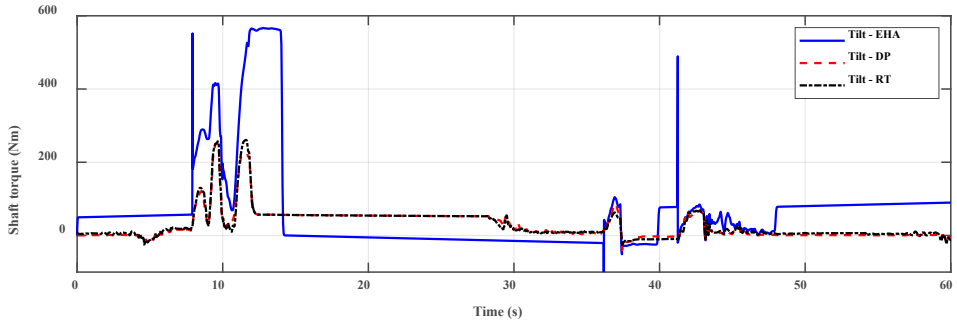

Figure 4.6. Comparison of tilt shaft torque between three systems

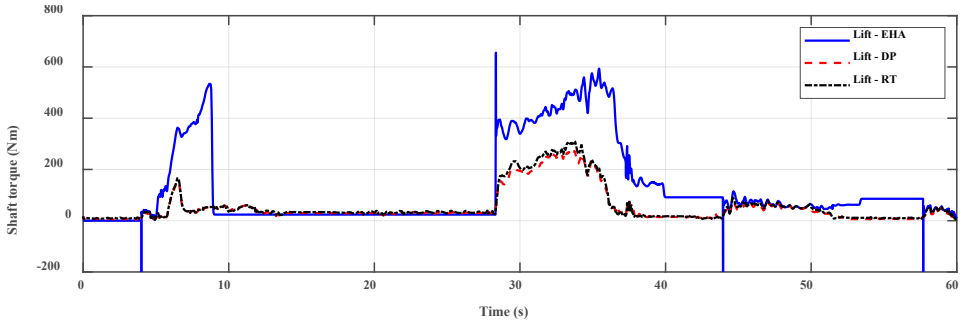

Figure 4.7. Comparison of lift shaft torque between three systems

The shaft torque results are shown in Figure 4.6 and Figure 4.7. Due to the reduction in hydraulic pump displacement, the motor output torque of the DP and RT systems in operating mode decreases significantly compared with EHA system. The pump displacement results between three systems are shown in Figure 4.8 and Figure 4.9. The pump displacement in the EHA system is always maintained at 100%, while the pump

displacement in the DP and RT systems is adjusted in real time according to operating conditions. By adjusting the pump displacement, the operating points of the motors in the DP and RT systems shift toward the high-efficiency region characterized by high speed and low torque. The 4/3 directional valves in the DP and RT systems are fully open from the beginning to the end. In the standby mode, both DP and real-time strategies keep the pump displacement close to zero to reduce the power loss of electric motor.

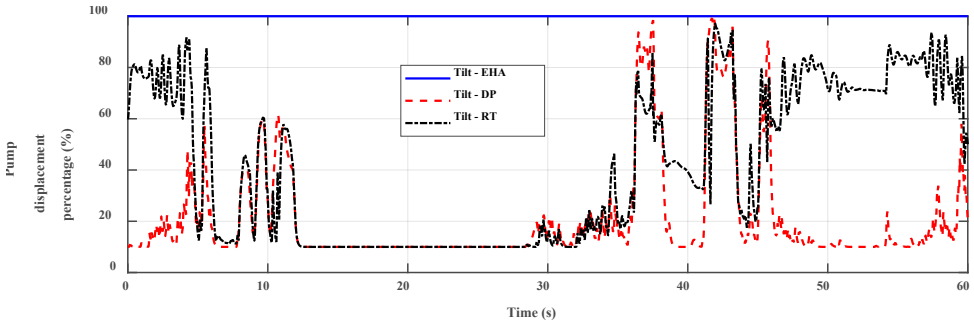

Figure 4.8. Comparison of tilt pump displacement between three systems

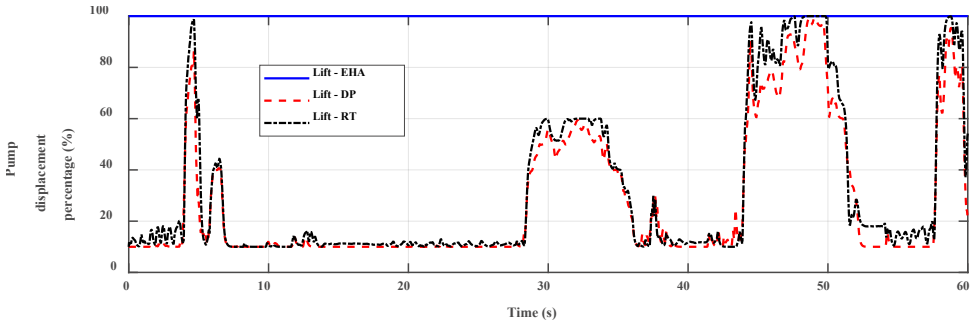

Figure 4.9. Comparison of lift pump displacement between three systems

The pump displacement percentage curves between DP and RT systems still have slight differences. Since the DP strategy accounts for dynamic constraints of the system, the obtained globally optimal displacement percentage exhibits smoother variations. In contrast, the real-time optimization strategy leads to more fluctuations. However, owing to the calibration of the real-time strategy based on DP results, the pump displacement from RT system is close to the results from DP with much smaller computational complexity.

The comparison of energy consumption between EHA, DP, optimized and non- optimized RT systems is shown in Figure 4.10. The total energy consumptions of these system are 218.3 kJ, 197.0 kJ, 198.4 and 202.9 kJ respectively. Compared with the EHA system, the energy consumptions of VSVD systems are reduced, primarily due to the decrease in electric motor energy loss. The DP system achieves the lowest energy consumption through offline global optimization. Compared to the EHA system, the non-optimized RT system saves 7.05% in energy consumption, while a 9.12% reduction is achieved in the optimized RT system, approaching the optimal result of the DP system.

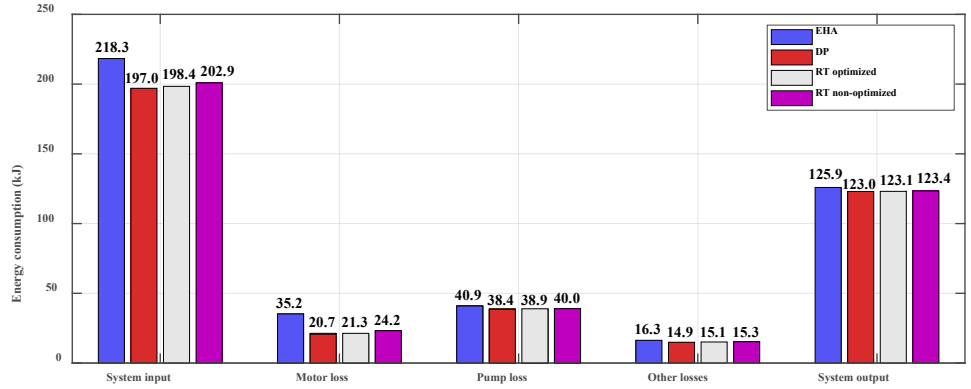

Figure 4.10. Comparison of energy consumption between systems

The aforementioned results verify the energy-saving effectiveness of the real-time optimization strategy under specific operating conditions. To investigate the influence of different operating conditions on the proposed method, an unfamiliar loading cycle lasting 32 s is selected as the system input. The hydraulic cylinder piston displacement curve under the new cycle is shown in Figure 4.11. Compared with the previous cycle, the piston displacement variation is greater, and the intervals between movements are shorter.

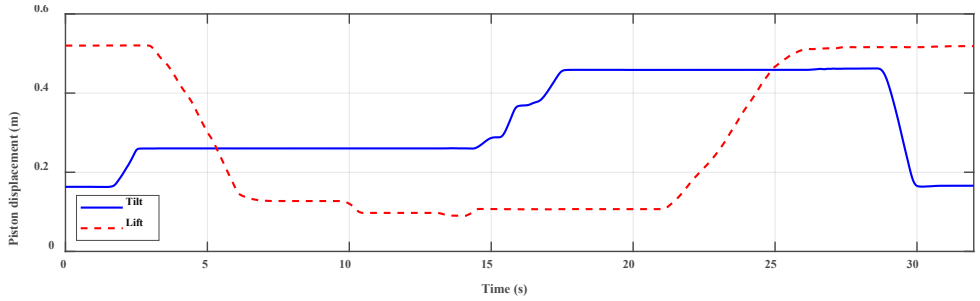

Figure 4.11. Piston displacement under 32 s long loading cycle

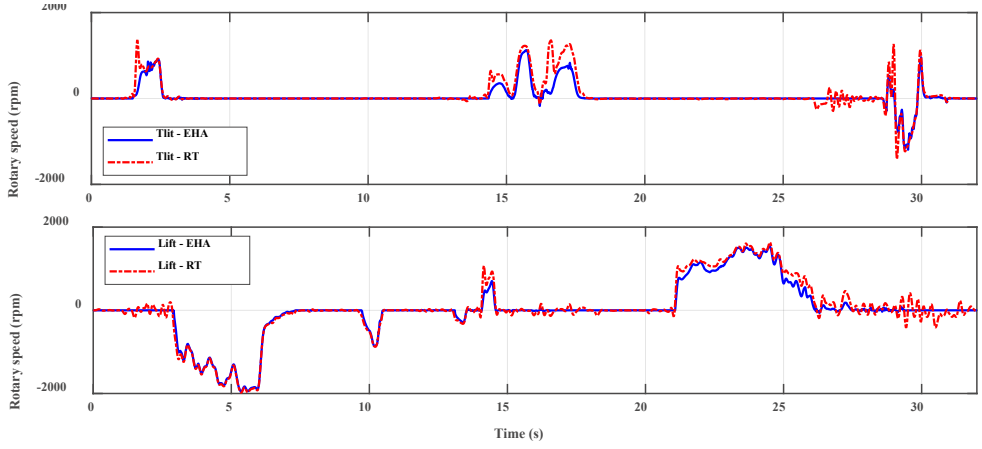

Figure 4.12. Comparison of rotary speed between EHA and RT systems

The comparison of rotary speed between EHA and RT systems is shown in Figure 4.12. The shaft speed of RT system is slightly higher than that of the EHA system. From the results of lift working function, it can be observed that when the cycle requires high flowrate, the motor rotary speeds of the EHA and RT systems are essentially the same, indicating that the hydraulic pump operates at full displacement under such conditions.

The comparison of shaft torque between EHA and RT systems is shown in Figure 4.13. The mean motor shaft torque of the RT system is significantly lower than that of the EHA system. The RT optimization strategy can rapidly reduce motor torque by adjusting the hydraulic pump displacement after the operation is completed, thereby minimizing motor energy loss.

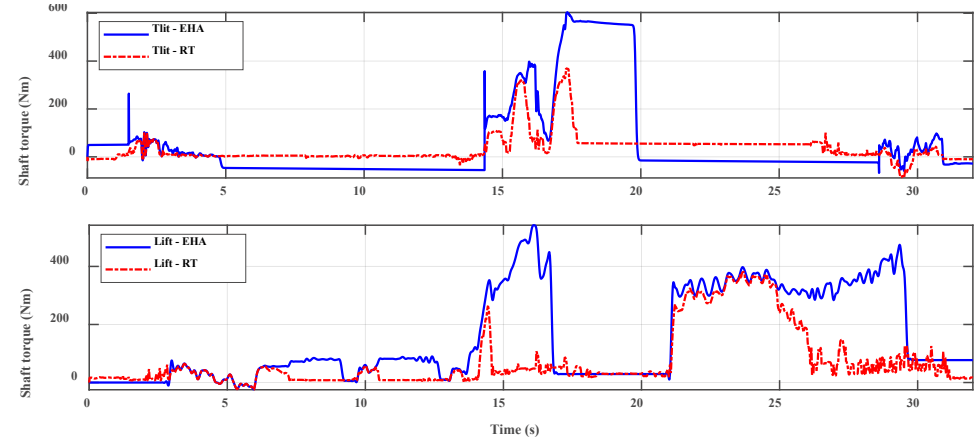

Figure 4.13. Comparison of shaft torque between EHA and RT systems

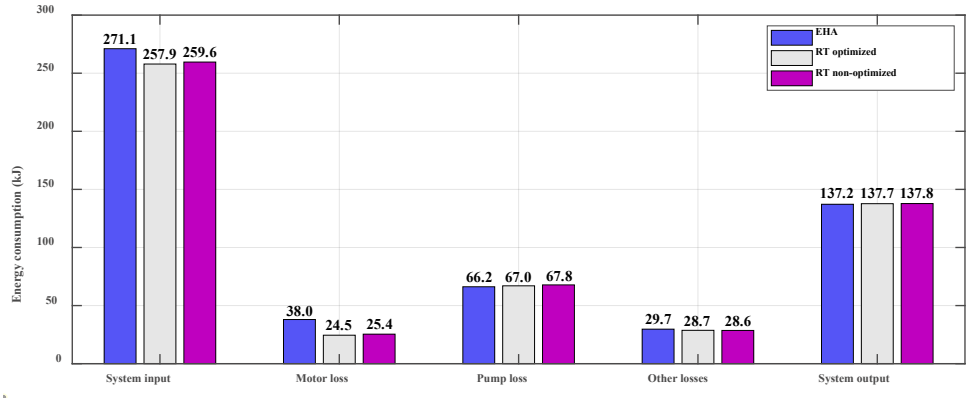

Figure 4.14. Comparison of energy consumption between EHA and RT systems

The comparison of energy consumption between EHA, optimized and non- optimized RT systems is shown in Figure 4.14. The total energy consumptions of these system are 271.1 kJ, 257.9 kJ and 259.6 kJ respectively. Both VSVD systems have smaller energy consumptions than that of the EHA system under an unfamiliar loading cycle. Due to the increased power output required for short loading cycle, the operating time under full hydraulic pump displacement is extended in the VSVD systems, resulting in a reduced margin of energy consumption reduction compared to the EHA system. Although the new

cycle shortens the overall time with an increased piston displacement change, the motion pattern of the working functions remains similar to that of the long cycle. Consequently, the optimized RT strategy achieves additional system energy savings compared to the non-optimized one.

5. CONCLUSIONS

In this paper, a power optimization strategy for electric wheel loader work function with variable speed and pump displacement cooperative control is proposed. The dynamic programming algorithm is applied offline to obtain the efficiency-optimal operating parameters under typical working conditions of wheel loaders. Based on the optimized results, a real-time rotary speed and pump displacement optimization strategy is designed.

The dynamic simulation models of three hydraulic systems (EHA, VSVD-DP, VSVD-RT) are developed in Amesim. Two loading cycles are used in this study. Under the familiar cycle, VSVD-RT system achieves a 9.12% reduction in total energy consumption compared with the EHA system (9.76% for DP system). Under another unfamiliar cycle, the proposed system still has a 4.9% energy consumption reduction. The results indicate that the real-time optimization strategy possesses energy-saving potential across various operating conditions. In practical applications, the real-time model can be calibrated using DP global optimal solutions derived from multiple frequently-used loading cycle, thereby enhancing its adaptability to different operating scenarios.

A PID Controller Gain Adjustment Mechanism to Balance EHA Tracking and Health

Simo Käki, Mikko Huova, Tatiana Minav

Innovative Hydraulics and Automation, Tampere University, Tampere, Finland, firstname.lastname@tuni.fi

Abstract.

Electro-hydraulic systems power much of today's working machinery, which often operate in remote or harsh locations where maintenance is difficult. Given the cost and safety concerns of unplanned outages, strategies that prevent breakdowns between service intervals are crucial. One prominent approach is to adjust the parameters of existing controllers in a health-aware manner to potentially extend the remaining useful life (RUL) of the components.

Consequently, this paper presents a health-aware adjustment method for a PID-controlled electro-hydrostatic actuator that tunes the controller gain online to balance tracking and health. The method estimates a hidden degradation state using an extended Kalman filter and models the short-horizon degradation as a Wiener process. It derives an inverse-Gaussian RUL distribution from the degradation estimates and fits a ridge model that links control effort to degradation rate. Moreover, a supervisory cost function weighs an integral-squared error against a soft health constraint and selects gain updates accordingly.

In accelerated simulation studies, an update of the controller gain slowed degradation and thus extended the RUL. The system met a 95 percent survival target while keeping the control error modest. This approach adds improved life-extension potential with minimal architectural change, and it can run as a cloud-based supervisory layer that updates parameters using recorded data.

Keywords. Electro-hydrostatic actuator, external gear pump, health-aware control, PID-control, remaining useful life

1. INTRODUCTION

Maintaining working machinery is crucial, as the cost of unplanned outages can be significant. However, this is often challenging in practice, since machines frequently operate in remote and harsh environments. Accurate remaining useful life (RUL) prediction can provide key information for maintenance scheduling. In recent years, estimating the RUL of various components in electro-hydraulic systems has seen considerable research interest. Bejaoui et al. [1] and Dahal et al. [2] investigated the RUL of rotating machines using data-

All Open Access articles are peer-reviewed, distributed under the Creative Commons Attribution-Non Commercial 4.0 International

driven methods. On the hydraulic side, the pump has been the focus of multiple papers utilizing physics-based approaches [3, 4], data-based approaches [5–7], or a combination of these, i.e., hybrid approaches [8, 9], to estimate the RUL.

Previous research has tended to focus on RUL prediction and fault-tolerant control rather than on failure prevention [10–13]. However, there has been growing interest in life-extending control or health-aware control (HAC) for systems that are difficult to maintain [14–16]. A recent survey by Zagorowska et al. [17] highlights the potential of HAC and underlines the need for more research that integrates degradation-dependent models in simulations when validating optimization and scheduling layers.

A regulatory control system requires accurate knowledge of the system behavior over short timescales. In contrast, degradation is often a very slow process and depends on the way in which the system is operated as well as on external factors. Thus, integrating both the performance and degradation mitigation in the same control loop leads inevitably to computational problems [18]. This problem naturally leads to a multi-layer approach where a long-run RUL problem is solved separately from the lower-level regulatory problem.

The aim of this paper is to develop an adjustment method for a proportional-integral-derivative (PID) controller in an electro-hydrostatic actuator (EHA) system. The EHA is selected, as it combines tight servo performance with compact, self-contained hydraulics. Moreover, the adoption of EHAs is anticipated to increase substantially with the growing introduction of electrification of working machinery and aerospace applications [19].To enable RUL-extending capabilities, measurements of oil flow, pressures, and pump rotational speed are required. This approach provides an alternative to complex HAC systems by adjusting the existing controller rather than designing degradation-aware control from scratch. This has the added benefit that the adjustment mechanism can be executed as a cloud-based service. Additionally, minimal assumptions are made about the hidden degradation model of the gear pump in the degradation estimation step.

The remainder of this paper is structured into four sections. Section 2 outlines the methodology applied throughout the study. Section 3 introduces the simulation model and explains the techniques. Section 4 discusses the main results in detail, and Section 5 concludes with a summary of the key findings and their relevance to fluid power applications.

2. METHODOLOGY

2.1. Degradation Model

In this paper, the RUL optimization is called the adjustment mechanism, which updates the parameters of the regulatory controller. To simulate the behavior of an adjustment mechanism, accurate knowledge of the degradation is needed. A single-input single-output (SISO) system with degrading actuator is considered. Here, the time-varying and hidden degradation variable is defined $\phi(t)$. To model the evolution of the degradation, a nonlinear Wiener process model is employed [19–21] with the following equation:

$$\phi(t) = \phi_0 + \int_0^t \varphi(\tau, \boldsymbol{\theta}, \dots) d\tau + \sigma B(t), \tag{1}$$

where ϕ_0 is the initial value, $\varphi(\tau, \boldsymbol{\theta}, \dots)$ is the deterministic nonlinear function of τ with the parameter vector $\boldsymbol{\theta}$ and possible other inputs that describe the degradation rate, σ is the diffusion parameter which reflects the degradation variation, and $B(t)$ is the standard Brownian motion.

The deterministic part of Equation (1) is often coupled with the state, inputs, and/or outputs of the actuator, making this a factor-based model. This coupling is heavily content dependent, and a considerable amount of research has been conducted to investigate suitable formulations [17].

The degradation variable represents the strength of an item. The item fails when the process reaches an adverse threshold state for the first time. In this case, the lifetime in component-level prognostics is usually defined as the first hitting time (FHT) of the degradation process reaching a failure threshold ϕ_f [23], which is denoted as

$$t_f = \inf\{t \geq 0 : \ \phi(t) \geq \phi_f \mid \phi(0) < \phi_f\}, \tag{2}$$

where t_f is the failure time. Here, it is worth noting that the above definition is only applicable to a case with an increasing degradation process. Additionally, the choice of failure threshold is not obvious. Thus, careful engineering knowledge of the system requirements should be used to determine a sufficient value.

Differentiating Equation (1) yields

$$\frac{d}{dt}\phi(t) = \varphi(t, \boldsymbol{\theta}, \dots) + \sigma w(t), \tag{3}$$

where $w(t) \sim \mathcal{N}(0,1)$ is white noise. The degradation rate $\varphi(\dots)$ is often quite slow, so it is safe to assume that an average rate gives a reasonable estimate of the immediate future degradation behavior. This assumption holds when the variation in the degradation rate over time is negligible, making the average rate particularly suitable for short-term prediction. Otherwise, a time-dependent rate should be considered for improved accuracy. Following this assumption, the nonlinear degradation model (1) can be estimated with the linear Wiener process model

$$\phi(t) \approx \phi_0 + \mu t + \sigma B(t), \tag{4}$$

where μ is the (constant) degradation rate. This simplification can be improved with historical knowledge of degradation progression.

2.2. Extended Kalman Filter

An extended Kalman filter (EKF) is a nonlinear state estimation technique that extends the classical Kalman filter to systems with nonlinear dynamics and/or measurement models [24]. By linearizing the system around the current estimate with first-order Taylor expansion, the EKF enables recursive estimation of the system state in real time. This makes the EKF an effective choice for estimating the current degradation rate in addition to the current degradation. To achieve this, Equation (4) is written as

$$\begin{bmatrix} \dot{\mu} \\ \dot{\phi} \end{bmatrix} = \begin{bmatrix} 0 & 0 \\ 1 & 0 \end{bmatrix} \begin{bmatrix} \mu \\ \phi \end{bmatrix} + w, \tag{5}$$

where $w \sim \mathcal{N}(0, \Sigma_w)$ is the process noise with a zero-mean Gaussian distribution and $\boldsymbol{x}_{kf} = [\mu \quad \phi]^{\mathrm{T}}$ is the state vector. Equation (5) should be supplemented with (possibly) the nonlinear measurement function

$$\boldsymbol{y}_{kf} = h(\boldsymbol{x}_{kf}, \boldsymbol{u}_{kf}) + v, \tag{6}$$

where $v \sim \mathcal{N}(0, \Sigma_v)$ is the measurement noise with a zero-mean Gaussian distribution that relates the degradation $\phi(t)$ to the measured values $\boldsymbol{y}_{kf}$ and inputs $\boldsymbol{u}_{kf}$.

The EKF algorithm consists of a prediction step and an update step. In the prediction step, the state and covariance are propagated forward in time using the system model. This *a priori* information is denoted by a superscript minus sign ($^-$). In the update step *a posteriori* information is denoted by a superscript plus sign ($^+$).

The EKF algorithm requires the Jacobians of the system dynamics and measurement functions. For the case of Equation (5), the discrete time Jacobians are

$$F = \begin{bmatrix} 1 & 0 \\ t_{s,ekf} & 1 \end{bmatrix}, \tag{7}$$

$$H = \frac{\partial}{\partial \boldsymbol{x}_{kf}} h(\boldsymbol{x}_{kf}, \boldsymbol{u}_{kf}), \tag{8}$$

where $t_{s,ekf}$ is the sampling time of the filter. These are then utilized in the prediction step to update the state estimate and covariance with equations

$$\hat{\boldsymbol{x}}_{kf}^{-}[k] = F\hat{\boldsymbol{x}}_{kf}^{+}[k-1], \tag{9}$$

$$\Sigma_{\boldsymbol{x}}^{-}[k] = F\Sigma_{\boldsymbol{x}}^{+}[k-1]F^{\mathrm{T}} + \Sigma_w, \tag{10}$$

where k is the current sampling timestep.

The update step starts with calculating the *a priori* measurements

$$\hat{\boldsymbol{y}}_{kf}^{-}[k] = h(\hat{\boldsymbol{x}}_{kf}^{-}[k], \boldsymbol{u}_{kf}[k]), \tag{11}$$

and the Kalman gain

$$K = \Sigma_{\boldsymbol{x}}^{-}[k]H^{\mathrm{T}}(H\Sigma_{\boldsymbol{x}}^{-}[k]H^{\mathrm{T}} + \Sigma_v)^{-1}. \tag{12}$$

The *a priori* measurements and the Kalman gain are then used to update the state estimate

$$\hat{\boldsymbol{x}}_{kf}^{+}[k] = \hat{\boldsymbol{x}}_{kf}^{-}[k] + K(\boldsymbol{y}_{kf}[k] - \hat{\boldsymbol{y}}_{kf}^{-}[k]). \tag{13}$$

Finally, the covariance matrix is updated with the Joseph form

$$\Sigma_{\boldsymbol{x}}^{+}[k] = (I - KH)\Sigma_{\boldsymbol{x}}^{-}[k](I - KH)^{\mathrm{T}} + K\Sigma_v K^{\mathrm{T}}, \tag{14}$$

where I is the identity matrix of a necessary size. The use of the Joseph form prevents the loss of positive definiteness in the covariance matrix due to numerical errors. This formulation is crucial when dealing with small numerical updates in long-term estimation tasks. Moreover, this formulation of the EKF enables an estimate of the degradation and the drift of a wide range of components. However, there are limits, which are outside the scope of this paper, as to the extent to which EKF can be utilized in this manner.

2.3. RUL Estimation

To estimate the RUL of the component, the remaining degradation margin is calculated with

$$L = \phi_f - \hat{\phi}[k], \tag{15}$$

where $\hat{\phi}[k]$ is the current degradation estimate from the EKF. For a meaningful prognostic horizon, $L > 0$ is required. Utilizing the slow degradation assumption in Equation (4), the RUL for this process becomes a classical FHT problem. For Brownian motion with a positive drift, the FHT to a fixed level has an inverse Gaussian (IG) distribution [23]. This link between drifted Brownian motion and the IG law is a standard result in stochastic process theory and is widely used in degradation-based reliability modeling.

In particular, if L is the distance to the failure threshold, then

$$\hat{t}_{RUL} \sim \mathrm{IG}\left(\frac{L}{\mu}, \frac{L^2}{\sigma^2}\right). \tag{16}$$

The corresponding cumulative distribution function (CDF) can be written using the standard normal distribution $\Phi(\cdot)$

$$F_{IG}(t) = \Phi\left(\frac{\hat{\mu}t - L}{\hat{\sigma}\sqrt{t}}\right) + \exp\left(\frac{2\hat{\mu}L}{\hat{\sigma}^2}\right)\Phi\left(-\frac{\hat{\mu}t + L}{\hat{\sigma}\sqrt{t}}\right), \tag{17}$$

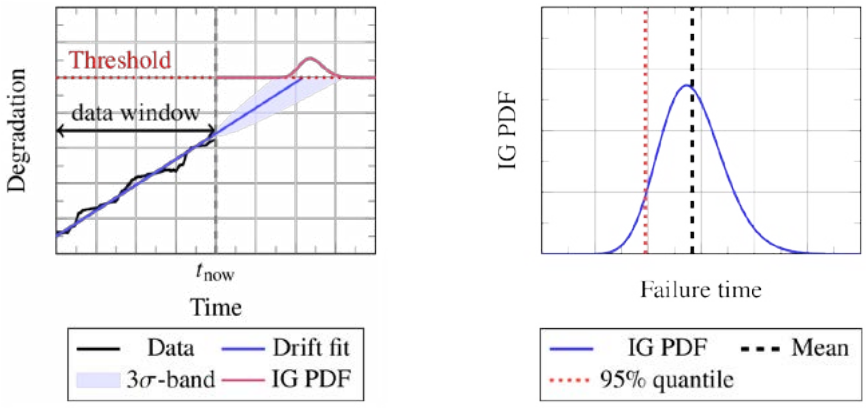
where $\hat{\mu}$ is the current drift estimate and $\hat{\sigma}$ is the current diffusion estimate.

For a stable estimate of RUL, an evaluation time with a moving average can be utilized. As the EKF estimates the degradation with a low sampling time, a variety of unwanted dynamics and noise can negatively impact the calculations. At every evaluation time t_{eval}, the average from a recent data window for $\hat{\mu}$ can be calculated. Accordingly, the current diffusion estimate measures the random variability of degradation that is not explained by the drift estimate. The maximum likelihood estimate for the diffusion can be calculated with

$$\hat{\sigma}^2 = \frac{1}{\sum t_s}\sum_k \frac{(\boldsymbol{\phi}_W[k] - \boldsymbol{\phi}_W[k-1] - \hat{\mu}t_s)^2}{t_s}, \tag{18}$$

where $\boldsymbol{\phi}_W$ is the vector of degradation estimates from the EKF with the length of the moving window. For numerical stability, it is recommended to normalize $\hat{\phi}$ and $\hat{\mu}$ by dividing them with the failure threshold.

Finally, the mean RUL can be calculated with



$$\hat{t}_{RUL} = \frac{L}{\hat{\mu}}. \tag{19}$$

For a more conservative estimate, a survival percentage can be chosen (i.e., 95%). Then, the RUL must be solved from

$$F_{IG}(\hat{t}_{RUL,p}) = 1 - p, \tag{20}$$

where p is the survival probability.

The RUL estimate is visualized in Figure 2.1. The Figure 2.1 (a) shows the recent degradation estimate date from the EKF and the failure threshold. Then, the model from Equation (4) is fitted to this data and plotted forward in time with a 3σ-band to show the uncertainty. The IG probability density function (PDF) from Figure 2.1 (b) is also plotted in Figure 2.1 (a). In Figure 2.1 (b), the mean RUL and the more conservative 95% survival RUL are plotted with vertical lines.

(a) **(b)**

Figure 2.1: Visualization of the RUL estimation from buffered data. (a) Drift fit to recent degradation data. (b) IG PDF with $\hat{t}_{RUL}$ and $\hat{t}_{RUL,95\%}$.

2.4. Adjustment Mechanism

The adjustment mechanism requires information on the effect of the control signal $u(t)$ on the degradation speed. A simple linear model

$$\hat{\mu} \approx X\boldsymbol{\beta}, \tag{21}$$

where X is the feature matrix and $\boldsymbol{\beta}$ is the fitted coefficients of the model, can be fitted to buffered degradation rate estimates $\hat{\mu}$ from the EKF. The fitting can be achieved using ridge regression [25]. In this study, the features are chosen as constant, rotational speed, and rotational acceleration. The corresponding drift term becomes $\hat{\mu}(t) \approx \beta_0 + \beta_1 u(t) + \beta_2 \dot{u}(t)$. These features were selected to be consistent with the deterministic degradation contributions in later Equations (34) and (35), and because $u(t)$ is the only variable the controller can directly influence, making it the most relevant regressor for analyzing how control actions correlate with degradation speed in this framework.

More generally, degradation can also depend on exogenous and operating-condition variables such as pressure, temperature, and contamination level. Such variables can be appended as additional columns in X when reliable measurements are available. However, they are not included here because the present study focuses on a simplified simulation setting and isolates the influence of the control action.

It is assumed that the controlled system can be presented as a SISO discrete time linear state-space model

$$\boldsymbol{x}_p[k+1] = A_d\boldsymbol{x}_p[k] + B_d u[k], \tag{22}$$

$$y[k] = C_d\boldsymbol{x}_p[k] + D_d u[k], \tag{23}$$

where $\boldsymbol{x}_p$ is the state vector, A_d is the dynamics matrix, B_d is the input matrix, C_d is the output matrix, and D_d is the feedthrough matrix. The system output y is controlled by discrete 2DOF-PID controller of the form [26]

$$x_{f,2}[k] = q_1 x_{f,2}[k-1] + q_2\Big((cr[k] - y[k]) - x_{f,1}[k-1]\Big), \tag{24}$$

$$x_{f,1}[k] = x_{f,1}[k-1] + t_s x_{f,2}[k], \tag{25}$$

$$u[k] = k_p(br[k] - y[k]) + u_i[k] - k_p t_d x_{f,2}[k], \tag{26}$$

$$u_i[k+1] = u_i[k] + \frac{k_p t_s}{t_i}(r[k] - y[k]), \tag{27}$$

where r is the target value for y, $x_{f,1}$ and $x_{f,2}$ are the states of a lowpass filter, k_p is the controller gain, t_i is the integral time, t_d is the derivative time, t_s is the sampling time, b is the proportional reference weight, and c is the derivative reference weight. The internal gains of the lowpass filter are calculated with

$$q_1 = \frac{\tau_f^2}{\tau_f^2 + 2t_s\tau_f + 2t_s^2}, \tag{28}$$

$$q_2 = \frac{2t_s}{\tau_f^2 + 2t_s\tau_f + 2t_s^2}, \tag{29}$$

where τ_f is the filter time constant.

Finally, the adjustment mechanism can be formulated as

$$\min_{k_p} J(k_p) \text{ such that } k_{p,min} < k_p < k_{p,max}, \tag{30}$$

where $J(k_p)$ is the cost function that relates the performance and RUL of the system to the controller gain k_p. To ensure dimensional consistency and allow tuning of priorities, the cost function is formulated as

$$J(k_p) = w_1 \cdot ISE(k_p) + w_2 \cdot HEALTH(k_p), \tag{31}$$

where w_1 and w_2 are weighting factors that balance tracking and health preservation, $ISE(k_p)$ is the integral squared error that can be calculated from the past reference values and simulated with Equations (22)–(27) and $HEALTH(k_p)$ is the health constraint. The health constraint is formulated as a soft constraint

$$HEALTH(k_p) = \begin{cases} 0 & \text{if } \hat{t}_{RUL,95\%}(\hat{\mu}(k_p)) \geq t_{RUL,req} \\ 10^6\left(t_{RUL,req} - \hat{t}_{RUL,95\%}(\hat{\mu}(k_p))\right)^2 & \text{otherwise} \end{cases}, \tag{32}$$

where $t_{RUL,req}$ is the remaining mission time, $\hat{t}_{RUL,95\%}(\hat{\mu})$ is the 95% quantile RUL from Equation (20), and $\hat{\mu}(k_p)$ is the degradation rate from Equation (21), where the feature matrix can be constructed from the simulation.

The complete framework for the adjustment mechanism is presented in Figure 2.2. The extended Kalman filter is utilized to estimate the degradation and degradation rate from the rotation speed, generated flow, and port pressures of the pump. From these, a RUL estimate can be made. The degradation rate is used in the feature extraction block to estimate how the rotational speed affects the degradation speed. Finally, the optimizer employs this information to find the best value for the controller gain.

3. SIMULATION MODEL

A Simulink model of an EHA system is used to evaluate the effectiveness of the adjustment mechanism. The whole simulation model is presented in more detail in a previous publication [27]. This section focuses on the main differences in the simulation model to the previous usage. The hydraulic diagram of an EHA is shown in Figure 3.1.

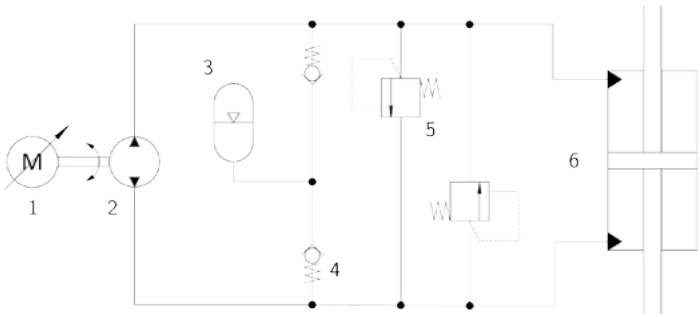

Figure 3.1: EHA hydraulic diagram. 1. Electric motor. 2. Hydraulic pump. 3. Accumulator. 4. Check-valves. 5. Pressure-relief valves. 6. Double-acting cylinder.

The hydraulic pump is modeled as an external gear pump. The outflow of the pump is modeled with Schlösser's loss coefficient model [28]

$$Q_A = V_p n - C_{sl}\frac{V_p(p_{h,A} - p_{h,B})}{2\pi\nu} - C_{st}V_p^{\frac{2}{3}}\sqrt{\frac{2(p_{h,A} - p_{h,B})}{\rho}} - C_{se}p_{h,A}, \quad (33)$$

where V_p is the volumetric displacement, n is the rotational speed, C_{sl} is the laminar slip coefficient, $p_{h,A}$ and $p_{h,B}$ are the hose pressures, ν is the dynamic viscosity, C_{st} is the turbulent slip coefficient, ρ is the oil density, and C_{se} is the external leakage coefficient.

During the system operation, the performance of the actuator gradually deteriorates. This degradation can be represented by certain actuator parameters. In this study, the slip coefficients C_{sl} and C_{st} are utilized as hidden variables to characterize the degradation of the pump. This is motivated by the fact that internal leakage increases over time [29]. This choice is illustrative as other parameters could also be used. Based on Equation (1), the hidden degradation process is modelled as

$$C_{sl}(t) = C_{sl}(0) + \int_0^t \lambda_1|n(\tau)| + \lambda_2\left|\frac{d}{d\tau}n(\tau)\right| d\tau + \sigma B_1(t), \quad (34)$$

$$C_{st}(t) = C_{st}(0) + \int_0^t \lambda_1|n(\tau)| + \lambda_2\left|\frac{d}{d\tau}n(\tau)\right| d\tau + \sigma B_2(t), \quad (35)$$

where λ_i is the degradation rate coefficient. Here, it is assumed that both slip coefficients increase by the same proportion, but the Brownian motion is different. It is also assumed that the amount of degradation per unit of time is proportional to the amplitude of the rotational speed and the rotational acceleration. This assumption reflects the fact that stress is usage-dependent and increases with higher rotational speed and fast changes between operation points. Therefore, increasing controller aggressiveness can increase peak acceleration, but may still reduce cumulative degradation if it shortens transients and reduces the time spent at elevated rotational speed. The resulting effect is not necessarily monotonic in k_p and depends on the duty cycle and the coefficients of the speed- and acceleration-dependent terms.

In the EKF, a lumped parameter model for internal leakage

$$Q_A = V_p n - \hat{\phi}(p_{h,A} - p_{h,B}) - C_{se}p_{h,A}, \quad (36)$$

was utilized as the measurement function in Equation (6). This formulation allows for a straightforward definition of the failure threshold based on the operation requirements of the cylinder. For the simulations, the failure threshold was set to $\phi_f = 4 \cdot 10^{-12}\ (m^3/s)/Pa$. It is assumed that the volumetric displacement and the external leakage coefficient are known, while flow, rotational speed, and pressures are measured.

The simulation model parameters are summarized in

Table 1. The table presents only the parameters that differ from the previous publication [27]. The position reference and load forces are also identical to the previous publication. These were repeated until the degradation reached the specified failure threshold in the simulation.

Table 1: EHA simulation model parameters compared to previous publication [27]

Parameter	Symbol	Value
Pump displacement	V_p	$1.2732 \cdot 10^{-6}\ m^3/rad$
Initial laminar slip coeff.	$C_{sl}(0)$	$5 \cdot 10^{-9}$
Initial turbulent slip coeff.	$C_{st}(0)$	10^{-11}
External leakage coeff.	C_{se}	10^{-13}
Rot. speed degradation rate coeff.	λ_1	$2 \cdot 10^{-11}$
Rot. accel. degradation rate coeff.	λ_2	$8 \cdot 10^{-12}$
Diffusion coefficient	σ	10^{-9}
Dynamic viscosity	ν	$0.03\ Pa \cdot s$
Bulk modulus (cylinder)	β_{cyl}	$1200 \cdot 10^6\ Pa$
Bulk modulus (hose)	β_{hose}	$400 \cdot 10^6\ Pa$

The EHA position is controlled by a 2DOF-PID controller. The control signal is calculated according to Equations (24)–(27). The parameters of the controller are presented in Table 2. The controller gain is adjusted with the previously described adjustment mechanism. The parameters of the prognostics and health monitoring system are presented in Table 3.

Table 2: PID controller parameters

Parameter	Symbol	Value
Nominal gain	k_p	$4000\ (rad/s)/m$
Integral time	t_i	$1.6000\ s$
Derivative time	t_d	$0.3750\ s$
Filter time constant	τ_f	$0.0250\ s$
Proportional reference weight	b	0.5
Derivative reference weight	c	0
Controller sampling time	t_s	$0.01\ s$

Table 3: Prognostics and health monitoring system parameters

Parameter	Symbol	Value
EKF sampling time	$t_{s,ekf}$	$0.05\ s$
EKF state covariance	Σ_w	$\begin{bmatrix} 0.0006 & 0.0179 \\ 0.0179 & 0.7170 \end{bmatrix} \cdot 10^{-16}$

EKF measurement covariance	Σ_v	$2 \cdot 10^{-5}$
Buffer time	t_{buf}	$200\ s$
Adj. mech. evaluation step	t_{eval}	$400\ s$
Controller gain, lower bound	$k_{p,min}$	$1000\ (rad/s)/m$
Controller gain, upper bound	$k_{p,max}$	$10000\ (rad/s)/m$
Cost function tracking weight	w_1	$1/m^2 s$
Cost function health weight	w_2	$1/s^2$

4. RESULTS

The deterioration of the gear pump in an EHA is inevitable but can be delayed by adjusting the controller parameters. To illustrate this application of the predicted RUL and adjustment mechanism, the proposed method is applied to the EHA position control system. The simulations were conducted with MATLAB Simulink in accelerated conditions, i.e., the coefficients of Equations (34) and (35) are greatly exaggerated. This leads to the pump failing in about 30 minutes rather than thousands of hours. In the simulations the EHA is supposed to operate for longer than $t_{RUL,req} = 1850\ s$ with the probability $p = 95\%$. The adjustment mechanism evaluation times were set $400\ s$ apart.

Figure 4.1 shows the degradation evolution for the baseline system and the system with the adjustment mechanism enabled. The points where the controller gain is adjusted are highlighted with dashed grey lines. After the first adjustment at $t = 400\ s$, it is evident that the degradation rate slows down compared to the baseline. Although the gain increase can raise peak acceleration during reference transitions, the net degradation slows because Equations (34) and (35) depend on the integrated rotational speed/acceleration. Under this duty cycle the updated gain reduces the duration and average level of the stress terms. In the baseline simulation, $t_{RUL,req}$ was broken with 25 seconds. The adjustment mechanism successfully extended the RUL of the system by 46 seconds, which fulfilled the operation time requirement.

As an additional reference, a fixed-gain simulation was conducted by setting the proportional gain k_p to $8000\ (rad/s)/m$. This was done to maximize useful life for this specific duty cycle and model parameterization. In this case, the achieved useful life increased to approximately $2060\ s$, compared with $1825\ s$ for the nominal fixed-gain baseline and $1871\ s$ for the gain-updated case. This result should be interpreted as scenario specific as the optimal fixed gain depends on the duty cycle, load, and modeling uncertainty, and therefore serves as an upper bound rather than a generally applicable tuning.

In Figure 4.2, the adjusted controller gain of the PID controller is shown with the constant gain of the baseline simulation. The effect of changing the controller gain to the squared control error is illustrated in Figure 4.3. At the first adjustment time, there is a small increase in the control error caused by the sudden change of controller gain. Figure 4.3 also shows that the peaks of the control error increase over time. This is caused by the deterioration of the pump, which causes it to produce less flow and in turn makes it more difficult to follow

the changing reference points. The error peaks of the adjusted controller are slightly smaller, caused by the cost function (31) including the ISE in the optimization.

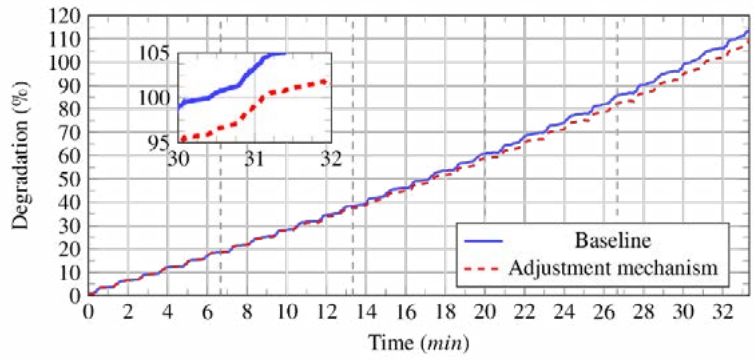

Figure 4.1: Evolution of estimated degradation in accelerated simulation conditions.

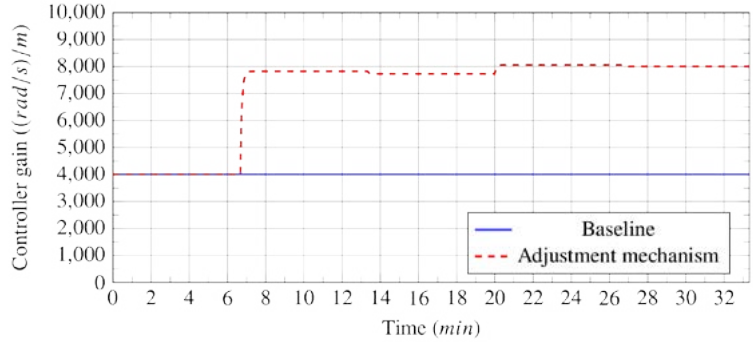

Figure 4.2: Proportional gain in the baseline test and under the adjustment mechanism.

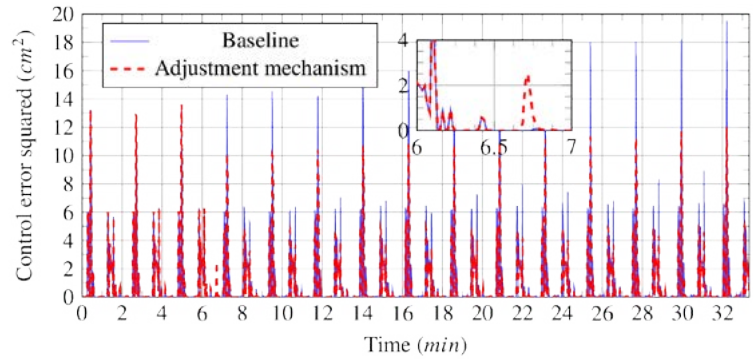

Figure 4.3: Squared control error for the two scenarios with zoomed in section of the first adjustment time.

From Figure 4.2, it is evident that after the first adjustment, there is no need for the subsequent adjustments. This is mostly due to the assumption of linear degradation evolution holding very well for the whole simulation, which is caused by two main factors. Firstly, the cyclic nature of the position reference and load signals utilized in the simulation cause the degradation to increase almost the same amount per cycle. This is somewhat offset by the increased leakage flow for which the controller must compensate by increasing the rotational speed, which in turn accelerates the degradation towards the end of the simulation. Secondly, the chosen degradation models, i.e., Equations (34) and (35), increase the degradation speed independently from the age/degradation of the component. In real systems this might not be true, as the degradation speed of the component can be considerably faster near the end of its life.

5. CONCLUSION

This paper introduced a degradation-aware adjustment method for a PID-controller in an EHA system. An extended Kalman filter-based degradation estimator was combined with an inverse-Gaussian RUL formulation and a simple ridge model linking the control effort to the degradation rate. These were used in a cost function that trades tracking performance against a soft health constraint. The approach targets systems where maintenance is challenging and controller retrofits are preferred over a full health-aware control redesign.

Simulations with an EHA model under accelerated degradation showed that the proposed mechanism met the mission-time requirement at the specified survival-probability level. The nominal fixed-gain baseline achieved a useful life of $1825\ s$, whereas the system with the proposed adjustment mechanism increased the useful life to $1871\ s$ with only a modest transient increase in control error. As an additional benchmark, selecting the near scenario optimal fixed gain increased the useful life to approximately $2060\ s$. This gap indicates that, for a static and known duty cycle, offline tuning can outperform delayed online adjustment. Accordingly, the proposed mechanism is primarily aimed at settings where the best tuning is not known beforehand and/or operating conditions evolve over time.

The practical implication is that existing PID-controlled electro-hydraulic installations can gain significant life-extension potential with minimal architectural change. The method can be implemented as a supervisory layer (potentially cloud-based) that periodically re-tunes a small set of controller parameters using rotational speed, flow, and pressure data. While speed feedback and pressure are commonly available, direct flow sensing typically is not and may require added instrumentation or a validated virtual-sensing alternative. For practitioners, this provides a low-intrusion pathway to improve availability and maintenance planning by aligning controller aggressiveness with the remaining mission time, provided the required measurements are available.

This study has limitations worth noting. The results are based on simulations with accelerated degradation and simplified Wiener-type models whose parameters and threshold selection impact RUL accuracy. The controller adjustment tuned only the controller gain, and other PID parameters were kept fixed. The simulated duty cycle was cyclic, which favored near-linear degradation over the horizon, and may not generalize to all duty cycles or late-life behaviors where degradation can accelerate.

Future work should include experimental validation on hardware and the identification of more detailed degradation mechanisms and thresholds to improve model fidelity. In addition, the supervisory strategy should be evaluated under dynamic duty cycles, including varying loads and reference trajectories, to quantify robustness and to determine when online supervision provides a clear advantage over a priori fixed-gain tuning. Robust estimation under changing operating conditions, adaptive evaluation schedules, and integration with maintenance planning tools are also recommended to broaden applicability and reliability.

Abstract.

As energy efficiency becomes an increasingly important property of hydraulic working machines, new ways of improving the system need to be explored. This paper explores the potential of improving the energy efficiency of the hydraulic system by how it is operated. With a kinematically redundant system, such as the boom system of a loader crane, there is a possibility of reducing the energy consumption of a given task by optimizing how the different actuators are operated to form the crane tip motion. This work considers the semi-automatic function Crane Tip Control (CTC) where the operator controls the velocity of the crane.

A new, energy efficient, CTC controller with two parts is developed. The first part of the controller decides the strategy of the crane tip motion by setting the speed command for one of the boom actuators. The second part handles the reference velocity following by calculating the required speed commands for the other two boom actuators. The input to the controller is the reference velocity, both speed and direction, of the crane tip together with the state of the crane boom cylinders. In its current state, the controller is optimized for a single payload, but in future versions, the payload can be estimated or measured and set as input.

The strategy part of the controller is represented by a neural network, that is trained by a Reinforcement Learning approach with a hydraulic energy minimization objective. The training is performed on a simulation model of the crane, which includes geometrical relations for the crane booms and cylinders, and an energy consumption estimation.

The performance of the new CTC controller is benchmarked with regards to two other CTC controllers. The first one is a near-optimal offline controller implemented by a dynamic programming optimization. The second one is a a rule-based controller with a strategy that always holds one of the actuators still. An energy flow analysis has revealed great losses due to simultaneous operation of several actuators. Although the rule-based controller is not optimized with respect to the crane's operation, it is an important comparison since it provides a less development heavy solution.

1. INTRODUCTION

Although, improving the energy efficiency of hydraulic working machines has been widely investigated for a long time with many interesting concepts being presented, very few solutions has been implemented by the industry due to the associated cost and complexity with changing to a new architecture. This study explores a way of reducing the energy consumption by automating the movement of the machine, and thus, does not require any hardware changes. The work is applied to a loader crane, which is a kinematically redundant system, meaning it has an extra degree of freedom which can be used for optimizing the movements with regards to some objective. Loader cranes are not yet fully automated, but there is a commercially available semi-automatic feature by several manufacturers, see for example [12], [14] and [13], where the motion of the crane tip is controlled by the operator and the corresponding motions of the hydraulic cylinders are controlled by the control system. The feature can be denoted Crane Tip Control, CTC, and in this paper an approach to minimize the energy consumption during CTC operation is investigated.

1.1 Problem Formulation

The CTC feature which is used as reference here is provided by crane manufacturer Hiab [12]. It is optimized for lifting capacity, and in order to investigate how large impact an optimized automated feature can have on the energy consumption, the aim of this study is to develop a new CTC controller that is optimized for energy efficiency. A complete CTC controller should be able to take any valid operator command, which is given in the form of a speed command in the horizontal direction of the crane tip and a speed command in the vertical direction, and provide a set of cylinder speed commands that result in this motion. The CTC feature considered here works in a two-dimensional plan and controls the three boom cylinders of the crane, the slewing function is excluded. The scope of this study is limited to investigate movements in the horizontal direction with a fixed positive speed. CTC is a realtime feature which must be executed on the embedded control system of the crane. For this reason, traditional offline optimization methods are excluded. Instead, a machine learning approach, where part of the CTC controller is set up as a neural network, is explored. A simple rule-based controller is also developed to form a baseline. As a best case benchmark, near-optimal solutions to a limited number of test cases are calculated by an offline Dynamic Programming algorithm developed in previous work by the authors [8].

1.2 Delimitations

The scope of this paper is limited to investigating one type of neural network structure, feed forward neural network, as well as using one Reinforcement Learning approach, policy optimization, as training method. Further, the CTC controller is limited to working with a fixed speed and payload in the positive x-direction of the working area of the crane. The main focus will be on presenting results from one such controller, although results for training controllers with different speed and payload will be briefly presented to show the potential for extending the method in future work.

1.3 System Description

The system used as reference application in this work is a medium sized loader crane with three hydraulic cylinders used by the CTC feature,the first boom, "1b", cylinder, the second boom, "2b", cylinder and the extension, "ext", cylinder. The first and second boom cylinders control revolute joints with angles denoted α_{1b} and α_{2b} respectively. The extension cylinder works as a prismatic joint with a position denoted l_{ext}. The position of the three joints together with the dimensions of the crane defines the crane pose. The

kinematic redundancy gives that there can be an infinite amount of different crane poses for a single crane tip position. The crane tip position is given in Cartesian coordinates in the plane with axes x and y.

The cylinders of the crane are connected to a pressure compensated load sensing hydraulic system with a variable displacement pump. The pressure compensation gives that the speed commands to each cylinder, denoted u_{1b}, u_{2b} and u_{ext}, can be directly translated to spool position commands to the directional valve.

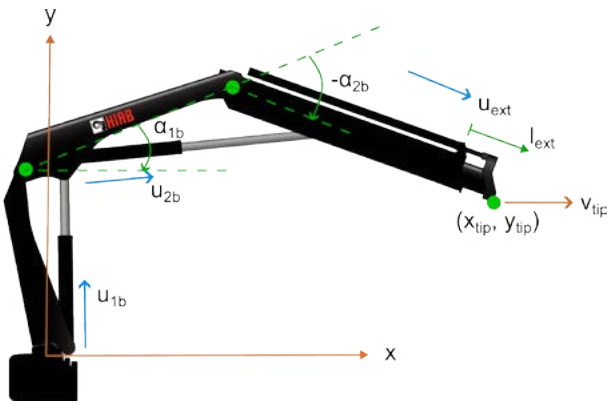

Figure 1: Crane with cylinders, joints and crane tip position.

1.4 Prior Art

The problem for a CTC controller or similar is to translate a desired motion in the task space (crane tip movement in the CTC case) to a motion in the joint space (cylinder velocities in the CTC case). To go from tip velocity to joint velocities the inverse of the so called jacobian matrix has to be somehow calculated. For a redundant system, the exact inverse of the jacobian does not exist. A common way to solve the problem is to compute the pseudo-inverse of the matrix, which gives the solution with the smallest joint velocity magnitude. This method is described for example in [4] and [3]. The drawback with this approach is that only locally optimal solutions can be found and that minimizing the joint velocity magnitude is the only objective. In [5] it is shown that the energy consumption performance of the pseudo-inverse method is significantly worse than for a dynamic programming algorithm.

In [11], the pseudo-inverse solution is used for precision tracking of a three degree of freedom robotic arm and combined with a minimization of the kinetic energy by a velocity vector pointing in the direction where the kinetic energy integral is minimized for a chosen trajectory. The optimal control is predicted for a window and continuously updated as the simulation is rolled out. The resulting controller is shown to perform pretty close to the global optimal solutions on trajectories with a length of 10 s. However, to only minimize the kinetic energy is too much a simplification for the crane with a load sensing hydraulic system, where kinetic energy cannot be directly translated to input energy to the system.

The possibility of using a neural network as CTC controller has been presented by [10]. In this work, the CTC controller is optimized with the objective of moving the crane tip as fast as possible. The same methodology has been applied to the crane used as application in this study with good results considering the speed and precision of the crane tip movement.The promising results gives an incentive for exploring a similar methodology and controller structure but with an energy minimization objective. This work was started in [8] where an energy efficient CTC controller was trained for a very limited part of the working area of the crane with good results.

A neural network controller has also been implemented for controlling the automatic log collecting of a forwarder in [1]. The network is trained with a reinforcement learning approach in a simulation environment and shows promising results with regards to energy efficiency. In another recent publication, [2], a controller for autonomous operation of a forwarder is also developed by reinforcement learning. The controller is trained in a simulation environment and later deployed on a real forwarder with good results.

2. Baseline and Benchmark

The energy consumption of moving the crane tip according to some specified trajectory with different strategies for moving the cylinders differ mainly due to three properties of the system:

Total oil need The total traveled distance of the cylinders can differ and affects the average flow demand of the pump.

Cylinder pressures Different cylinders require different pressure levels for lifting the payload in different crane poses. The cylinder pressures depend on the load force, friction and cylinder dimensions. The highest cylinder pressure (or more accurately the highest load pressure sensed by the directional valve) sets the pump pressure.

Simultaneous losses In a load sensing system with a single pump, the flow to all cylinders active simultaneously is supplied at the same pressure. If a cylinder requires a lower pressure, the excess pressure is wasted at the compensator valve.

For an optimized system, all these three properties and how they together form the flow and pressure demand of the pump at every instant must be taken into account, as well as the total energy of a movement of some length of time. A Dynamic Programming, DP, algorithm that can make this optimization for a discretized version of the system has been developed in previous work [8]. Results from this algorithm will serve as a benchmark for the new controller in Section 5.

Without any optimization, a simple rule-based controller that tries to minimize the third property, simultaneous losses, can be developed. The strategy of this controller is to always keep one cylinder still and to use the other two to make the necessary motion. A previous study, [7], of the reference loader crane shows that simultaneous losses account for about 30% of the losses in the hydraulic system. At the start of a motion, the controller tries to keep the 1st boom still, as this is often the cylinder that has to carry the most weight. If this leads to an illegal solution, due to violation of maximum cylinder positions or speeds, it tries to keep the 2nd boom cylinder or extension cylinder still. During the motion, it then keeps the strategy of the previous timestamp as long as possible, in order to achieve smooth motions. Results from this controller will serve as a baseline for the new controller in Section 5.

3. Controller Structure

The new CTC controller optimized for energy consumption consists of two parts, a strategy controller and a velocity controller, and its layout is presented in Figure 2. The inputs to the controller are the crane state, represented by the joint angles and extension position, and the reference tip velocity. The outputs are the speed commands to the three boom cylinders. Development of the controller was started in the work presented in [8], and the method has now been extended to training a controller that is able to control the crane tip motion in the whole working area of the crane.

The strategy controller is implemented as a feed forward neural network with three hidden layers with 32 nodes each. Adding more nodes than that does not improve the performance of the network.

LeakyRelu is used as activation function for all layers except the output layer, where instead HardTanh is used in order to get the output saturated to [-1,1]. -1 corresponds to maximum negative speed command, and 1 to maximum positive speed command. LeakyReLU stands for leaky rectified linear unit and introduces non-linearity to the network with reduced risk of de-activating neurons compared to simple ReLU. LeakyReLU is defined according to eq. (1), where α is set to 0.01.

$$LeakyReLU(x) = \begin{cases} x, & \text{if } x > 0 \\ \alpha x, & \text{if } x \leq 0 \end{cases} \tag{1}$$

The task of the strategy controller is to select a strategy that minimizes the required pump energy to move the crane some distance with CTC. It should be noted that the objective is not to minimize the instant pump power, but to look ahead some distance and minimize the energy consumption of a movement that goes on for some time. An assumption then has to be made regarding how the crane tip reference will be in the near future. In this work, the energy is optimized on trajectories of a length of 13 s with a constant reference speed of 200 mm/s. With this speed, the crane can cover about a third to half of the working area in the horizontal direction during a trajectory, depending of the vertical position of the crane tip. This distance is considered a reasonable assumption of how far the crane is moved along a constant direction during normal work. The selection of the time horizon over which the accumulated cost during optimization is calculated can also be seen as a trade-off between promoting long term gains while still being able to adapt to changes in the input.

The output from the strategy controller is the speed command to the extension cylinder. It could just as well have been the command to the 1st or 2nd boom, the key is that the strategy is set by deciding the motion for a single one of the cylinders since the system only has one extra degree of freedom.

Once the output to the extension cylinder is given, the problem of finding the output to the 1st and 2nd boom has a unique solution. The velocity controller thus takes the output from the strategy controller and calculates the output to the 1st and 2nd boom while making sure that the reference crane tip trajectory is followed by using the inverse kinematics equations of the boom system.

If no valid combination of cylinder positions can be found, the velocity controller sets all outputs to zero. It thus functions as a layer between the neural network and the crane that can also act as a safety layer that can stop the crane, or reduce the speed, in unsafe situations when deployed on a real crane.

4. Training Environment and Simulation Model

The network is trained by Reinforcement learning policy optimization in a simulation environment implemented in Python, where the network functions as the policy approximator. The PyTorch framework is used for setting up the network and running the training loop. The crane is implemented as a quasi-static geometry model. Since the network only is trained to provide a high level motion strategy, no dynamics is needed in the crane model. It is however, important to have a good energy consumption model, since the strategy decisions are made based on this. The simulation model boundary is set at the outlet of the variable pump, so the signals of interest are the hydraulic pump pressure and pump flow.

The flow leakage in the crane is low and the pump flow is thus modelled directly as a summation of the oil required to move each cylinder according to the motion within the

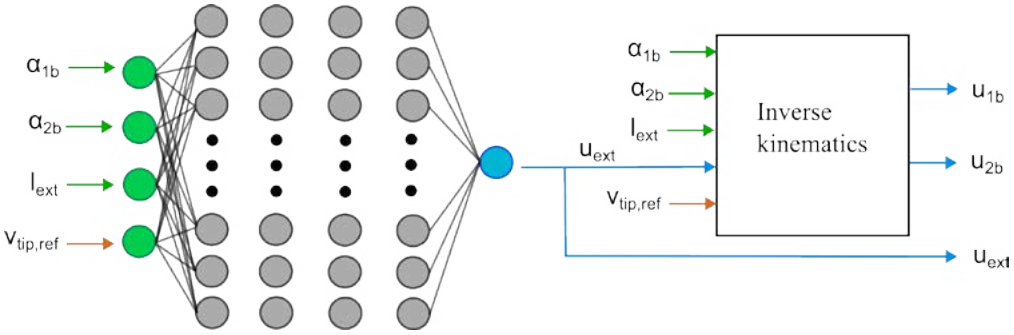

Figure 2: Layout of the neural network for the strategy controller and its connection to the velocity controller.

timestep, according to Equation 5. The hydraulic system is a load-sensing system, which gives that the pump pressure can be calculated as the maximum of the load pressures plus a pressure margin, according to Equation 6, where $p_{func,cyl}$ are the active side cylinder pressures, Δp_{func} are the pressure drops between the valve and the cylinders and Δp_{pump} is the pump pressure margin.

The cylinder pressure level required to move each cylinder depends on the force on the cylinder induced by the payload and the dead weight of the crane, on the counter pressure and on the friction in the system. The force can be calculated based on the geometry model, but given that it is hard to physically model the friction, especially in the extension system, the rest of the contribution to the cylinder pressure is modelled by a black-box model, with cylinder flow and force as inputs, fitted to measurement data.

Initially, a machine learning approach with gaussian process models, presented in [9], was tested. Although the fit of the model was very good in most working points, it was sensible to the distribution of the data points and its interpolation scheme could produce outputs that were not in line with the expected behavior. For example, if the force is kept constant, the pressure of a cylinder chamber is expected to increase with speed, but for some specific force values, the pressure could decrease for a small range of increasing speed.

Inconsistencies like this are easily exploited by the dynamic programming optimization, but more difficult for the gradient based optimization of the network to find, creating differences in the results that might not hold on the real system. For this reason, polynomials of the second degree are used instead, and the coefficients are fitted with with the least square minimization criterion. For the extension cylinder, different polynomial models are created depending on direction of movement and gravitational force, and the currently active pressure, P_{active}, can be calculated according to equations 3 to 4, where $P_{pist,static}$ and $P_{rod,static}$ are the contributions from the static force on the cylinder to the piston and rod side chamber pressure, and $P_{friction}$ is the contribution from the friction force given by the blackbox model. Figure 3 show the measurement data for the friction induced pressure as a function of cylinder flow for one of these cases, retraction of the cylinder and gravitation force pulling the cylinder in the extension direction, together with the fitted model. Figure 4 show the resulting fit of the active pressure to validation data from a test cycle when all four extension models are combined.

$$P_{pist,static} = \cdot \frac{F_{ext}}{A_{pist}} \tag{2}$$

$$P_{rod,static} = \cdot \frac{F_{ext}}{A_{rod}} \tag{3}$$

$$P_{active} = \begin{cases} |P_{rod,static}| + P_{friction,F-,v-} & \text{if } F_{ext} \leq 0 \text{ and } q \leq 0 \\ -|P_{pist,static}| + P_{friction,F-,v+} & \text{if } F_{ext} \leq 0 \text{ and } q > 0 \\ -|P_{rod,static}| + P_{friction,F+,v-} & \text{if } F_{ext} > 0 \text{ and } q \leq 0 \\ |P_{pist,static}| + P_{friction,F+,v+} & \text{if } F_{ext} > 0 \text{ and } q > 0 \end{cases} \tag{4}$$

The pressure drop between the valve and the cylinder is modelled as a simple flow dependent pressure drop model with coefficients fitted to measurement data together with load holding valve models. These models are presented in [6].

$$q_{pump} = \frac{\Delta 1b_{clen}}{T_s} * A_{1b,cyl} + \frac{\Delta 2b_{clen}}{T_s} * A_{2b,cyl} + \frac{\Delta ext_{clen}}{T_s} * A_{ext,cyl} \tag{5}$$

$$\begin{aligned} p_{pump} = &\max[p_{1b,cyl} + \Delta p_{1b}, p_{2b,cyl} + \Delta p_{2b}, p_{ext,cyl} + \Delta p_{ext}] + \\ &+ \Delta p_{pump} \end{aligned} \tag{6}$$

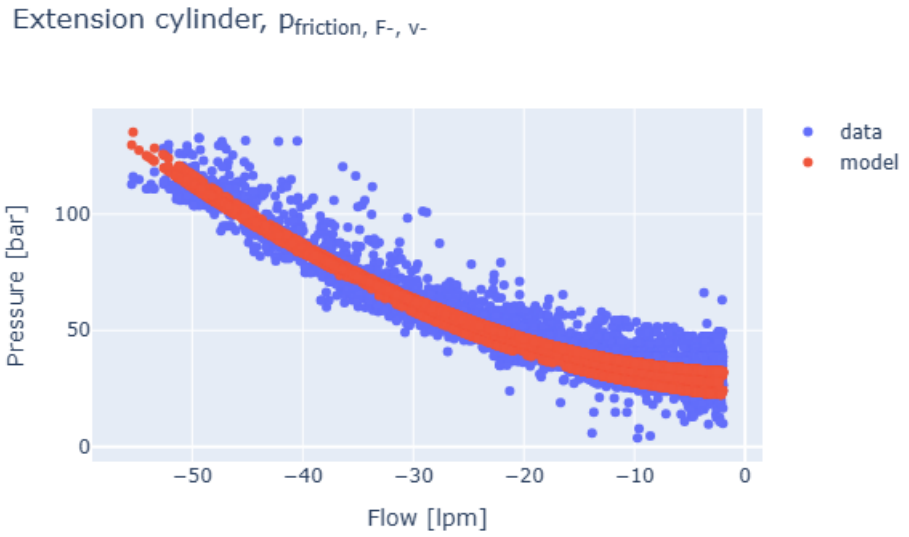

Figure 3: Model of extension friction based pressure as a function of flow. The variation for a fixed flow comes from the small impact of the static force.

During training of the network, a batch of 1000 cylinder positions that corresponds to crane tip positions within the working area of the crane, see Figure 5, is sampled. A simulation with a fixed timestep on a fixed horizon is rolled out on the batch for a number of episodes. Given that the objective of the optimization of the network is to minimize the energy consumption, the cost function is formulated according to eq. (7), where P_i is the pump power required during the current step and H is the time horizon of the simulation.

$$C = \sum_{i=1}^{H} P_i \tag{7}$$

$$P_i = q_{pump,i} * p_{pump,i} \tag{8}$$

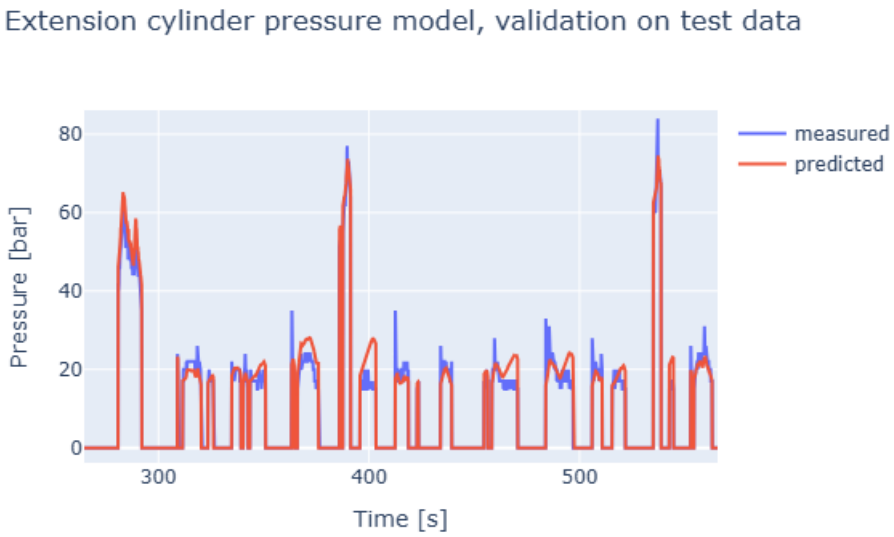

Figure 4: Validation of model of active extension cylinder pressure.

The policy, that is the network during training, is probabilistic. In order to allow the system to explore new solutions, the current best guess is not always selected as output from the policy. Instead, the network is set to produce a mean value and a standard deviation that can form a distribution from which the output (command to the extension cylinder) is sampled. When the controller later is deployed, the sampling from the distribution is replaced by directly taking the mean output from the network.

The network is trained until convergence. New batches of initial positions are sampled at regular intervals to ensure that the solution is generalized. The built-in gradient-descent optimizer AdamW of Pytorch is used to update the weights of the network after each episode based on the gradients of the average cost of all the trajectories in the batch with respect to the weights, or by using the Reinforcement learning terminology, the policy is optimized with respect to the (negative) reward it was given for the actions taken during the episode.

5. Results

The new controller is evaluated by comparing to the rule-based controller baseline and the dynamic programming benchmark on a number of pre-defined test cases. The test cases are divided on four different crane tip trajectories located at different parts of the working area of the crane. For each trajectory there are four different test cases formed by four different starting crane poses. The four trajectories, with one of their starting crane poses each, are displayed in Figure 6. The graphs visualize the motions of the crane when controlled by the new controller. The performance of the new controller, and its similarities and differences to the dynamic programming solutions, on each trajectory is presented in Sections 5.1 to 5.4. A summary of the energy performance comparing both with the dynamic programming benchmark and the rule-based controller baseline, is found in Section 5.5.

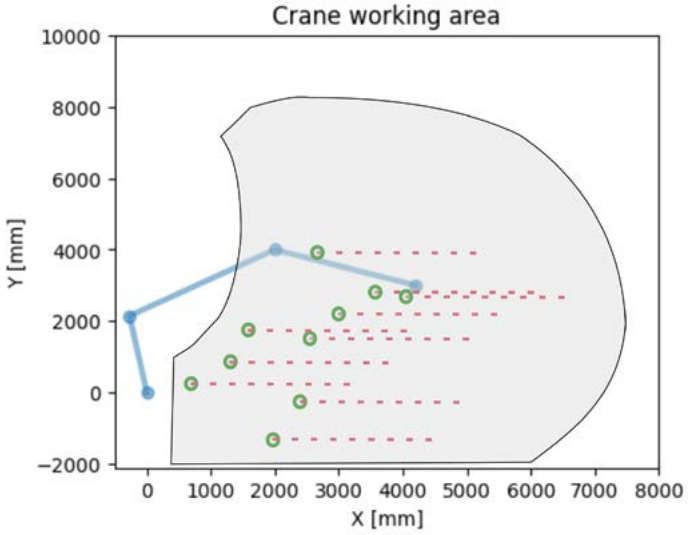

Figure 5: Working area of the crane, on which the neural network controller is trained. The figure also shows 10 example trajectories, with green circles for the starting points and dashed red lines for the trajectories, from a batch on which the controller is evaluated on during each episode.

5.1 Trajectory 1

A comparison between the cylinder commands, active side cylinder pressures, pump flow and pump pressure, for the dynamic programming, DP, controller and the new, neural network based, NN, controller is displayed in Figure 7 for one of the test cases for trajectory 1. At a quick glance, the cylinder commands are rather similar, but while the dynamic programming controller holds the extension still at most times, the new controller constantly runs it at a low speed. This creates a big difference in pump pressure, as the extension cylinder sets the highest pressure during the first half of the movements for the new controller. As the flow demand is similar for both controllers, the much higher pressure demand for the new controller results in a significantly bigger power demand.

The new controller is not able to find the solution where the extension is held still during training due to that the possibility for a neural network to output exactly zero is extremely small. It is however, possible to make adjustments after the training is completed. If the command to the extension is lower than a certain limit, it is plausible to assume that the power demand will be similar, or lower, if the command is set to zero. To keep the crane tip reference following, the 1st and 2nd boom have to be adjusted accordingly, which is handled by the velocity controller. If the adjusted outputs, or resulting cylinder positions, turn out to be illegal, the controller reverts back to the original solution. If this adjustment is applied to the test case 1.3, the pump power is now much more similar to that the DP controller, see Figure 8. The other three test cases of trajectory 1 follows a similar pattern.

5.2 Trajectory 2

Trajectory 2 shows a slightly different scenario, displayed in Figure 9 for one of the test cases. The dynamic programming controller once again keeps the extension still for a large part of the movement, but contrary to during trajectory 1 the extension does not set the highest pressure, so the pump pressure levels are rather similar for both controllers. The

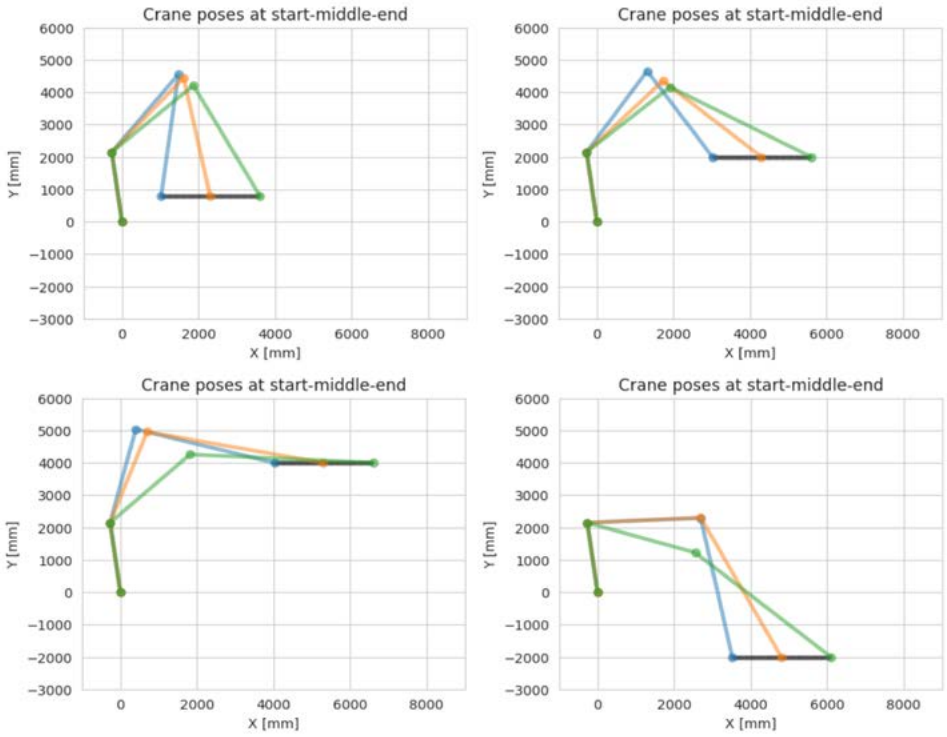

Figure 6: Four different trajectories on which the new controller will be evaluated. One of the four starting crane poses (blue lines), and the corresponding motion (orange lines for mid-time pose and green lines for end pose) of the crane while controlled by the new controller are displayed for each trajectory.

dynamic programming solution does, however, reduce the flow demand compared to the new controller.

5.3 Trajectory 3

The third trajectory is placed in the upper part of the working area of the crane. For all four test cases, the dynamic programming algorithm is able to find a smart solution where the 2nd boom is moved towards a horizontal position during the first part of the trajectory, allowing the extension to be the only function moved in the last part of the trajectory, exemplified by test case 3.2 in Figure 10. Finding exactly the state where the 2nd boom is horizontal is too difficult for the new controller, and consequently it suffers from a high pump pressure being set by moving the 2nd boom upwards during the whole trajectory. The difference between the 2nd boom and the extension pressure can be seen in the plot.

5.4 Trajectory 4

The last trajectory in the comparison is placed in the lower part of the working area of the crane. On this trajectory it is once again highlighted what a big difference to the energy consumption it can make between moving a function slowly or stopping it completely and compensating the movement by the other two functions. The new controller has found solutions where the 1st boom is initially driven slowly upwards, causing the pump pressure to be much higher than for the dynamic programming controller solution. By implementing a similar adjustment as for the extension, that is, a dead zone is placed for small positive

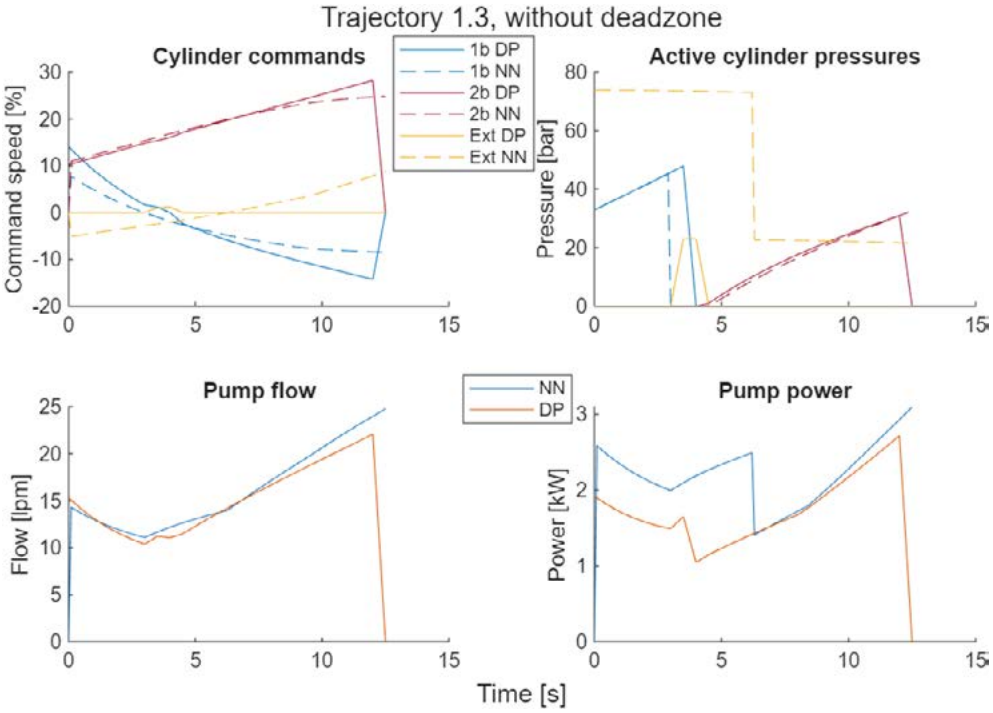

Figure 7: Test case 1.3 with original outputs from the neural network based controller. Note the high pressure set by the extension during the first half of the movement for the NN controller.

commands to the 1st boom which sets the 1st boom command to zero if the adjusted solution is legal. The resulting cylinder commands, as well as active cylinder pressure, pump flow and pump power, are displayed in Figure 11 together with the dynamic programming controller outputs. Even though there are some differences regarding when and how the extension is activated, the resulting mean power consumption is rather similar for both controller, since the 2nd boom is operated in the same direction and sets the highest pressure during the main part of the trajectory.

5.5 Power Comparison

The mean power consumption for each of the 16 test cases is displayed for the three different controllers, the dynamic programming controller (DP), the rule-based controller (r-b) and the neural network based controller (NN), in Table 1. The increase in average power consumption between the dynamic programming controller and the neural network controller varies between 5 % and 34 %, with a mean value of 15 %. In order to be able to draw any conclusions about the quality of these figures, the neural network controller is also compared to the rule-based controller. The average power consumption is most often lower for the neural network controller, with a maximum reduction of 22 %, but for some test cases the consumption is up to 10 % higher for the new controller. The mean value of the reduction is 5.6 %.

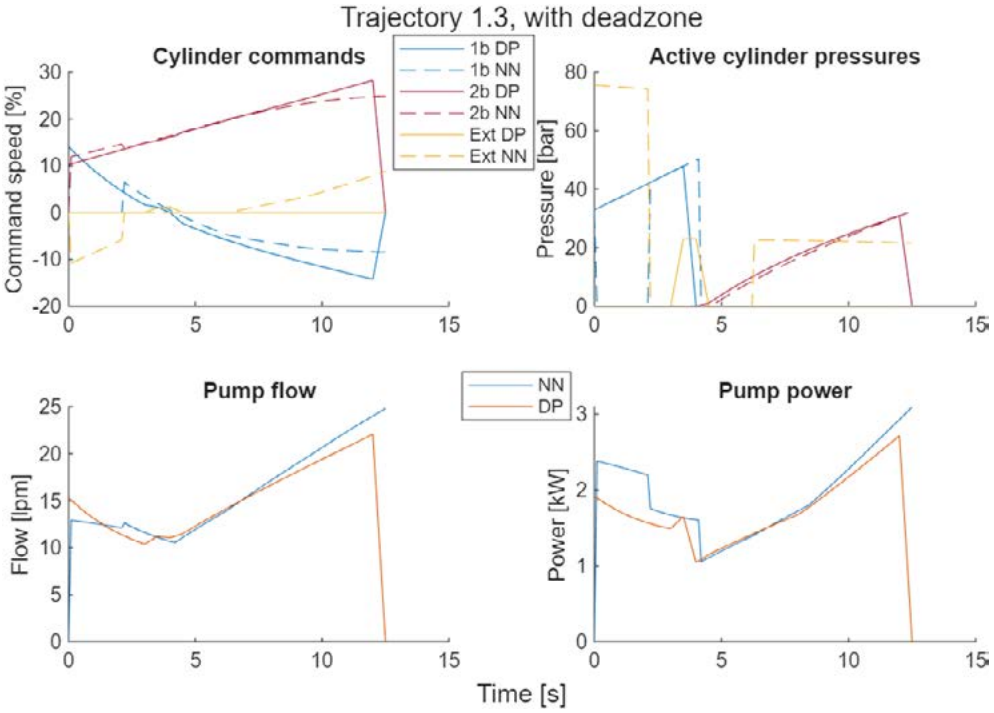

Figure 8: Test case 1.3 with adjusted outputs from the neural network based controller. Note the similar pump power for the two controllers.

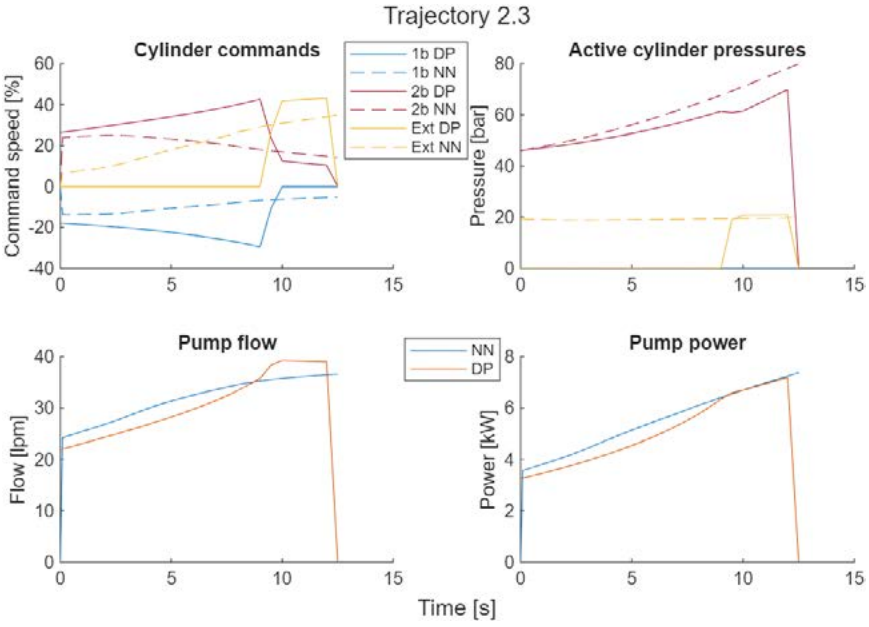

Figure 9: Test case 2.3. Note the lower pump flow for the dynamic programming controller.

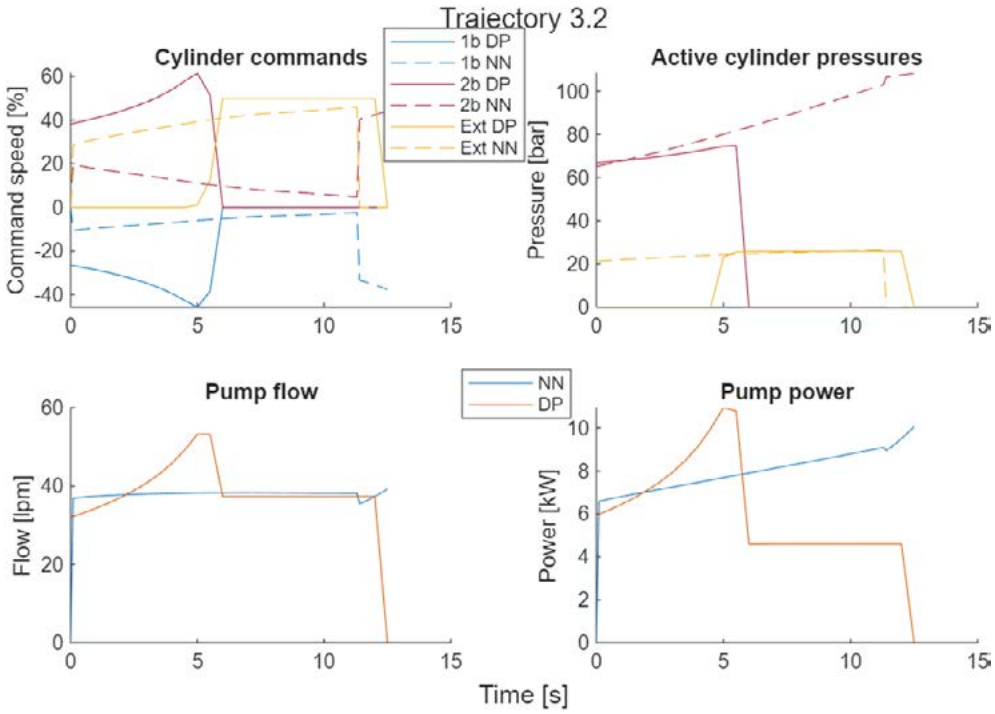

Figure 10: Test case 3.2. Note how only the extension is moved in the second half of the movement for the DP controller.

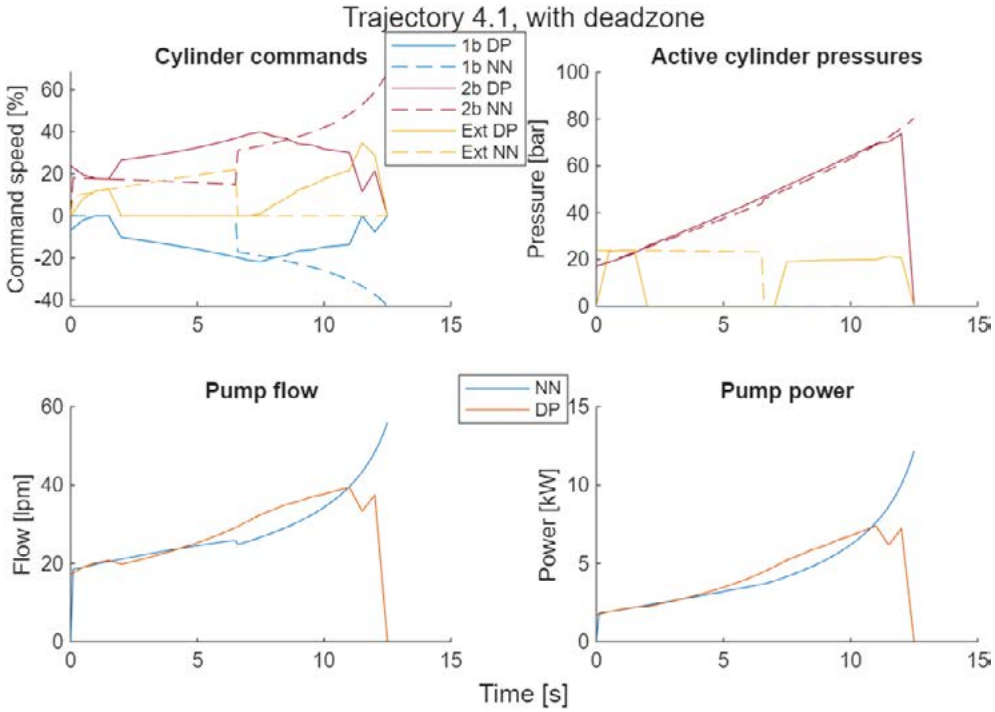

Figure 11: Test case 4.1. Note how the 2nd boom sets the highest pressure during the main part of the trajectory and how the power difference only comes from the flow.

The controller presented above has been optimized for the tip speed of 200 mm/s and the payload of 1000 kg. Two other controllers, one with 100 mm/s tip speed and 1000 kg payload, and one with 200 mm/s tip speed and 2000 kg payload, have also been optimized and evaluated on the same trajectories. The first one has an average power consumption that is 6.5 % higher than for its corresponding dynamic programming solution. The main reason for the smaller difference than for the faster test cases is that the optimizer more often outputs small cylinder commands that can be set to zero during deployment and then be more similar to the dynamic programming solutions. The one with a higher payload has an average power consumption that is 22 % higher than for its corresponding dynamic programming solution. The higher payload gives a larger relative difference in pump pressure between solutions from the dynamic programming where one of the cylinders is often kept still and solutions from the neural network controller where this rarely happens.

6. Discussion

For some of the tested trajectories, the neural network controller finds similar solutions as the near-optimal dynamic programming algorithm. These trajectories are characterized in that the cylinder commands have continuous like shapes that seems to be easier for the network to find than solutions where the commands vary more abruptly or take very specific values. Smooth motions of the cylinders are probably more easy for a real crane to follow without any noticeable small stops or small jerks of the crane tip, so in that perspective the new controller provides good solutions.

However, the results here show that energy efficiency of the neural network controller is rather low compared to the dynamic programming solution. The neural network controller only reduces the energy consumption about 6 % compared to a simple rule-based controller. When taking into account that a complete CTC controller needs to be able to control the crane tip in every possible direction, not just vertical or horizontal, the benefits of the neural network controller will be even smaller. It would be possible to train three more networks, horizontal inwards and vertical up and down, and then combine them with the network presented here for horizontal outwards. But whenever the crane tip should move along a diagonal, there is no guarantee that the energy minimization objective will hold. So in total, a lower energy reduction than 6 % compared to the rule-based controller can be expected.

If a semi-automatic function is required for the autonomy itself, rather than being a means for energy efficiency, it should be noted that there is a rather big difference in energy consumption between an optimized controller and more simple controller. If the semi-automatic function is considered as a means for energy efficiency, the results of the controller evaluated in this work must be put in relation to manual operation of the crane. In previous work, [8], it was shown that a CTC controller optimized with dynamic programming consumed about 14% less energy on a drive cycle than manual operation. Given that the results in this paper indicate that a realtime CTC consumes more than 15% more than the dynamic programming solution, automation through CTC is not considered an effective means of energy reduction. It should be noted that during the manual operation of the drive cycle in [8], the crane tip was not forced to follow straight lines. So automation could still potentially be a means of energy reduction, if given the freedom to move arbitrarily between waypoints.

Why is the trained network controller not better? The network structure and training method with a gradient based optimizer was chosen for his study due to its success in teaching a neural network to control the crane to be fast during CTC operation, proven in a previous study [10]. The kinematic equations of the crane are differentiable and worked well with the gradient based optimizer. Switching to energy consumption as objective introduced some properties that proved to be difficult for the selected method to handle.

Table 1: Comparison of average power demand [kW] for the three different controllers for the 16 test cases (four different trajectories with four different starting positions each).

A linear combination such as the output from the feed forward neural network has an inherent difficulty of taking on very specific values, such as exactly zero or the command the moves the extension cylinder to a very specific position. Small reference command outputs from the controller can be adjusted to exactly zero during deployment of the controller, which was shown to significantly improve the performance. It is however not possible to apply this deadband during training as it is a non-differentiable function that hinder the gradient based optimizer to track the gradients of the loss function. Another property of the system that it is difficult for the optimizer to track is the non-linearity of the hydraulic system. For a load sensing system, the highest load pressure of the currently active cylinders sets the pump pressure. When the setup of active cylinder changes, the pump pressure can make a large step. So, a neural network could be a good choice for controller if a deadband is applied during training, and if an optimizer that does not rely of gradients of the loss function is used. Non-gradient based optimizers are for example population based methods such as genetic algorithms and particle swarm optimization.

7. Conclusion

Training a neural network to learn an optimal control strategy with regards to energy efficiency that can control a large part of the working envelop of the crane has proven to be a difficult task with the investigated optimization method. On average, the network controller consumes 15 % more energy than the near-optimal solution on the test cases presented here, and only consumes 5.6 % less energy than a simple rule based controller.

During the work of this paper it has become clear that the properties of the system to be optimized, that is the energy consumption of the crane and its load sensing hydraulic system, is not very well suited for gradient-based optimization. For optimizing the speed of the crane tip, gradient-based optimization worked well. But when considering the energy consumption of the hydraulic system a significant non-linearity is introduced - the pump pressure can make a large step when the reference to a cylinder goes from zero to a non-zero value, if the load on that cylinder is higher than the previously active cylinders. Future work will be focused on investigating if other types of optimizers that does not need to calculate gradients, such as different population based methods, are better suited for training neural networks to act as controllers for a load sensing hydraulic system.

Abstract.

With the accelerated development of automation and unmanned operations in heavy-load engineering fields, higher demands are placed on the control performance of hydraulically driven heavy-load manipulators. However, hydraulic manipulators suffer from prominent issues such as large load fluctuations, significant dynamic model errors, and strong joint coupling characteristics, which readily lead to degraded control performance. To achieve high-precision pose control, this study proposes a nonlinear disturbances compensation controller. A multidimensional radial basis function neural network (mRBFNN) is used to approximate various uncertain nonlinearities present in the system. Combined with the backstepping method, a nonlinear robust integral of the sign of the error (RISE) controller is designed. Online compensation for uncertain nonlinearities is realized during the control law design process, thereby enhancing system robustness. The Lyapunov stability theory proves that the system is stable and all signals are bounded. Simulation results demonstrate that the proposed control strategy significantly improves joint tracking accuracy and anti-disturbance capability of the hydraulically driven manipulator, fully validating the effectiveness of the control strategy.

1. INTRODUCTION

In fields such as heavy equipment, hydraulic systems play an irreplaceable role[1]. However, hydraulic systems inherently possess strong nonlinearity, time-varying parameters, and sensitivity to external disturbances, posing significant challenges to achieving high-precision control[2]. In recent years, with the rapid development of nonlinear control theory,

All Open Access articles are peer-reviewed, distributed under the Creative Commons Attribution-Non Commercial 4.0 International

combining advanced control strategies with the characteristics of hydraulic systems to achieve high dynamic performance control for multi-degree-of-freedom (DOF) hydraulic manipulators has become a hot topic of common interest in academia and industry[3].

In the field of nonlinear control theory, methods such as sliding mode control, adaptive control, and robust control have been widely applied in hydraulic systems[4][5]. However, most current research focuses on single-DOF systems, leaving room for improvement in handling the coupled nonlinearities of multi-DOF hydraulic manipulators[6].

In recent years, significant progress has been made in the field of fluid power transmission and control regarding hydraulic system modeling and compensation. Liu et al.[7] proposed a model predictive control based on a state observer for large-scale offshore hydraulic systems, laying a foundation for high-precision control of hydraulic systems under complex working conditions. Literature[8][9] published in the journal Chinese Hydraulics & Pneumatics proposed compensation strategies for the nonlinear flow characteristics and pressure dynamics of valve-controlled asymmetric cylinders, respectively. Notably, Xia et al.[10] experimentally verified the good effect of friction compensation on improving the low-speed performance of hydraulic systems. Regarding parameter identification, intelligent algorithms such as particle swarm optimization[11] and deep reinforcement learning[12] have been introduced to improve model accuracy. However, most existing compensation methods rely on accurate system models, and their adaptability to parameter variations in multi-DOF systems needs further enhancement.

Traditional PID control is still widely used in industry due to its simple structure and few adjustable parameters, but its performance is limited when dealing with the nonlinear coupling characteristics of hydraulic manipulators. To address this issue, scholars have proposed various solutions: Yao et al.[13] designed an adaptive robust controller to handle model uncertainties; Chen et al.[14] combined a disturbance observer with the backstepping method to suppress the effects of external disturbances. In the study of manipulator trajectory tracking, Zhu et al.[15] verified the advantage of prescribed performance control in constraining tracking errors, but this study did not consider the dynamic characteristics of hydraulic actuators.

The remaining sections of this study are arranged as follows: Section 1 introduces the nonlinear mathematical model of the hydraulic manipulator; Section 2 details the design method of the multidimensional neural network; Section 3 presents the design process of the nonlinear integral robust controller; Section 4 verifies the effectiveness of the proposed algorithm through simulation examples; Section 5 summarizes the research.

2. NONLINEAR MATHEMATICAL MODEL OF THE HYDRAULIC MANIPULATOR

2.1. Dynamic Model of the Hydraulic Manipulator

Using the Lagrange energy method, the dynamic equation for a multi-DOF manipulator can be formulated as follows

$$\boldsymbol{\tau} = \boldsymbol{M}(\boldsymbol{y})\ddot{\boldsymbol{y}} + \boldsymbol{C}(\boldsymbol{y},\dot{\boldsymbol{y}})\dot{\boldsymbol{y}} + \boldsymbol{G}(\boldsymbol{y}) + \boldsymbol{\Delta}_{t1}(t) \tag{1}$$

where $\boldsymbol{M}(\boldsymbol{y}) \in \mathbb{R}^{n\times n}$ is the manipulator's mass matrix, which is positive definite and symmetric. Its off-diagonal elements $M_{ij} = M_{ji}$ represent force coupling effects between joints. $\boldsymbol{C}(\boldsymbol{y},\dot{\boldsymbol{y}}) \in \mathbb{R}^{n\times n}$ represents the Coriolis and centrifugal force matrix, describing the coupling between joint velocities and forces. $\boldsymbol{G}(\boldsymbol{y}) \in \mathbb{R}^{n}$ is the gravity vector. $\boldsymbol{\Delta}_{t1}(t) \in \mathbb{R}^{n}$ represents unmodeled uncertainties in the manipulator's dynamic model, such as link elasticity, joint clearance, and connection relationships. $\boldsymbol{y} = [y_1,...,y_n]^{\mathrm{T}} \in \mathbb{R}^{n}$ represents the rotation angle of each joint.

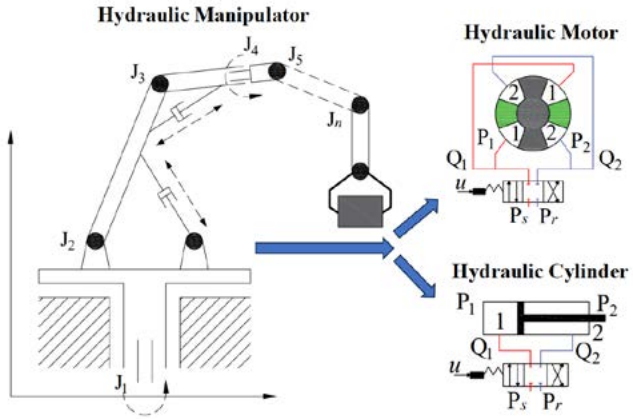

Figure 1 Configuration Diagram and Actuator of m-DOF Hydraulic Manipulator

As shown in Figure 1, hydraulic motors and hydraulic cylinders are responsible for driving different joints. The hydraulic cylinder is a single-rod cylinder, where 1 denotes the rodless chamber and 2 denotes the rod chamber. The hydraulic motor is a rotary actuator, with its position controlled by regulating the flow into and out of its ports via a servovalve.

Assumption 1: The servovalve's orifices are considered symmetric, and its dynamics are simplified as a proportional element.

Assumption 2: Considering the compact layout of the device and oil source, the oil in different chambers is assumed to have the same bulk modulus.

To maintain generality, the pressure dynamics of the electro-hydraulic servo system can be described as:

$$\begin{cases} \dot{p}_{1i} = \beta_e V_{1i}^{-1}\left(q_{1i} - A_{1i}\dot{x}_{si} - C_t\left(\dot{p}_{1i} - \dot{p}_{2i}\right)\right) + d_{1i}(t) \\ \dot{p}_{2i} = \beta_e V_{2i}^{-1}\left(-q_{2i} - A_{2i}\dot{x}_{si} + C_t\left(\dot{p}_{1i} - \dot{p}_{2i}\right)\right) - d_{2i}(t) \end{cases} \tag{2}$$

$$\begin{cases} V_{1i} = V_{01i} + A_{1i}x_{si} \\ V_{2i} = V_{02i} - A_{2i}x_{si} \end{cases} \tag{3}$$

where the subscript i denotes different joint numbers, $i = 1,2,...,n$; β_e represents the bulk modulus of the hydraulic oil, assumed constant; x_{si} represents the displacement of the actuator driving the joint. For a hydraulic motor, this is the joint rotation angle; for a hydraulic cylinder, it is the piston displacement. A_{1i} and A_{2i} are the effective areas of the piston or motor vane; V_{01i} and V_{02i} represent the initial volumes of the two chambers; V_{1i} and V_{2i} represent the actual volumes of the two chambers during motion; p_{1i} and p_{2i} represent the pressures in the two chambers; q_{1i} and q_{2i} denote the flow rates into/out of the two chambers; C_t is the internal leakage coefficient; $d_{1i}(t)$ and $d_{2i}(t)$ represent unmodeled uncertainties and external leakage in the pressure dynamics model.

The servovalve adjusts the orifice opening by changing the spool position, thereby regulating the flow into and out of the actuator chambers. The servovalve flow equation can be expressed as:

$$\begin{cases} q_{1i} = k_{qi}x_{vi}\left(s(x_{vi})\sqrt{p_s - p_{1i}} + s(x_{vi})\sqrt{p_{1i} - p_r}\right) \\ q_{2i} = k_{qi}x_{vi}\left(s(x_{vi})\sqrt{p_{2i} - p_r} + s(x_{vi})\sqrt{p_s - p_{2i}}\right) \end{cases} \tag{4}$$

$$k_{qi} = C_{di}w_i\sqrt{2/\rho_i}, \qquad x_{vi} = k_{ui}u_i \tag{5}$$

where k_{qi} represents the flow gain for the left and right spool displacements of the servovalve; p_s is the supply pressure, p_r is the return pressure; x_{vi} is the servovalve spool displacement; C_{di} is the flow coefficient of the servovalve orifice; w_i is the area gradient of the orifice; ρ is the density of the hydraulic oil. The function $s(*)$ is defined as:

$$s(*) = \begin{cases} 1, & \text{if } * \geq 0 \\ 0, & \text{if } * < 0 \end{cases} \tag{6}$$

Therefore, the flow equation (4) of the electro-hydraulic servo system can be rewritten as:

$$\begin{cases} q_{1i} = k_{ti}R_{1i}u_i \\ q_{2i} = k_{ti}R_{2i}u_i \end{cases} \tag{7}$$

where $k_{ti} = k_{qi}k_{ui}$. Also:

$$\begin{cases} R_{1i} = s(u_i)\sqrt{p_s - p_{1i}} + s(u_i)\sqrt{p_{1i} - p_r} \\ R_{2i} = s(u_i)\sqrt{p_s - p_{1i}} + s(u_i)\sqrt{p_{1i} - p_r} \end{cases} \tag{8}$$

The actual output force/torque of the electro-hydraulic servo system can be expressed as:

2.2. Linear-to-Rotational Nonlinear Transformation of the Actuator

The actuators of the multi-DOF hydraulic manipulator primarily consist of valve-controlled hydraulic cylinders and hydraulic motors. Two hydraulic cylinders are responsible for driving the joints with larger loads (joints 2 and 3), involving a nonlinear transformation from linear to rotational motion, i.e., a structural nonlinear relationship exists.

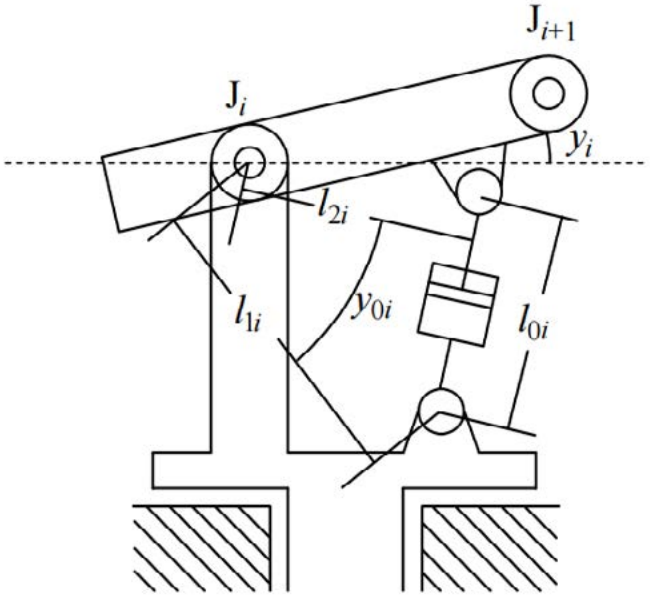

Figure 2 Schematic Diagram of Joint Linear-to-Rotational Nonlinear Transformation

The structural nonlinearity of the hydraulic manipulator is shown in Figure 2, where a hydraulic cylinder pushes a load to rotate about a pivot. Here, y_i represents the initial angle between the driven link and the horizontal plane; y_{0i} represents the initial angle between the two pivot points of the cylinder and the link's rotation axis; l_{1i} is the distance from the fixed pivot of the cylinder to the link's rotation axis; l_{2i} is the distance from the moving pivot of the cylinder to the link's rotation axis; l_{0i} is the initial length of the cylinder.

Based on the geometric relationships and the law of cosines, we obtain:

$$l_i = \sqrt{l_{1i}^2 + l_{2i}^2 - 2l_{1i}l_{2i}\cos\left(y_{0i} + y_i\right)} \tag{9}$$

Let the actual displacement of the cylinder be $x_{pi} = l_i - l_{0i}$. Thus, the actual velocity of the cylinder is:

$$\begin{aligned} v_{pi} = \dot{x}_{pi} &= \frac{\mathrm{d}\left(l_i - l_{0i}\right)}{\mathrm{d}t} = \frac{\mathrm{d}l_i}{\mathrm{d}t} \\ &= \frac{l_{1i}l_{2i}\sin\left(y_{0i} + y_i\right)}{\sqrt{l_{1i}^2 + l_{2i}^2 - 2l_{1i}l_{2i}\cos\left(y_{0i} + y_i\right)}}\dot{y}_i \\ &= S_i\left(y_i\right)\dot{y}_i \end{aligned} \tag{10}$$

where $S_i\left(y_i\right)$ is also the perpendicular distance from the cylinder to the link's rotation axis. Based on the above analysis, x_{si} in Eq. (3) can be expressed as:

$$x_{si} = \begin{cases} y_i & \text{, driven by motor} \\ \sqrt{l_{1i}^2 + l_{2i}^2 - 2l_{1i}l_{2i}\cos\left(y_{0i} + y_i\right)} - l_{0i} & \text{, driven by cylinder} \end{cases} \tag{11}$$

The actuator's own velocity can be obtained from Eq. (11):

$$\dot{x}_{si} = S_i\left(y_i\right)\dot{y}_i \tag{12}$$

$$S_i(y_i)=\begin{cases}1 & \text{,driven by motor}\\ \dfrac{l_{1i}l_{2i}\sin(y_{0i}+y_i)}{\sqrt{l_{1i}^2+l_{2i}^2-2l_{1i}l_{2i}\cos(y_{0i}+y_i)}} & \text{,driven by cylinder}\end{cases} \tag{13}$$

Combining Eq. (9), the actual output torque of the manipulator actuator for each joint can be expressed as:

$$T_i = S_i(y_i)(A_{1i}p_{1i} - A_{2i}p_{2i}) \tag{14}$$

2.3. State-Space Equation of the Hydraulic Manipulator

To facilitate subsequent controller design and analysis, define the state variables $\boldsymbol{x}=[\boldsymbol{x}_1^{\mathrm{T}},\boldsymbol{x}_2^{\mathrm{T}},\boldsymbol{x}_3^{\mathrm{T}}]^{\mathrm{T}}$, $\boldsymbol{x}_1=\boldsymbol{y}=[y_1,y_2,\cdots,y_n]^{\mathrm{T}}$, $\boldsymbol{x}_2=\dot{\boldsymbol{x}}_1=[\dot{y}_1,\dot{y}_2,\cdots,\dot{y}_n]^{\mathrm{T}}$, $\boldsymbol{x}_3=\boldsymbol{A}_1\boldsymbol{p}_1-\boldsymbol{A}_2\boldsymbol{p}_2$. Define the manipulator's time-varying rotation angle and angular velocity as y_i and $\dot{y}_i$, respectively. Combining the above equations, the nonlinear dynamic model of the multi-DOF hydraulic manipulator can be expressed in state-space form as:

$$\begin{aligned}\dot{\boldsymbol{x}}_1 &= \boldsymbol{x}_2\\ \dot{\boldsymbol{x}}_2 &= \boldsymbol{M}^{-1}(\boldsymbol{x}_1)\left[\boldsymbol{S}(\boldsymbol{x}_1)\boldsymbol{x}_3-\boldsymbol{G}(\boldsymbol{x}_1)-\boldsymbol{C}(\boldsymbol{x}_1,\boldsymbol{x}_2)\boldsymbol{x}_2\right]\\ &\quad+\boldsymbol{M}^{-1}(\boldsymbol{x}_1)\boldsymbol{\Delta}_{t1}\\ \dot{\boldsymbol{x}}_3 &= \boldsymbol{f}_1\boldsymbol{u}-\boldsymbol{f}_2-\boldsymbol{f}_3+\boldsymbol{\Delta}_{t2}\end{aligned} \tag{15}$$

where the control input vector for each joint's actuator in the hydraulic manipulator system is $\boldsymbol{u}=[u_1,u_2,\cdots,u_n]^{\mathrm{T}}$; expressions for other vectors can be found in [16].

Assumption 3: The commanded trajectory $\boldsymbol{x}_{1d}=\left[x_{11d},x_{12d},\cdots,x_{1nd}\right]^{\mathrm{T}}$ for each joint of the hydraulic manipulator is third-order differentiable, and all its derivatives are bounded.

Assumption 4: The elements of the unmatched uncertainty $\boldsymbol{\Delta}_{t1}=\left[\Delta_{t11},\Delta_{t12},\cdots,\Delta_{t1n}\right]^{\mathrm{T}}$ and the matched uncertainty $\boldsymbol{\Delta}_{t2}=\left[\Delta_{t21},\Delta_{t22},\cdots,\Delta_{t2n}\right]^{\mathrm{T}}$ are sufficiently smooth, and their first and second derivatives exist and are bounded.

3. MULTIDIMENSIONAL NEURAL NETWORK DESIGN

For hydraulic manipulators, complex joint coupling and unmodeled uncertainties are the main factors affecting high-precision position tracking. Therefore, this section employs a multidimensional radial basis function neural networks (mRBFNNs) to approximate and estimate the uncertain joint coupling dynamics and unmodeled disturbances of the hydraulic manipulator, achieving feedforward compensation during the controller design process.

From (16), it can be seen that $\boldsymbol{\Delta}_{t1}$ is related to the position, velocity, and acceleration signals of each joint, while $\boldsymbol{\Delta}_{t2}$ is only related to joint positions. Therefore, $\boldsymbol{\Delta}_{t1}$ and $\boldsymbol{\Delta}_{t2}$ can be designed in the following form:

$$\boldsymbol{\Delta}_{t1}=\left[\boldsymbol{W}_{11}^{\mathrm{T}}\boldsymbol{h}_{11}(\boldsymbol{\chi}_1),\cdots,\boldsymbol{W}_{1n}^{\mathrm{T}}\boldsymbol{h}_{1n}(\boldsymbol{\chi}_n)\right]^{\mathrm{T}}+\boldsymbol{\varepsilon}_1 \tag{16}$$

$$\boldsymbol{\Delta}_{t2}=\left[\boldsymbol{W}_{21}^{\mathrm{T}}\boldsymbol{h}_{21}(y_1),\cdots,\boldsymbol{W}_{2n}^{\mathrm{T}}\boldsymbol{h}_{2n}(y_n)\right]^{\mathrm{T}}+\boldsymbol{\varepsilon}_2 \tag{17}$$

where $\boldsymbol{W}_{1i}=\left[W_{1i1},\cdots,W_{1iH}\right]^{\mathrm{T}}\in\square^{H}$, H represent the number of neurons in the first neural network hidden layer; $\boldsymbol{W}_{2i}=\left[W_{2i1},\cdots,W_{2iL}\right]^{\mathrm{T}}\in\square^{L}$, L represent the number of neurons in the

second neural network hidden layer; $\boldsymbol{\chi}_i = \left[1, y_i, \dot{y}_i, \ddot{y}_i\right]^{\mathrm{T}}$ is the input signal to the first neural network; $\boldsymbol{\varepsilon}_i = \left[\varepsilon_{i1}, \cdots, \varepsilon_{in}\right]^{\mathrm{T}} \in \square^{n}$ represents the function reconstruction error; $\boldsymbol{h}_{1i} = \left[h_{1i1}, \cdots, h_{1iH}\right]^{\mathrm{T}} \in \square^{H}$ and $\boldsymbol{h}_{2i} = \left[h_{2i1}, \cdots, h_{2iL}\right]^{\mathrm{T}} \in \square^{L}$ are the Gaussian radial basis functions for the two different neural networks, expressed as follows:

$$h_{1ij} = \exp\left(-\frac{\left\|\boldsymbol{\chi}_i - \sigma_{1j} I_4\right\|^2}{2\iota_{1j}}\right), \begin{cases} i = 1, 2, \cdots, n \\ j = 1, 2, \cdots, H \end{cases} \tag{18}$$

$$h_{2ij} = \exp\left(-\frac{\left(y_i - \sigma_{2j}\right)^2}{2\iota_{2j}}\right), \begin{cases} i = 1, 2, \cdots, n \\ j = 1, 2, \cdots, L \end{cases} \tag{19}$$

where $\boldsymbol{\sigma}_1 = \left[\sigma_{1j}, \cdots, \sigma_{1H}\right]^{\mathrm{T}}$ and $\boldsymbol{\sigma}_2 = \left[\sigma_{2j}, \cdots, \sigma_{2L}\right]^{\mathrm{T}}$ represent acceptable center ranges; $\boldsymbol{\iota}_1 = \left[\iota_{1j}, \cdots, \iota_{1H}\right]^{\mathrm{T}}$ and $\iota_2 = \left[\iota_{2j}, \cdots, \iota_{2L}\right]^{\mathrm{T}}$ represent the widths of the Gaussian functions.

Assumption 5: The function reconstruction error $\boldsymbol{\varepsilon}_i = \left[\varepsilon_{i1}, \cdots, \varepsilon_{in}\right]^{\mathrm{T}}$ and its second derivative with respect to time are bounded:

$$\begin{cases} \left\|\boldsymbol{\varepsilon}_1\right\| \le \varepsilon_{1d1}, \ \left\|\dot{\boldsymbol{\varepsilon}}_1\right\| \le \varepsilon_{1d2}, \ \left\|\ddot{\boldsymbol{\varepsilon}}_1\right\| \le \varepsilon_{1d3} \\ \left\|\boldsymbol{\varepsilon}_2\right\| \le \varepsilon_{2d1}, \ \left\|\dot{\boldsymbol{\varepsilon}}_2\right\| \le \varepsilon_{2d2}, \ \left\|\ddot{\boldsymbol{\varepsilon}}_2\right\| \le \varepsilon_{2d3} \end{cases} \tag{20}$$

where ε_{id1}, ε_{id2}, and ε_{id3} are positive constants.

Considering that increasing the number of neural network hidden layers and manipulator joints makes tuning the weight matrices $\boldsymbol{W}_{1i}$ and $\boldsymbol{W}_{2i}$ extremely difficult, this study introduces an adaptive method for self-tuning the weight matrices. Based on (17) and (18), their adaptive approximation expressions can be obtained as follows:

$$\hat{\boldsymbol{\Delta}}_{t1} = \left[\hat{\boldsymbol{W}}_{11}^{\mathrm{T}} \boldsymbol{h}_{11}\left(\boldsymbol{\chi}_1\right), \cdots, \hat{\boldsymbol{W}}_{1n}^{\mathrm{T}} \boldsymbol{h}_{1n}\left(\boldsymbol{\chi}_n\right)\right]^{\mathrm{T}} \tag{21}$$

$$\hat{\boldsymbol{\Delta}}_{t2} = \left[\hat{\boldsymbol{W}}_{21}^{\mathrm{T}} \boldsymbol{h}_{21}\left(y_1\right), \cdots, \hat{\boldsymbol{W}}_{2n}^{\mathrm{T}} \boldsymbol{h}_{2n}\left(y_n\right)\right]^{\mathrm{T}} \tag{22}$$

where $\hat{\boldsymbol{W}}_{1i} = \left[\hat{W}_{1i1}, \cdots, \hat{W}_{1iH}\right]^{\mathrm{T}} \in \square^{H}$ and $\hat{\boldsymbol{W}}_{2i} = \left[\hat{W}_{2i1}, \cdots, \hat{W}_{2iL}\right]^{\mathrm{T}} \in \square^{L}$ represent the estimated values of the ideal weights.

The adaptive laws for the neural network weights are as follows:

$$\begin{cases} \dot{\hat{\boldsymbol{W}}}_{1i} = \mathrm{sat}_{\hat{\boldsymbol{W}}_{1iM}}\left(\mathrm{Proj}_{\hat{\boldsymbol{W}}_{1i}}\left(\boldsymbol{\Gamma}_{1i}\boldsymbol{\tau}_{1i}\right)\right) \\ \dot{\hat{\boldsymbol{W}}}_{2i} = \mathrm{sat}_{\hat{\boldsymbol{W}}_{2iM}}\left(\mathrm{Proj}_{\hat{\boldsymbol{W}}_{2i}}\left(\boldsymbol{\Gamma}_{2i}\boldsymbol{\tau}_{2i}\right)\right) \end{cases} \tag{23}$$

$$\begin{cases} \boldsymbol{\tau}_{1i} = \boldsymbol{h}_{1i} z_{2i} \\ \boldsymbol{\tau}_{2i} = \boldsymbol{h}_{2i} z_{3i} \end{cases} \tag{24}$$

where $\boldsymbol{\Gamma}$ is a positive definite matrix determining the adaptive rate of the weights; $\boldsymbol{\tau}$ is defined as the adaptive function for the neural network weights; other function definitions are as shown in [17].

Define the estimation errors as follows:

$$\tilde{\bullet} = \bullet - \hat{\bullet} \tag{25}$$

According to (22), define the following variables:

$$\tilde{\boldsymbol{\Delta}}_{t1} = \left[\tilde{\boldsymbol{W}}_{11}^{\mathrm{T}} \boldsymbol{h}_{11}\left(\boldsymbol{\chi}_1\right), \cdots, \tilde{\boldsymbol{W}}_{1n}^{\mathrm{T}} \boldsymbol{h}_{1n}\left(\boldsymbol{\chi}_n\right)\right]^{\mathrm{T}} \tag{26}$$

$$\tilde{\boldsymbol{\Delta}}_{tw1}=\left[\dot{\tilde{\boldsymbol{W}}}_{11}^{\mathrm{T}}\boldsymbol{h}_{11}(\boldsymbol{\chi}_1),\cdots,\dot{\tilde{\boldsymbol{W}}}_{1n}^{\mathrm{T}}\boldsymbol{h}_{1n}(\boldsymbol{\chi}_n)\right]^{\mathrm{T}} \tag{27}$$

$$\tilde{\boldsymbol{\Delta}}_{th1}=\left[\tilde{\boldsymbol{W}}_{11}^{\mathrm{T}}\dot{\boldsymbol{h}}_{11}(\boldsymbol{\chi}_1),\cdots,\tilde{\boldsymbol{W}}_{1n}^{\mathrm{T}}\dot{\boldsymbol{h}}_{1n}(\boldsymbol{\chi}_n)\right]^{\mathrm{T}} \tag{28}$$

To simplify the proof process, the transformed form of (23) follows the same principle.

4. CONTROLLER DESIGN AND STABILITY ANALYSIS

4.1. Nonlinear Integral Robust Controller Design

Define the error variable vectors as follows:

$$\begin{cases} \boldsymbol{z}_1=\boldsymbol{x}_1-\boldsymbol{x}_{1d} \\ \boldsymbol{z}_2=\dot{\boldsymbol{z}}_1+\boldsymbol{k}_1\boldsymbol{z}_1 \\ \boldsymbol{z}_3=\boldsymbol{x}_3-\boldsymbol{\alpha}_2 \\ \boldsymbol{r}_1=\dot{\boldsymbol{z}}_2+\boldsymbol{k}_2\boldsymbol{z}_2 \\ \boldsymbol{r}_2=\dot{\boldsymbol{z}}_3+\boldsymbol{k}_3\boldsymbol{z}_3 \end{cases} \tag{29}$$

where $\boldsymbol{r}_1$ and $\boldsymbol{r}_2$ are auxiliary error variable vectors, which can help suppress matched and unmatched uncertainties during controller design; $\boldsymbol{k}_1=\mathrm{diag}\{k_{11},k_{12},\cdots,k_{1n}\}$, $\boldsymbol{k}_2=\mathrm{diag}\{k_{21},k_{22},\cdots,k_{2n}\}$, $\boldsymbol{k}_3=\mathrm{diag}\{k_{31},k_{32},\cdots,k_{3n}\}$ represent tunable controller gain matrices.

Based on the above equation, the virtual control law https://media/image111.wmf can be designed as follows:

$$\begin{aligned} \boldsymbol{\alpha}_2&=\boldsymbol{S}^{-1}(\boldsymbol{x}_1)\left[\boldsymbol{\alpha}_{2a}+\boldsymbol{\alpha}_{2s1}+\boldsymbol{\alpha}_{2s2}\right] \\ \boldsymbol{\alpha}_{2a}&=\boldsymbol{G}(\boldsymbol{x}_1)+\boldsymbol{C}(\boldsymbol{x}_1,\boldsymbol{x}_2)\boldsymbol{x}_2-\hat{\boldsymbol{\Delta}}_{t1} \\ &\quad+\boldsymbol{M}(\boldsymbol{x}_1)\ddot{\boldsymbol{x}}_{1d} \\ \boldsymbol{\alpha}_{2s1}&=-(\boldsymbol{k}_{r1}+\boldsymbol{k}_s)\boldsymbol{z}_2-\boldsymbol{M}(\boldsymbol{x}_1)\boldsymbol{k}_1\dot{\boldsymbol{z}}_1-\boldsymbol{M}(\boldsymbol{x}_1)\boldsymbol{k}_2\boldsymbol{z}_2 \\ \boldsymbol{\alpha}_{2s2}&=-\int_0^t\left[(\boldsymbol{k}_{r1}+\boldsymbol{k}_s)\boldsymbol{k}_2\boldsymbol{z}_2+\boldsymbol{v}(\boldsymbol{z}_2)\boldsymbol{\beta}_1\right]\mathrm{d}\tau \end{aligned} \tag{30}$$

where $\mathrm{sign}(*)$ represents the sign function; the sign function matrix $\boldsymbol{v}(\boldsymbol{z}_2)$ is $\boldsymbol{v}(\boldsymbol{z}_2)=\mathrm{diag}\{\mathrm{sign}(z_{21}),\cdots,\mathrm{sign}(z_{2n})\}$; the control gain is $\boldsymbol{k}_{r1}=\mathrm{diag}\{k_{r11},k_{r12},\cdots,k_{r1n}\}$, and all elements in the matrix are positive; $\boldsymbol{\beta}_1=[\beta_{11},\beta_{12},\cdots,\beta_{1n}]^{\mathrm{T}}$ is a gain vector with all positive elements; $\boldsymbol{k}_s=\mathrm{diag}\{k_{s1},k_{s2},\cdots,k_{sn}\}$ is an auxiliary constant variable matrix with all elements being real numbers greater than 0.

The expanded form of the auxiliary error vector $\boldsymbol{r}_1$ is:

$$\boldsymbol{M}(\boldsymbol{x}_1)\dot{\boldsymbol{r}}_1=\boldsymbol{S}(\boldsymbol{x}_1)\dot{\boldsymbol{z}}_3-(\boldsymbol{k}_{r1}+\boldsymbol{k}_s)\boldsymbol{r}_1-\boldsymbol{v}(\boldsymbol{z}_2)\boldsymbol{\beta}_1+\boldsymbol{N}_1 \tag{31}$$

From (31), it is known that $\boldsymbol{N}_1$ is bounded. The bound of $\boldsymbol{N}_1$ can be expressed as:

$$\|\boldsymbol{N}_1\|\le\delta_1,\ \ \|\dot{\boldsymbol{N}}_1\|\le\delta_2 \tag{32}$$

where δ_1 and δ_2 are constants greater than 0.

Based on the expansion of the auxiliary error function $\boldsymbol{r}_2$, the actual control law can be designed as follows:

$$\begin{aligned}\boldsymbol{u} &= \boldsymbol{f}_1^{-1}\left(\boldsymbol{u}_a + \boldsymbol{u}_{s1} + \boldsymbol{u}_{s2}\right)\\ \boldsymbol{u}_a &= \boldsymbol{f}_2 + \boldsymbol{f}_3 + \dot{\boldsymbol{\alpha}}_2 - \hat{\boldsymbol{\Delta}}_{t2}\\ \boldsymbol{u}_{s1} &= -\boldsymbol{k}_{r2}\boldsymbol{z}_3 - \boldsymbol{k}_3\boldsymbol{z}_3\\ \boldsymbol{u}_{s2} &= -\int_0^t\left[\boldsymbol{k}_{r2}\boldsymbol{k}_3\boldsymbol{z}_3 + \boldsymbol{v}\left(z_3\right)\boldsymbol{\beta}_2\right]\mathrm{d}\tau\end{aligned} \tag{33}$$

where $\boldsymbol{\beta}_2 = \left[\beta_{21}, \beta_{22}, \cdots, \beta_{2n}\right]^{\mathrm{T}}$ is a gain vector; $\boldsymbol{u}_a$ is the model compensation term; $\boldsymbol{u}_{s1}$ represents the linear feedback term for system tuning; the sign function matrix $\boldsymbol{v}\left(z_3\right) = \mathrm{diag}\left\{\mathrm{sign}\left(z_{31}\right), \cdots, \mathrm{sign}\left(z_{3n}\right)\right\}$; $\boldsymbol{u}_{s2}$ is the system's RISE feedback term, which can suppress the influence of matched uncertainties on system control performance to some extent.

Combining the specific form of the actual control law in (42), the time derivative of $\boldsymbol{r}_2$ can be expanded as:

$$\dot{\boldsymbol{r}}_2 = -\boldsymbol{k}_{r2}\boldsymbol{r}_2 - \boldsymbol{v}\left(z_3\right)\boldsymbol{\beta}_2 + \boldsymbol{N}_2 \tag{34}$$

From (34), it is known that $\boldsymbol{N}_2$ is bounded. The bound of $\boldsymbol{N}_2$ can be expressed as:

$$\left\|\boldsymbol{N}_2\right\| \le \xi_1, \quad \left\|\dot{\boldsymbol{N}}_2\right\| \le \xi_2 \tag{35}$$

where δ_1 and δ_2 are constants greater than 0.

4.2. Controller Stability Analysis

To analyze the controller's performance and stability, the following theorems are given.

Theorem 1: There always exist real vectors $\boldsymbol{\beta}_1 = \left[\beta_{11}, \beta_{12}, \cdots, \beta_{1n}\right]^{\mathrm{T}}$ and $\boldsymbol{\beta}_2 = \left[\beta_{21}, \beta_{22}, \cdots, \beta_{2n}\right]^{\mathrm{T}}$, whose elements always satisfy the following conditions:

$$\beta_{1i} \ge \delta_{1i} + \frac{1}{k_{2i}}\delta_{2i} \tag{36}$$

$$\beta_{2i} \ge \xi_{1i} + \frac{1}{k_{3i}}\xi_{2i} \tag{37}$$

Here, the functions $P_1(t)$ and $P_2(t)$ are defined as:

$$P_1(t) = \boldsymbol{\beta}_1^{\mathrm{T}}\left|z_2(0)\right| - \boldsymbol{z}_2^{\mathrm{T}}(0)\boldsymbol{N}_1(0) - \int_0^t L_1(\tau)\mathrm{d}\tau \tag{38}$$

$$P_2(t) = \boldsymbol{\beta}_2^{\mathrm{T}}\left|z_3(0)\right| - \boldsymbol{z}_3^{\mathrm{T}}(0)\boldsymbol{N}_2(0) - \int_0^t L_2(\tau)\mathrm{d}\tau \tag{39}$$

$$L_1(t) = \boldsymbol{r}_1^{\mathrm{T}}\left[\boldsymbol{N}_2 - \boldsymbol{v}\left(z_2\right)\boldsymbol{\beta}_1\right] \tag{40}$$

$$L_2(t) = \boldsymbol{r}_2^{\mathrm{T}}\left[\boldsymbol{N}_1 - \boldsymbol{v}\left(z_3\right)\boldsymbol{\beta}_2\right] \tag{41}$$

From the above equations, it can be concluded that the functions $P_1(t)$ and $P_2(t)$ are always positive definite.

Theorem 2: By selecting sufficiently large and appropriate controller gain matrices $\boldsymbol{k}_1$, $\boldsymbol{k}_2$, $\boldsymbol{k}_3$, $\boldsymbol{k}_{\mathrm{r1}}$, and $\boldsymbol{k}_{\mathrm{r2}}$, the following matrix:

$$\Lambda = \begin{bmatrix} \boldsymbol{k}_1 & -\frac{\mathbf{I}_{6\times6}}{2} & \mathbf{0}_{6\times6} & \mathbf{0}_{6\times6} & \mathbf{0}_{6\times6} \\ -\frac{\mathbf{I}_{6\times6}}{2} & \boldsymbol{k}_2 & -\frac{\mathbf{I}_{6\times6}}{2} & \mathbf{0}_{6\times6} & \mathbf{0}_{6\times6} \\ \mathbf{0}_{6\times6} & -\frac{\mathbf{I}_{6\times6}}{2} & \boldsymbol{k}_{\mathrm{r1}} & \mathbf{0}_{6\times6} & \mathbf{0}_{6\times6} \\ \mathbf{0}_{6\times6} & \mathbf{0}_{6\times6} & \mathbf{0}_{6\times6} & \boldsymbol{k}_3 & -\frac{\mathbf{I}_{6\times6}}{2} \\ \mathbf{0}_{6\times6} & \mathbf{0}_{6\times6} & \mathbf{0}_{6\times6} & -\frac{\mathbf{I}_{6\times6}}{2} & \boldsymbol{k}_{\mathrm{r2}} \end{bmatrix} \tag{42}$$

is always positive definite. Then, the designed controller is semi-globally asymptotically stable and ensures that all signals in the closed-loop system are bounded, i.e., $\|z_1\|_\infty = \max\left(|z_{11}|,|z_{12}|,\cdots,|z_{1n}|\right) \to 0$, $t \to \infty$.
The proof process can be referred to in [17].

5. SIMULATION RESULTS

This section verifies the advancement and effectiveness of the designed multidimensional neural network-based integral robust controller for hydraulic manipulators through a simulation example of a three-DOF hydraulic manipulator wrist system. The system parameters are consistent with those in [18]. The structure of the three-DOF hydraulic manipulator wrist system is shown in Figure 3.

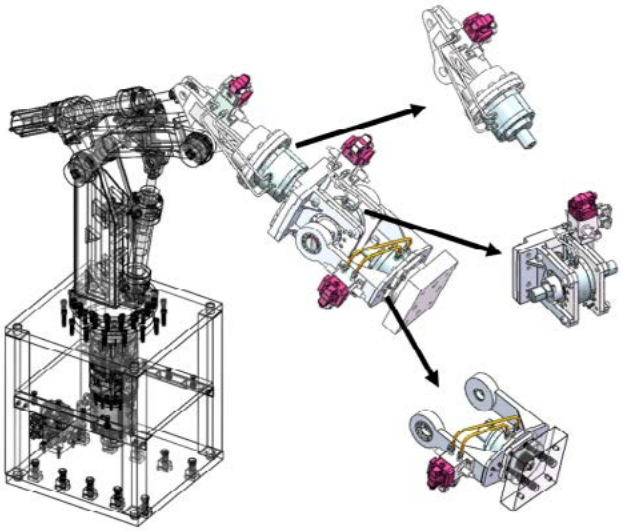

Figure 3 Schematic Diagram of The Hydraulic Manipulator Wrist Structure

To verify the fitting performance of the neural network, matched and unmatched uncertainties are designed as follows:

$$\begin{cases} \boldsymbol{\Delta}_{t1} = \dot{\boldsymbol{x}}_{1d} + \begin{bmatrix} 50 \\ 50 \\ 50 \end{bmatrix} \\ \boldsymbol{\Delta}_{t2} = \begin{bmatrix} 2\times10^4 \sin(0.5t) \\ 1\times10^4 \sin(0.5t) \\ 1\times10^4 \sin(0.5t) \end{bmatrix} \end{cases} \tag{43}$$

To compare the differences in simulation results under different controllers, the controller parameters are set as follows:

(1) Multidimensional Neural Network-Based Integral Robust Controller (C1): This is the controller proposed in this study. Its gains are: $\boldsymbol{k}_1 = \mathrm{diag}\{60,20,20\}$, $\boldsymbol{k}_2 = \mathrm{diag}\{500,800,500\}$, $\boldsymbol{k}_3 = \mathrm{diag}\{60,80,80\}$, $\boldsymbol{k}_{r1} = \mathrm{diag}\{4,5,4\}$, $\boldsymbol{k}_{r2} = \mathrm{diag}\{10,5,10\}$, $\boldsymbol{k}_{\mathrm{s}} = \mathrm{diag}\{10,5,10\}$, $\boldsymbol{\beta}_1 = [8,2,1]^{\mathrm{T}}$, $\boldsymbol{\beta}_2 = [1000,100,150]^{\mathrm{T}}$, $H = 16$, $L = 12$, $\Gamma_{1i} = 25$, $\Gamma_{2i} = 20$.

(2) Feedback Linearization Controller (C2): This is a feedback linearization pose controller. Apart from the parameters not included, other controller gains remain the same as in C1.

The initial tracking command signals for each joint are:

$$\boldsymbol{x}_{1d} = \begin{bmatrix} 0.25\sin(0.5t)\times\left(1-e^{-0.01t^3}\right) \\ 0.20\sin(0.5t)\times\left(1-e^{-0.01t^3}\right) \\ 0.25\sin(0.5t)\times\left(1-e^{-0.01t^3}\right) \end{bmatrix} \tag{44}$$

The simulation results are shown in the following figures. Figure 4 shows the tracking control performance of each joint of the hydraulic manipulator wrist under different controllers. Figure 5 displays the tracking error results for Joint 1 under the two controllers. Figure 6 compares the tracking errors for Joint 2 under different controllers. Figure 7 shows the errors for Joint 3 under the two controllers.

From Figure 4, it can be observed that both controllers, C1 and C2, enable each joint to track the command signal (46) well, with no significant visual difference. However, Figures 5 to 7 more clearly demonstrate the tracking performance of the two controllers. Since the command signal exhibits periodic fluctuations, significant error fluctuations are observed during each hydraulic motor reversal due to the influence of unmodeled errors such as friction and disturbances. Controller C2 is a classic feedback linearization controller. However, lacking disturbance approximation and compensation capabilities, its tracking performance is noticeably inferior to that of the C1 neural network integral robust controller during simulation startup and reversal phases. This verifies the effectiveness of the proposed control strategy.

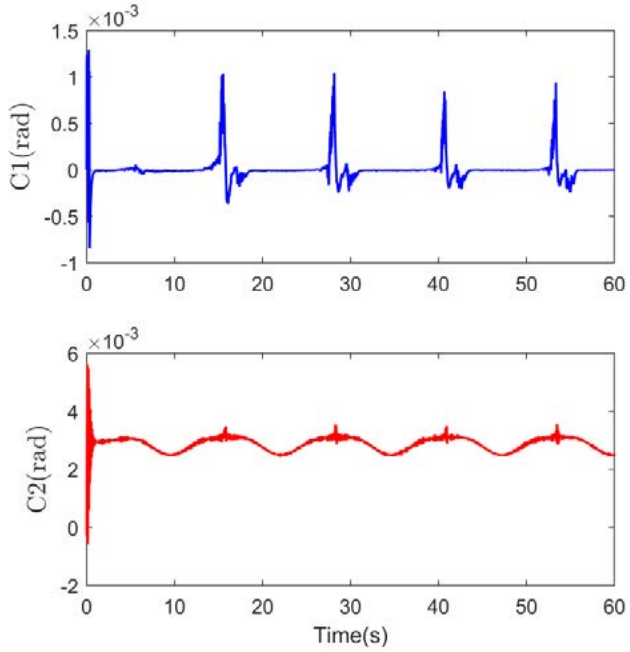

Figure 6 Comparison of Tracking Errors of Joint 2 Under Different Controllers

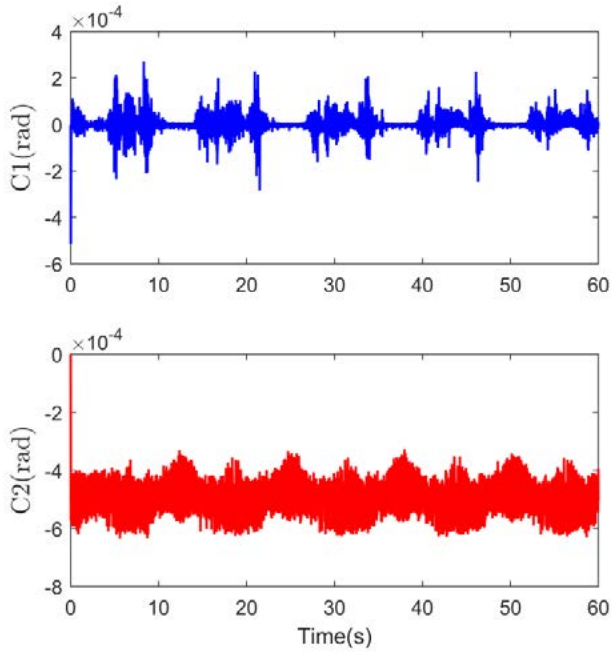

Figure 7 Comparison of Tracking Errors of Joint 3 Under Different Controllers

6. CONCLUSION

With the increasing demand for automation and intelligence in heavy-load operations, higher requirements are placed on the comprehensive control performance of hydraulically driven multi-DOF manipulators. Addressing major problems such as large model errors, high operational risks, and poor pose positioning accuracy in heavy-load hydraulic manipulator control, this study proposes an integral robust control strategy integrated with neural networks, achieving the approximation and compensation of unmodeled uncertainties. The main conclusions are as follows:

This study provides a robust and dynamically compensated solution for high-precision, high-reliability pose tracking control of heavy-load multi-DOF hydraulic manipulators, offering a new approach for high-performance controller design in complex scenarios.

Abstract

Dissolved gas is a critical factor in many technical systems, since it influences fluid properties like compressibility, viscosity or thermal conductivity in a negative manner. Cavitation due to dissolved gas can lead to damage of components and increased wear in hydraulic applications. Therefore, a precise understanding of the dissolving and release processes of gases in liquids is essential for efficient and reliable hydraulic systems.

Despite its relevance for technical applications, literature on the gas solubility of hydraulic oils and lubricants is sparse. This is particularly true for data above ambient pressure at pressures relevant for hydraulic application. To close this gap, a measurement set up using volumetric-manometric approach was designed, which can be used to determine the gas solubility of hydraulic oils and other technical liquids. For the investigation of flammable or hazardous liquid/gas combinations an indirect measurement method was developed. In this contribution the design of the measurement set up is presented as well as results for one hydraulic oil in combination with nitrogen. Based on the obtained results, it is evident that substantial amounts of gas may be released during the operation of hydraulic systems.

1. INTRODUCTION

The ability of a liquid to dissolve gas is of great importance for a variety of technical applications. For example, the formation of bubbles in hydraulic systems is influenced by the amount of dissolved gas in the fluid. Bubbles are generally undesirable in hydraulic systems as they can lead to cavitation damage and have a negative impact on fluid properties such as compressibility or viscosity. Therefore, a precise understanding of the dissolving and release processes of gases in liquids is essential for efficient and reliable hydraulic systems [1, 2].

The same applies to cooling systems where bubbles and foam hinder heat transfer between liquid and environment. This becomes increasingly important in terms of the ongoing growth of e-mobility, as efficient temperature management is a prerequisite for e-motors with high power density and battery systems with large storage capacities. Gas solubility

All Open Access articles are peer-reviewed, distributed under the Creative Commons Attribution-Non Commercial 4.0 International

also plays a crucial role for combustion engines. Gaseous fuel or combustion gases can dissolve in the lubricating film on the cylinder wall and be drawn in via the piston and thus accumulate in the engine oil. This is particularly important for alternative fuels such as ammonia or hydrogen, which are either toxic or highly explosive [3].

Although gas solubility is extremely relevant for many technical applications as described, gas solubility values can only be found to a limited extent in the literature. Coefficients for gas solubility are mainly available for short-chain molecules and pure liquids. Especially, information on pressure dependent gas solubility is very sparse, since most measurements were performed at ambient pressure. Solubility data in the range of pressures relevant for hydraulic applications is primarily available for crude oil or bitumen, but not for lubricants and hydraulic oils [4].

For this reason, this article will examine the gas dissolving capacity of various hydraulic oils. To determine the gas solubility, several measurement approaches are available [5, 6]. Traditionally, these can be categorized into chemical and physical methods [5]. For analyzing gas solubility in liquids, physical methods are generally more appropriate [5]. These physical approaches can be further divided into manometric-volumetric, mass spectrometric, gas chromatographic, and radiometric techniques [5, 6]. Currently, there is no standardized procedure for determining the solubility of gases in liquids [5]. However, the literature provides some examples of experimental setups used to investigate gas solubility at elevated pressures [7, 8].

In this contribution a volumetric-manometric approach was utilized for the determination of gas solubility at different temperatures and pressures, which is based on preliminary work by Rambaks et al. [9] and has been extensively revised [3]. In the following, first the basic measuring principle is described. Then the design of the test bench and the measurement process are shown. A particular focus is on the determination of gas solubility for highly reactive or toxic liquid/gas mixtures using an indirect measurement method.

Finally, the measurement results for hydraulic oil will be presented. Where possible, the results are compared with data from the literature. Both pressure- and temperature-dependency of the Bunsen coefficient is evaluated by means of the Krichevsky Kasarnovsky equation and the Henry–Van't Hoff relationship. With help of the corresponding parameters the interpolation and extrapolation of the measured data is possible.

2. METHODOLOGY

In the literature, various definitions and measures are used to describe the ability of liquids to dissolve gases. Therefore, this work first provides a general overview of the relevant variables and definitions employed herein, followed by a description of the measurement procedure and its fundamental functionality. Then, the thermodynamic principles underlying the method are derived, and the applicability of the approach to hazardous or flammable gas–liquid systems is discussed.

2.1. Definition of gas solubility

The most common measures used to represent gas solubility are listed in Table 2.1. The most fundamental quantity is the concentration c_G, which expresses the amount of dissolved gas n_G per unit volume of liquid V_L, typically in $\mathrm{mol/m^3}$. Alternatively, the mole fraction x_G

represents the ratio of dissolved gas moles n_G to the total moles of all components in the liquid phase ($n_G + n_L$). This dimensionless quantity is widely employed in thermodynamic modeling. Henry's law constant k_H establishes a proportional relationship between the equilibrium gas partial pressure p and its concentration c_G in the liquid. It serves as a convenient measure to relate experimentally accessible pressures to dissolved amounts, particularly in dilute solutions where the law holds. The Bunsen coefficient is defined as the volume of gas V_G (referred to standard conditions, e.g. $T_0 = 298.15$ Kand $p_0 = 1$ bar) that dissolves in a unit volume of liquid V_L under a partial pressure p.

Table 2.1 Summary of definitions and interrelations of gas solubility parameters

	Concentration $[\mathrm{mol \cdot m^{-3}}]$	Mole fraction [–]	Henry constant $[\mathrm{Pa \cdot m^3 \cdot mol^{-1}}]$	Bunsen coefficient [–]
	$c_G = \frac{n_G}{V_L}$	$x_G = \frac{n_G}{n_G + n_L}$	$k_H = \frac{p}{c_G}$	$\alpha = \frac{V_G}{V_L}\frac{p_0}{p}$
$f(c_G)$	—	$x_G = c_G \frac{M_L}{\rho_L}$	$k_H = \frac{p}{c_G}$	$\alpha = c_G \frac{RT_0}{p_0}$
$f(x_G)$	$c_G = x_G \frac{\rho_L}{M_L}$	—	$k_H = \frac{M_L p}{\rho_L}\frac{x_G}{1 - x_G}$	$\alpha = x_G \frac{RT_0}{p_0}\frac{\rho_L}{M_L}$
$f(k_H)$	$c_G = \frac{p}{k_H}$	$x_G = \frac{pM_L}{k_H \rho_L + pM_L}$	—	$\alpha = \frac{1}{k_H}\frac{RT_0 p}{p_0}$
$f(\alpha)$	$c_G = \alpha \frac{p_0}{RT_0}$	$x_G = \alpha \frac{p_0}{RT_0}\frac{M_L}{\rho_L}$	$k_H = \frac{1}{\alpha}\frac{RT_0 p}{p_0}$	—

Since the Bunsen coefficient has historically been used to describe the gas solubility of hydraulic oils and many other technical liquids, this parameter will also be used in this paper. In addition, many oils are mixtures with largely unknown compositions, meaning that no molar mass M_L can be determined and the amount of substance n_L cannot be calculated for a given liquid volume V_L either. As shown in Table 2.1, the parameters used to describe the ability of liquids to dissolve gases can be converted into one another if necessary.

2.2. General determination of gas solubility according to the manometric-volumetric principle

In this study, the Bunsen coefficient is determined by using a volumetric-manometric method, in which different states of a defined gas volume in thermodynamic equilibrium are evaluated. The pressure in the gas phase is used to quantify the amount of gas that has dissolved in the liquid as illustrated in **Figure 2.1**. The gas and liquid phases are at the same temperature and pressure. In the initial state (0), the liquid contains no dissolved gas, whereas in state 1, a certain amount of gas has already dissolved in the liquid.

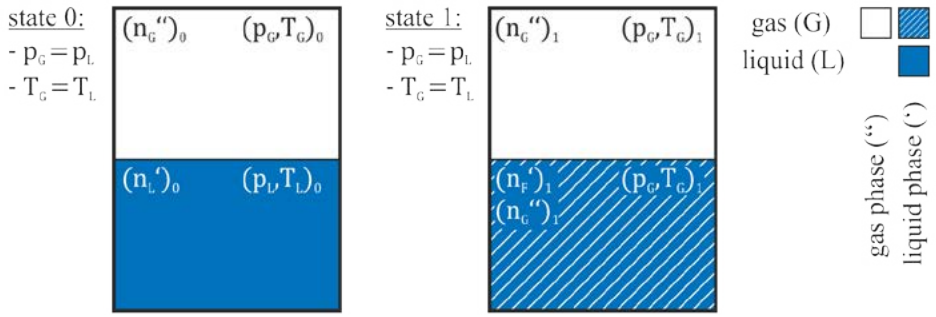

Figure 2.1. Ideal closed system

Since the example system is a closed system, the total amount of gas $(n_G)_i$ is constant and can be represented as the sum of the amount of dissolved gas $(n_G')_i$ and free gas in the gaseous phase $(n_G'')_i$ (2.1).

$$(n_G)_i = (n_G')_i + (n_G'')_i = \text{const.} \tag{2.1}$$

The amount of gas $(n_G'')_i$in the gaseous phase can be described using the real gas law, which is a function of temperature $(T_G'')_i$ and pressure $(p_G'')_i$ as well as the gas volume $(V_G'')_i$, the gas constant R and the compressibility factor $(z_G)_i$.

$$(n_G'')_i = \frac{1}{R}\left(\frac{p_G'' V_G''}{T_G'' z_G}\right)_i \tag{2.2}$$

The amount of dissolved gas $(n_G')_1$ in state 1 corresponds to the difference of the amount of gas in the gaseous phase in state 0 $(n_G'')_0$ and state 1 $(n_G'')_1$. The underlying assumption is that the amount of dissolved gas in state 0 $(n_G'')_0$ is equal to 0.

$$(n_G')_1 - \underbrace{(n_G')_0}_{\approx 0} = (n_G'')_0 - (n_G'')_1 \tag{2.3}$$

As shown in Table 2.1 Bunsen coefficient α_i is the ratio of dissolved gas volume at standard conditions $(V_G')_S$ and the liquid volume $(V_L')_S$. In accordance with the ideal gas law, the gas volume can be also expressed as a function of $(n_G')_S$.

$$\alpha_i = \frac{(V_G')_S}{(V_L')_S} = \frac{R(T)_S}{(V_L')_S (p'')_S}(n_G')_S \tag{2.4}$$

By combining equations (2.2), (2.3) and (2.4), the resulting expression (2.5) is obtained. Finally, the Bunsen absorption coefficient can be determined by comparing the state variables temperature and pressure in both states and by evaluating the volumes $(V_L')_i$ and $(V_G'')_i$.

$$\alpha_i = \frac{(T)_S}{(V_L')_S (p'')_S}\left[\left(\frac{p'' V_G''}{T''}\right)_0 - \left(\frac{p'' V_G''}{T''}\right)_1\right] \tag{2.5}$$

2.3. Measurement setup

For practical implementation of the measurement method described above and to determine the unknown parameters from equation (2.5), the test bench shown in **Figure 2.2** was used. The setup mainly consists of a cylinder which can be filled with liquid and gas. To determine the state variables p'' and T'', corresponding pressure and temperature sensors are located inside the cylinder. The pressure in the gas and liquid phase is equal, so that a single sensor is sufficient to obtain the required pressure data. Since gases and liquids generally heat up at different rates when pressure changes, two separate temperature sensors are used for the respective phases. The volume of the gas phase $(V_G'')_i$ can be calculated using equation (2.6). The piston position x required for this is measured by the installed LVDT sensor.

$$(V_G'')_i = (V_L')_i - [V_0 + A(x_0 - x)] \tag{2.6}$$

The initial volume of the cylinder V_0 was determined in advance by filling it with water. To do this, a container was filled with water and weighed with a precision scale both before and after pouring it into the cylinder. The accuracy of the scale is 0.01 g. The total volume of the cylinder V_0 can then be calculated in accordance with equation (2.7).

$$V_0 = \frac{(m'_{H2O})_0}{(\rho'_{H2O})_0}, \qquad (V_L')_0 = \frac{(m'_L)_0}{(\rho'_L)_0} \tag{2.7}$$

Before filling the test liquid, its mass is also weighed using a precision scale, so that the same relationship as in equation (2.7) can be applied to determine $(V_L')_i$. The required density values are either taken from the literature or determined according to standard DIN 12790 [10]. Changes of $(V_L')_i$ due to compression are neglectable for most liquids at low pressures and are considered for high pressures using a suitable density model.

Adjusting the piston changes the cylinder volume and, thus, the thermodynamic state of the system, enabling the comparison of different states according to equation (2.5).

After the filling process, the cylinder is sealed. To avoid contamination from dissolved gases and the ambient air above the liquid, the cylinder is connected to a vacuum pump. The pump allows the gas phase inside the cylinder to be evacuated, while the resulting pressure reduction promotes the release of any gases previously dissolved in the liquid. During evacuation, care must be taken to ensure that the pressure does not fall below the vapor pressure of the liquid.

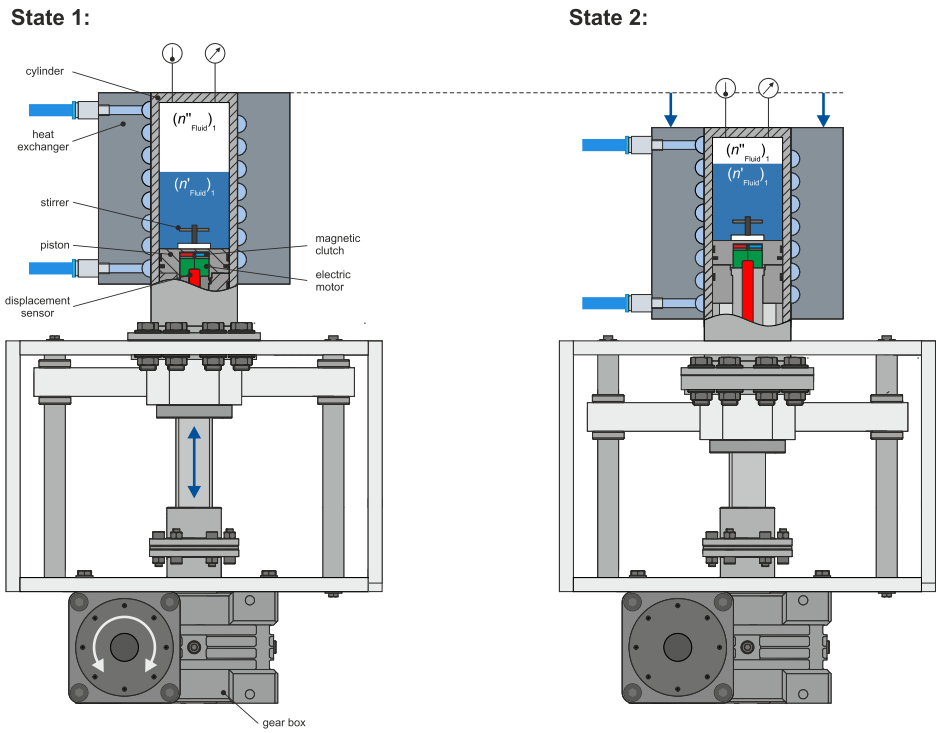

Figure 2.2. Bunsen test bench

After the evacuation of the cylinder, the chamber pressure and volume are adjusted using the piston position. A control loop is implemented to regulate the deviation between the setpoint and the actual pressure in the cylinder, which is translated into a motion of the stepper motor. The stepper motor is mechanically coupled to the piston via a gearbox. In the exemplary measurement shown in **Figure 2.3**, a chamber pressure of 18 bar was set for the first measuring point (1), corresponding to a piston position of approximately 38.8 mm. The increased pressure drives the system out of thermodynamic equilibrium, causing gas to start dissolving into the test liquid. To accelerate the diffusion process, the stirrer mounted on the piston is activated indicated by voltage U. If no change in pressure and temperature outside a small tolerance range can be detected, it is assumed that thermodynamic equilibrium has been reached again. To ensure that the measurement is not influenced by heat generated by the stirrer, it is turned off prior to data acquisition (voltage U: 2 V → 0 V). Thereafter, the quantities temperature T, pressure p, and piston displacement x are recorded for a duration of 10 minutes.

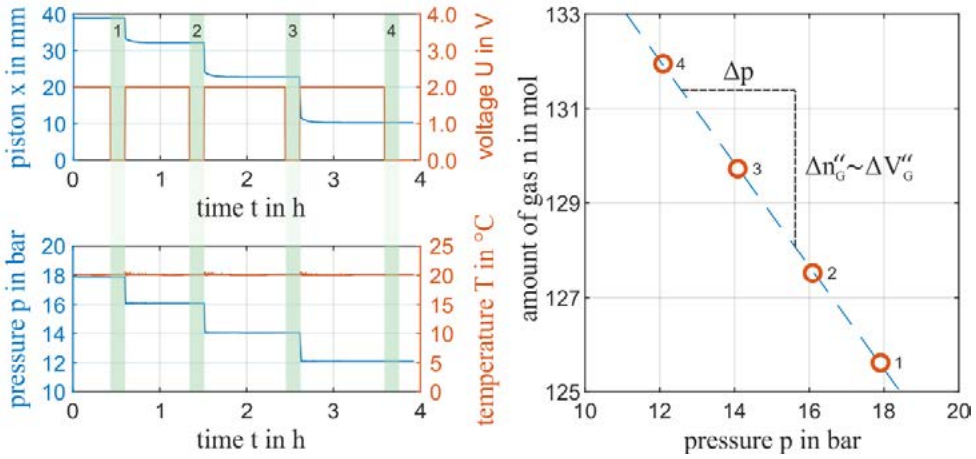

Figure 2.3. Example measurement trace showing the recorded signals

This procedure was repeated for three additional measurement points at 16, 14, and 12 bar. Using the mean values of the recorded quantities, a regression analysis based on equation (2.5) can be performed, as illustrated in the right panel in Figure 1. The slope of the resulting dashed line corresponds to the Bunsen coefficient at the given temperature of 20 °C.

To maintain a constant temperature level, a heat exchanger is mounted on the cylinder. The heat exchanger is connected to a tempering unit controlled by the measuring computer. With help of the temperature signals a closed control loop is feasible. The utilized material for the heat exchanger allows operating temperatures between -20 and +80 °C. In combination with the stepper motor, the described temperature control allows the automated measurement of pressure/temperature maps up to 400 bar. The lower pressure limit is primarily constrained by the vapour pressure of the investigated liquid; in principle, pressures below ambient conditions are attainable.

2.4. Indirect determination of gas solubility for flammable and hazardeous liquid/fuel combinations

The handling of certain mixtures of technical fluids and gases involves significant safety risks. Fuels, as well as hydraulic oils and other lubricants, can ignite upon contact with oxygen. In the context of carbon-free combustion, gaseous fuels such as hydrogen and ammonia, which can be dissolved in considerable amounts in the engine oil of internal combustion engines, are becoming increasingly relevant. In the case of hydrogen, there is a high risk of explosion due to its strong reactivity, whereas ammonia poses serious environmental and health hazards at elevated concentrations. To determine the Bunsen coefficient of such mixtures safely, an indirect measurement method was developed. [3]

Whether a potentially explosive mixture ignites depends on the composition of the gaseous phase. This relationship is illustrated in **Figure 2.4** for a hypothetical ternary system. The a-axis represents the volumetric fraction of vaporized oil or fuel in the gas phase, while the b- and c-axes indicate the respective fractions of nitrogen and oxygen. Mixtures located within the yellow explosion region can potentially ignite.

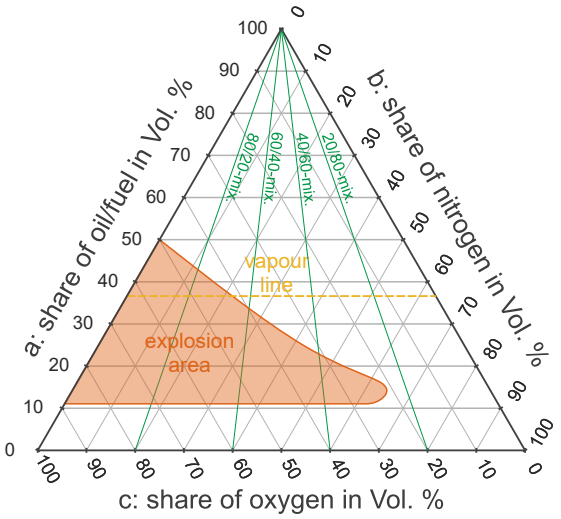

Figure 2.4. flammability diagram for hypothetical oil(fuel)/gas mixture

To estimate the explosion risk of a specific oil or fuel, the molar fraction x_i of the vaporized liquid in the gas phase is calculated according to Raoult's and Henry's law. According to equation (2.8), the molar fraction can be expressed as a function of the total pressure p and the vapor pressure p_i of the liquid.

$$p_{vap} = p \cdot x_i \iff x_{vap} = \frac{p_{vap}}{p} \tag{2.8}$$

Assuming an ideal gas behavior, the molar fraction x_i is equal to the volumetric fraction, and the vapor line (orange) can be plotted in Figure 2.4. For low pressures the volumetric fraction of the vapor increases, while at higher pressures it decreases.

The ratio of the remaining gases, oxygen and nitrogen, is indicated by the green lines in Figure 2.4 and corresponds to the original composition of the gas phase during the filling of the test bench. For an N_2/O_2 ratio of 20/80, the intersection with the vapor line falls within the explosion region. Increasing the fraction of nitrogen shifts the intersection to the right, so that, for example, for synthetic air (N_2/O_2 = 80/20) it lies outside the explosion region. By adjusting the composition of the gas phase in the cylinder, the risk of explosion can thus be eliminated. Similarly, this approach can be used to reduce the toxicity of hazardous gases such as ammonia by mixing them with inert gases.

With the presence of a gas mixture, the Bunsen coefficient of the individual pure components can no longer be determined directly using the method described in Section 2.3. Instead, the Bunsen coefficient of the mixture α_{mix} can be evaluated, based on the individual Bunsen coefficients of the constituent gases and their respective molar fractions (2.9).

$$\alpha_{mix} = \alpha_{N2} \cdot x_{N2} + \alpha_{O2} \cdot x_{O2} \iff \alpha_{O2} = \frac{\alpha_{mix} - \alpha_{N2} \cdot x_{N2}}{x_{O2}} \tag{2.9}$$

By rearranging (2.9), the Bunsen coefficient of oxygen α_{O2} can be determined for the example illustrated in Figure 2.4, based on the corresponding values of the mixture and of pure nitrogen ($\alpha_{mix}, \alpha_{O2}$).

3. RESULTS AND DISCUSSION

Measurements were carried out for hydraulic oil. The results for the temperature and pressure dependent Bunsen coefficient of a HLP 46 oil and nitrogen are shown in **Figure 3.1** [11]. The Bunsen coefficient was determined for pressures between 150 and 350 bar and temperatures ranging from 273.15 K to 323.15 K. The pressure was varied in 50 bar increments and the temperature in increments of 25 K. For each temperature and pressure step two measurements were conducted. The shown results correspond to the mean value obtained for all sensor signals recorded over a duration on 10 minutes with a frequency of 1 Hz. The left panel shows the Bunsen coefficient as a function of pressure, while the right panel illustrates the effect of temperature on gas solubility. The dashed lines indicate model data obtained from a regression analysis. The underlying equations of the analysis will be described later. The measured values for an identical measuring point in some cases differ greatly from one another. This deviation is particularly large for high pressures and low temperatures. Here, the measured Bunsen coefficient for identical boundary conditions differs by a value of 0.005.

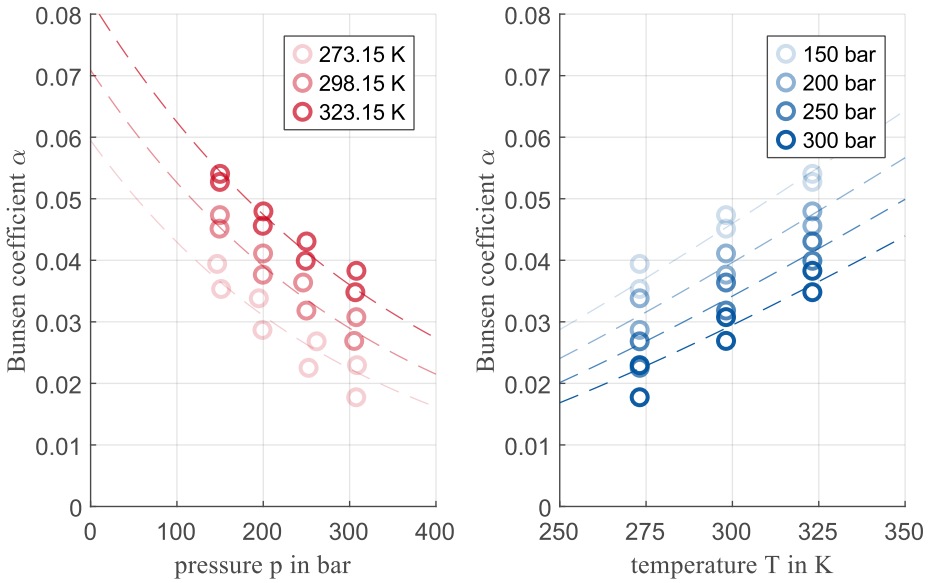

Figure 3.1. Bunsen coefficient of HLP 46 and nitrogen

As can be seen, the Bunsen coefficient decreases for rising pressure values. This trend is consistent with the behavior that emerges from the Krichevsky-Kasarnovsky equation (3.1) for positive values of the partial molar volume ΔV_{solv}. [12]

$$\alpha(p,T) = \alpha(p_0,T) \cdot \exp\left[-\frac{\Delta V_{solv}}{RT}(p - p_S)\right] \tag{3.1}$$

The dependence of gas solubility on temperature can be described using the Henry–Van't Hoff relationship in equation (3.2). According to this, gas solubility follows an exponential curve. For a positive solution enthalpy ΔH_{solv}, increasing solubility is to be expected at rising temperatures, which is also reflected in the experiment. [13]

$$\alpha(p_0, T) = \alpha(p_0, T_0) \cdot \exp\left[\frac{\Delta H_{solv}}{R}\left(\frac{1}{T_S} - \frac{1}{T}\right)\right] \tag{3.2}$$

The nearly proportional relationship between gas solubility and temperature can be explained by the small temperature changes, where the exponential relationship from equation (3.2) can be simplified by a Taylor series expansion and approximately corresponds to the linear expression from (3.3).

$$\alpha(p_0, T) \approx \alpha(p_0, T_0) \cdot \left[1 - \frac{\Delta H_{solv}}{R{T_S}^2}(T - T_S)\right] \tag{3.3}$$

Based on the Krichevsky-Kasarnovsky equation and the Henry–Van't Hoff relationship a regression analysis was performed using a trust-region-reflective algorithm to minimize the sum of squared residuals while accounting for parameter bounds. The derived values for ΔV_{solv}, ΔH_{solv} and $\alpha(p_0, T_0)$ are listed in **Table 3.1** together with the corresponding goodness-of-fit criteria ($R^2, {R^2}_{adj.}, SSE$). Here, the coefficient of determination R^2 quantifies the proportion of variance in the dependent variable that is explained by the model. The adjusted coefficient of determination ${R^2}_{adj.}$ accounts for the number of model parameters and penalizes overfitting. The sum of squared errors (SSE) represents the cumulative squared deviation between observed and predicted values and serves as an absolute measure of the model's residual error. Even though the values for identical measurement points in some cases diverge significantly, the high values for R^2 and ${R^2}_{adj.}$ and low values for SSE indicate that the measurement method is capable of representing the underlying physical laws that determine the pressure- and temperature-dependent gas solubility of oils.

Thermodynamic measures		Goodness-of-fit criteria	
$\alpha(p_0, T_0)$	0.0709	R^2	0.952
ΔV_{solv}	$7.3955\ \frac{m^3}{mol}$	${R^2}_{adj.}$	0.947
ΔH_{solv}	$4756.1\ \frac{J}{mol}$	SSE	$1.015e-4$

Table 3.1 Thermodynamic measures and goodness-of-fit criteria for HLP 46

Since the recorded measurement signals− and consequently the calculated Bunsen coefficient−showed only minor deviations for a single measuring point, the corresponding error bars are not visible in Figure 3.1. Therefore, a detailed analysis of the recorded sensor signals was conducted, as shown in **Figure 3.2**.

The results are shown in Figure 3.2 in the form of box plots, illustrating the deviations from the respective mean value of each measurement. It can be observed that, for the pressure, both the lower and upper quartiles lie within a band of at least ±0.5 bar, indicating a low

pressure variability. Furthermore, the median is located close to the mean value, suggesting a symmetric and evenly distributed temperature signal. The observed deviations can be primarily attributed to uniform noise in the measurement signal, with external influences exerting negligible impact.

For the temperature measurements, the boxes indicate greater variability in both magnitude and position relative to the mean. Nevertheless, the overall deviations are minor, with both the lower and upper quartiles confined to a range of approximately ±0.05 °C.

Deviations in piston position are also minimal, on the order of a few hundredths of a millimeter. Notably, the median consistently lies above the mean value across all measurements, suggesting the presence of a systematic error. Additionally, two individual data points exhibit larger deviations.

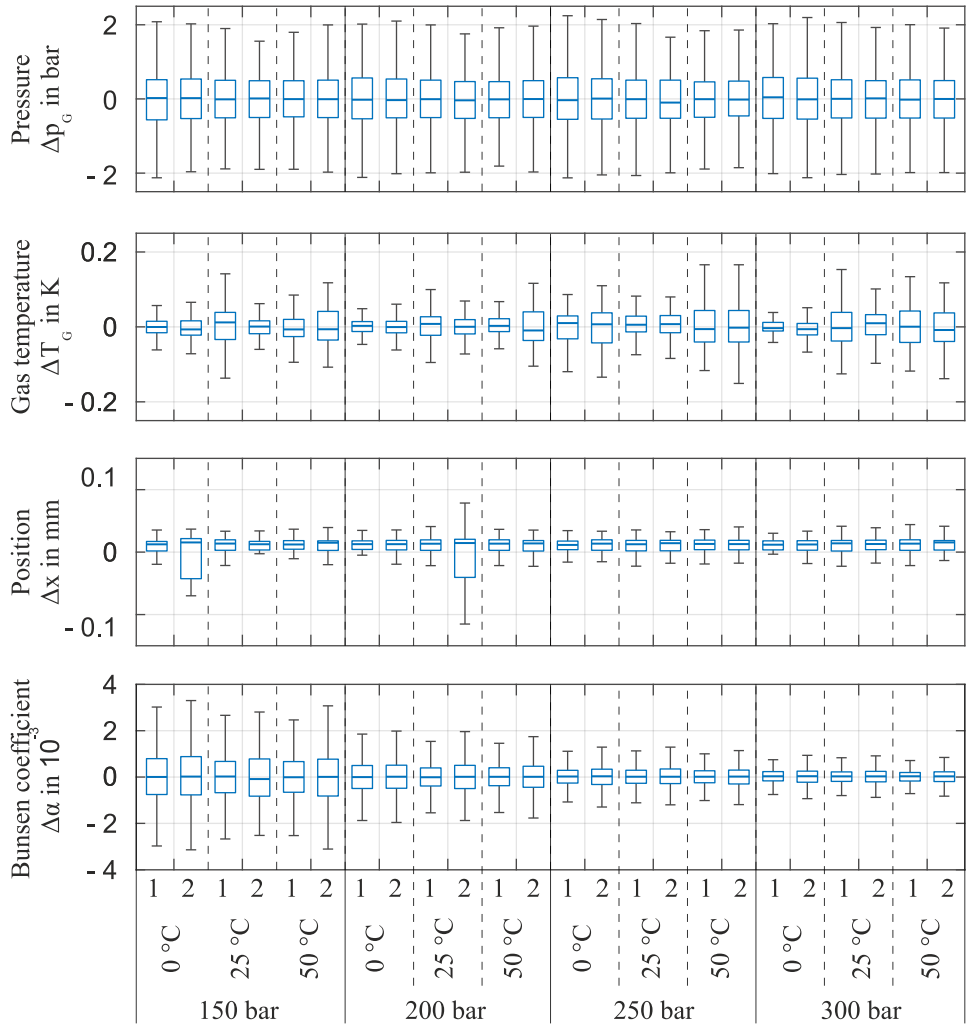

Figure 3.2. Statistical deviations of the sensor signals (gas temperature T_G, pressure p_G, and position x) and the resulting deviations of the Bunsen coefficient α.

Despite the asymmetries observed in the temperature and position data, the Bunsen coefficient demonstrates a uniform distribution around the mean. The bounds of the upper and lower quartiles remain within a narrow range of ±0.001. It is, however, evident that the coefficient values at lower pressures exhibit greater scatter compared to those at higher pressures, whereas temperature appears to have no significant influence on the variation. Consequently, the discrepancies between the two measurement series from Figure 3.1 are unlikely to result from measurement errors. A more plausible explanation is that improper filling of the test rig led to inaccurate assumptions regarding the volumes of liquid and gas and therefore to small deviations between both measurement series.

Since the composition of hydraulic oils is widely unknown, validation with literature data is difficult. The exact composition of the investigated oil is also unknown, so that no calculation of the Bunsen coefficient based on data for pure liquids is possible. However, it can be assumed that HLP oils consist of a mixture of paraffins, naphthenes, and aromatics, allowing for a comprehensive plausibility check [14]. Gas solubility data for the named molecule groups were transferred to the Bunsen coefficient using the interrelations from Table 2.1 and assembled in Figure 3.3 [15]. As can be seen, for most listed hydrocarbons the ability to dissolve nitrogen decreases increasing number of C-atoms. The Bunsen coefficient of the investigated HLP oil is lower than for all n-Alkanes with number of C-atoms lower than 20 and all other hydrocarbons listed. Given that mineral oil-based hydraulic oils within this viscosity class can contain hydrocarbons ranging between 15 and 50 C-atoms, the measured value of 0.0709 seems plausible [16].

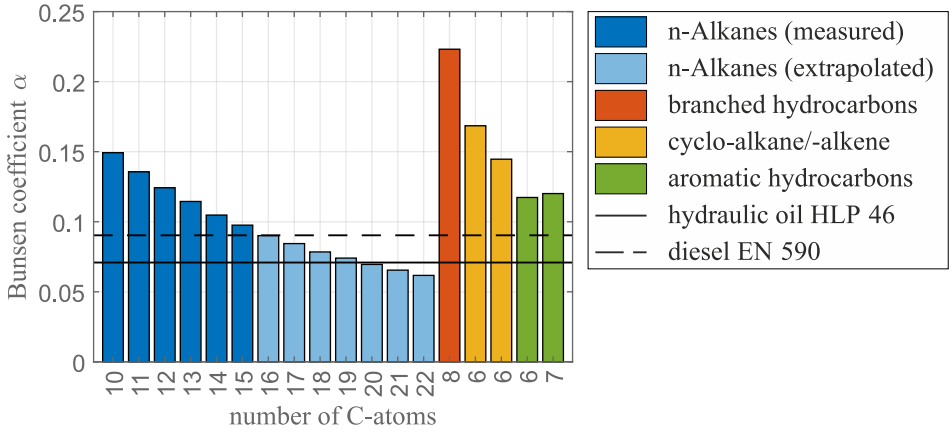

Figure 3.3. Comparison of literature data for the Bunsen coefficient of different hydrocarbons and nitrogen [15]

In a previous study, diesel EN 590 was examined and a Bunsen coefficient of 0.903 was determined [17]. Given that the gas solubility of the hydrocarbons considered decreases with increasing number of C-atoms, the lower values for the comparatively long-chain HLP 46 (Diesel: C13 - C18) are plausible, too [18].

Of particular interest for hydraulic systems is the amount of gas that can be released during operation, as cavitation may damage components and the fluid mechanical properties of the oil can be affected by undissolved gas.

Using the parameters from Table 3.1 and Equations 3.1–3.2, the volume of dissolved gas at standard conditions per unit volume of oil was calculated for pressures and temperatures typical of hydraulic applications. **Figure 3.4** shows that, at high pressures and temperatures, theoretically large amounts of nitrogen can dissolve. For instance, at 400 bar and 80 °C, the gas volume reaches nearly 14 times the oil volume. However, under such extreme conditions, achieving equilibrium is highly unlikely because dissolution processes are slow and gas may immediately re-release at ambient pressure in the tank.

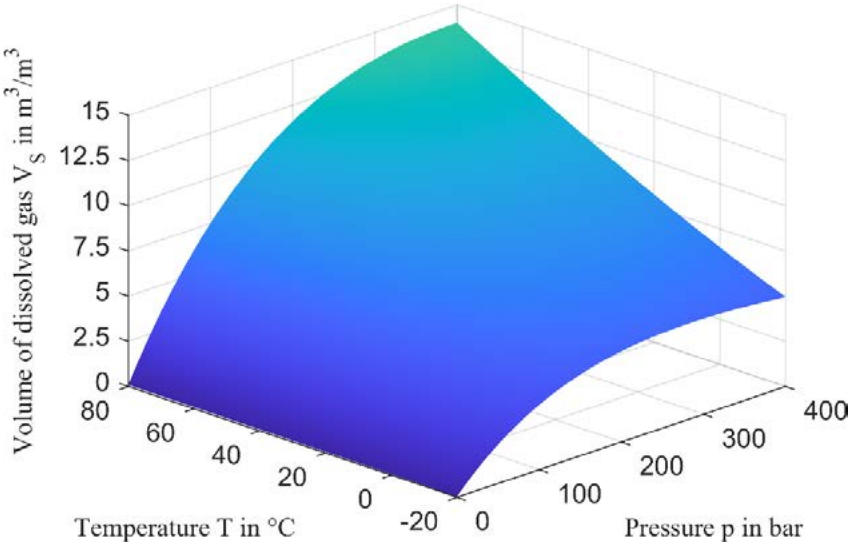

Figure 3.4. Volume of dissolved nitrogen at standard conditions per unit volume of oil

For practical hydraulic operation, the amount of gas that can dissolve under tank pressure and temperature is more relevant. Assuming a system operating at 40 °C and tank pressure equal to ambient, approximately 7.77 % of the oil volume could be saturated with gas. If the pressure drops by 0.1 bar, as might occur in a suction line, the dissolved gas fraction would decrease to 6.99 %, corresponding to about 0.78 % of the oil volume forming bubbles.

Gas release can also be triggered by temperature changes. For example, consider a mobile hydraulic machine operating with a tank temperature of 50 °C. During operation, the oil has sufficient time to reach saturation under these conditions. If the machine is then stored outdoors at −20 °C, and assuming released bubbles remain trapped within pipes, cylinders, or pump housings, the gas volume would occupy approximately 3.18 % of the oil volume after cooling to ambient temperature.

These examples demonstrate that, under normal operating conditions, only a small fraction of the maximum solubility of hydraulic oils is realized. Nevertheless, both operational and standstill conditions can lead to the release of relative gas volumes of a few percent of the oil volume, which may still be significant for system performance. It should be noted that these estimations are based solely on nitrogen values. Accurate determination would require the Bunsen coefficient for oxygen; however, since air consists predominantly of nitrogen, the results are considered to be of the correct order of magnitude.

4. SUMMARY AND OUTLOOK

In this study, a measurement principle for determining the gas solubility of technical liquids was presented, and pressure- and temperature-dependent results for a hydraulic oil (HLP 46) were discussed. Although a direct validation of the results using literature data is challenging, the obtained values were found to be plausible and in good agreement with the underlying thermodynamic models. The obtained gas solubility values indicate that, during hydraulic system operation, dissolved gas can occupy a few percent of the oil volume, potentially causing cavitation and altering the fluid properties of the oil.

In future work, additional oils will be investigated to analyze the influence of oil composition and additives on gas solubility in more detail. Of particular relevance is the study of the solubility behavior of alternative gaseous fuels such as hydrogen and ammonia in engine oils. Understanding how much of these gases can be dissolved, how much may be released to the environment, and how the dissolved gases affect oil degradation is essential for safe and efficient engine operation. Within the framework of the Excellence Cluster *The Fuel Science Center*, a simulation model is currently being developed to describe gas diffusion within the lubricating film between piston ring and cylinder wall. The required material data will be determined experimentally using the measurement method presented in this work.

Abstract.

Additive manufacturing (AM) of metals enables lightweight, customizable, and high-performance components, with maraging steel (MS1) being widely used for its strength and hardness. While much research exists on AM steels' microstructure and processing, limited studies address their tribological behavior, especially under lubrication. This study investigated the sliding performance of 3D-printed MS1 against aluminium alloys (EN AW 6082) for water hydraulics applications. Aluminium alloy, despite its low hardness, offers advantages in weight reduction and conductivity, and its performance can be improved by surface treatments such as anodization. Reciprocal sliding tests were conducted demineralized water, comparing untreated, conventionally anodized, and hard-anodized aluminium alloy compared to conventional oil lubricated conditions and hardened steel (AISI 440C). Results showed that in oil, sliding speed had little effect, and conventional anodization improved aluminium's wear resistance to nearly match steel. In water, however, sliding speed significantly influenced wear: at low speeds, anodized aluminium performed comparably to steel, but at higher speeds, severe wear occurred for aluminium, even after anodization. The findings suggest aluminium alloys can be potential counterparts to AM maraging steel in water-lubricated systems if sliding speed is carefully controlled.

1. INTRODUCTION

Additive manufacturing (AM) of various materials offers unique advantages over conventional manufacturing processes, such as flexibility in geometric design, rapid component production, and product customisation, while reducing product mass through optimised design or cellular structures. In the last decade, AM has reached a technological level suitable for manufacturing high-performance components, and it is predicted that the

All Open Access articles are peer-reviewed, distributed under the Creative Commons Attribution-Non Commercial 4.0 International

market will be worth nearly $60 billion by 2030 [1]. Although plastics hold the largest share of the AM market, 3D metal printing enables the production of high-performance, lightweight, and customised metal parts, while eliminating most traditional tooling by allowing integrated cooling channels, lattice structures, and internal features not possible with conventional machining. This approach is highly attractive for the aerospace, defence, robotics, and automotive industries, and also supports efficient material use, rapid prototyping, and replacement of damaged parts. Among the different powder-bed-based approaches for metal printing, selective laser melting (SLM) and selective laser sintering (SLS) are the most common [2]. Extensive fundamental research has been conducted on the microstructure of 3D-printed steel, printing parameters, heat treatments, porosity, manufacturing technology, and post-treatments [2–4]. AM has also been successfully used in hydraulics for manufacturing valves, manifolds, and pump parts [5–8].

There are various metal-based components made from pure metals, alloys, or metal matrices, such as 316L stainless steel, titanium Ti-6Al-4V, aluminium Al 6061, ALSi10MG, Inconel, cobalt-chrome, or maraging steel [1, 2]. There is limited experimental data on the specific wear and friction properties of these materials. Tribological sliding tests are typically conducted under dry conditions, against different steels, carbide, or ceramic counterparts, at room or elevated temperatures. There are fewer studies on the behaviour of these 3D-printed steels under lubricated conditions. Stainless SLM steel 316L has been tested in hydraulic oil compared to brass or nitrided steel, where grinding and polishing [9] and brass counterpart [10] have been suggested for improved performance of SLM steel. Recently, the cavitation erosion resistance of AM materials was found to be lower than that of conventionally produced steel at the beginning of the test [11]. Maraging steel (MS1), also known as 18Ni-300 (1.2709) maraging steel, is a martensitic iron-nickel alloy with low carbon content that has been widely used due to its high yield strength, tensile strength, and hardness, especially in automotive, aerospace, and tooling applications, where high wear resistance is expected. However, most studies focus on microstructure, microhardness, tensile, and impact properties [3, 12–15]. Recently, conventionally and laser bed fusion fabricated MS1 were compared under different normal loads (5–35 N), sliding speeds (1–5 Hz), and temperatures (30–125 °C), but were tested under dry conditions [16] emphasising the importance of testing under specific real-time application conditions. Another study suggested comparable wear but superior corrosion resistance of additively manufactured MS1 components compared to conventional MS1 [17]. In particular, intercritical heat treatment was shown to enable better tribological properties of MS1 under dry conditions [14].

In our recent study, we analysed the tribological properties of 3D-printed maraging steel (MS1) in sliding contact with materials commonly used in hydraulics, particularly water hydraulics: nitrided steel AISI 440C, bronze, and aluminium alloy [18]. The aluminium alloy demonstrated results comparable to conventional nitrided steel and exhibited better wear performance than bronze under the tested conditions. Due to their low specific density, light weight, high thermal and electrical conductivity, and wide availability, aluminium and its alloys are among the most commonly used metals for reducing overall system weight and the energy required for production and operation [19]. However, their relatively low hardness and greater sensitivity to abrasive wear often limit their use to applications with low friction and lower loads. To improve surface hardness, treatments such as conventional or hard anodising, plasma electrolytic oxidation, and heat hardening are applied [20–23]. Hard anodising can produce oxide layers 25–150 μm thick, increasing surface hardness by

5–8 times [24]. The anodising process also affects corrosion resistance. Although aluminium alloys are widely used, their tribological behaviour is typically studied under dry or oil-lubricated conditions.

In this study, the aluminium alloy (EN AW 6082) was tested before and after both conventional and hard anodising in a reciprocal sliding test against 3D-printed maraging steel (MS1) in demineralised water at two different sliding speeds. For comparison, the same tests were also conducted in conventional hydraulic oil ISO VG 46, conventional HFC 46 lubricant, and with conventional nitrided AISI 440C steel. The results of the tribological tests were used to analyse the influence of the surface treatment of the aluminium alloy and the effect of sliding speed when sliding against MS1, to assess potential material pairs for efficient proportional valves designed for water hydraulics.

Common tribological test methods designed to reproduce simplified contact geometries and loading conditions in sliding interfaces include ball-on-disc (BoD), pin-on-disc (PoD), and cylinder-on-disc (CoD) configurations, often implemented in reciprocating sliding tests to simulate short-stroke motions. Standardized procedures such as ASTM G99 for pin-on-disc and ASTM G133 for linearly reciprocating tests (ISO 7148, ISO 6601-6605) are widely employed in both academic and industrial studies for comparative friction and wear analyses [25–27]. The ball-on-disc configuration provides a well-defined Hertzian point contact at relatively high local pressures, making it suitable for fundamental contact stress and lubricant behavior characterization, whereas the pin-on-disc test offers a more stable contact area and medium–low nominal pressures relevant to a broader range of engineering materials. Although a cylinder-on-disc or line contact test would more closely approximate the geometry, contact mechanics, and lubrication regime of a hydraulic valve spool within a valve body, there is no single fully standardized tribological test that exactly reproduces the quasi-line contact of spool/body interfaces. For this reason, we selected an established pin-on-disc setup, which ensures methodological rigor and comparability through well-defined standards, and provides effective material screening and ranking; this choice is complemented by consideration of reciprocating cylinder-on-disc testing when higher representativeness is required. A reciprocating pin-/cylinder-on-disc configuration therefore represents a practical compromise between the representativeness of the real valve contact and the experimental control necessary for reproducible and comparable tribological assessment of material pairs in proportional hydraulic valve spool–body contacts.

The simplified tribological test configuration provides an effective platform for preliminary material screening and is routinely employed within our research group for assessing novel materials, surface coatings, reinforcements, and finishing processes for hydraulic components [28, 29], as well as for evaluating new lubricant formulations [30]. Comparable methodologies have recently been applied to investigate the performance of various ceramic materials intended for water-lubricated axial piston pump friction pairs using ball-on-disc tests [31], and to examine the tribological behaviour of valve plate pairs through ring-on-block experiments [32]. Nevertheless, such laboratory-scale tests should be complemented by full-component experiments or simulations incorporating the selected material pairs to ensure realistic performance assessment. Extensive research on axial piston pumps has demonstrated the importance of validating numerical simulations with experimental data, particularly when integrating wear prediction, running-in behaviour, and

friction analyses following innovative component redesign [33, 34]. This combined approach enables a comprehensive evaluation of overall component efficiency [35].

2. METHODOLOGY

2.1. Sample preparation

An EOS M290 3D metal printer using the SLM (selective laser melting) method was employed for sample preparation, with a laser beam speed of 1010 mm/s, power of 305 W, and a powder layer thickness of 50 µm. The material was in powder form with spherical grains ranging from 15 to 45 µm. As the material is melted in specific areas, the high temperature of the laser beam also locally hardens it. The final product exhibits anisotropic properties due to the layer-by-layer manufacturing process, which are eliminated by subsequent heat treatment. For the tribological tests (Figure 1.) 3D printed discs (25 x 25 x 6 mm), made of maraging steel (MS1/1.2709 also known as 18Ni-300) were used, representing a hydraulic valve body. The disc samples were polished in several steps using a RotoForce-3 automatic sample polishing and preparation device, achieving a final roughness of 0.1 µm.

The pin samples (Φ 10 × 20 mm, with a 12.5 mm radius) were prepared from two different materials: aluminium alloy (EN AW 6082/3.2315) and commercially available standard hardened stainless steel (AISI 440-C/1.4125). The pin samples were polished using the same procedure as the MS1 discs. After polishing, the aluminium samples were anodised using the standard procedure and underwent hard anodization. The pin samples represented hydraulic valve spools.

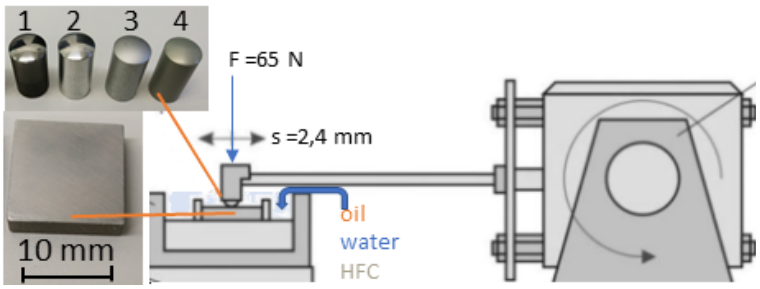

Figure 1. Experimental procedure: pins: 1- AISI 440-C; 2-Al 6082; 3-Al 6082 anodised; 4-Al 6082 hard anodised and disc - 3D printed MS1 at tribological tests set-up;

Materials microhardness was measured using a standard Vickers hardness tester, Leitz - Miniload 2, with an indentation force of 1.9 N (according to DIN 50133). However, with the measurement method employed, we were unable to measure the hardness of anodised aluminium samples successfully. Therefore, we assumed that the anodised samples had the hardness specified by the manufacturer. For soft anodised samples, this ranged from 200 to 250 HV. For hard anodised samples, it ranged from 500 to 600 HV. Before each test, the samples, clamps and pins were cleaned with ethanol and dried in air.

Table1. Mechanical properties of prepared samples

Material	Density [kg/m^3]	Young modulus [GPa]	Ultimate tensile strength [MPa]	Hardness [HV]
pin				
AISI 440-C	7.6	200	760-1960	~ 1330
Al 6082	2.7	70	260	~ 132
disc				
MS1	8-8.1	180	2080	~ 460

The first lubricant used was commonly available ISO VG46 hydraulic oil. The second lubricant was demineralised water (W). Additionally, commercially available HIDROL HFC 46 lubricant was tested. The selected HFC 46 is a water-glycol mixture (35–40% glycol content) with special additives that provide excellent corrosion protection. This lubricant contains no mineral oils, nitrites, PCBs, or phenols. The properties of the lubricants used were measured using an automatic viscometer, Anton Paar SVM 3001, and are presented in Table 2.

Table 2. Chemical properties od used lubricants

Lubricant	Density at 25°C [g/cm^3]	Density at 45°C [g/cm^3]	Kin. viscosity at 25°C [mm^2/s]	Kin. viscosity at 40°C [mm^2/s]
ISO VG46	0.86	0.84	100	41.4
Demin.water	0.997	0.99	0.89	0.66
Hidrol HFC 46	1.075	1.06	90	43

2.2. Experimental procedure

Tribological tests were conducted on a Cameron-Plint TE 77 high-frequency tribometer (Figure 1). During the test, the pin slides in a reciprocal mode on the 3D-printed disk-like plate. The average sliding velocity was set to two values: 0.05 m/s (corresponding to a frequency of 10 Hz) and 0.2 m/s (corresponding to a frequency of 40 Hz). The applied frequencies correspond to the dynamic opening and closing of the proportional spool valve. The maximum excitation frequency achievable with the tribometer was 40 Hz. The stroke length was 2.4 mm, representing the valve spool stroke in a CETOP 3 size 4/3-way slide valve. This value also represents the minimum stroke length available with the tribometer. The normal load was set to 65 N. Before each test, the pins and plate samples were fully immersed in the selected lubricant. During the tests, the current value of the friction coefficient was automatically recorded. The tests were conducted for 60 minutes, based on preliminary tests that showed a stable coefficient of friction and measurable wear. Each test (material and lubricant combination) was repeated three times, and the average values of the steady-state coefficient of friction were used for the comparative analysis.

2.3. Wear evaluation

After testing, the wear on the pins and wear tracks was analysed using a 3D digital microscope with a nano-point profilometer Hirox HRX-01 & NPS. The wear volume of the pins was calculated from the dimensions of the wear tracks. The 3D profile and dimensions of the wear calotte were determined with Mountain Map software [25]. The specific wear

rate was determined by dividing the measured wear volume by the product of the normal load and sliding distance. The surface films on the printed plates were also characterised for shape and size.

3. RESULTS AND DISCUSSION

3.1. Evolution of coefficient of friction

Figure 2 shows the evolution of measured coefficient of friction during individual tests of pin samples againts MS1 printed disks, in water and hydraulic oil at two different sliding frequences.

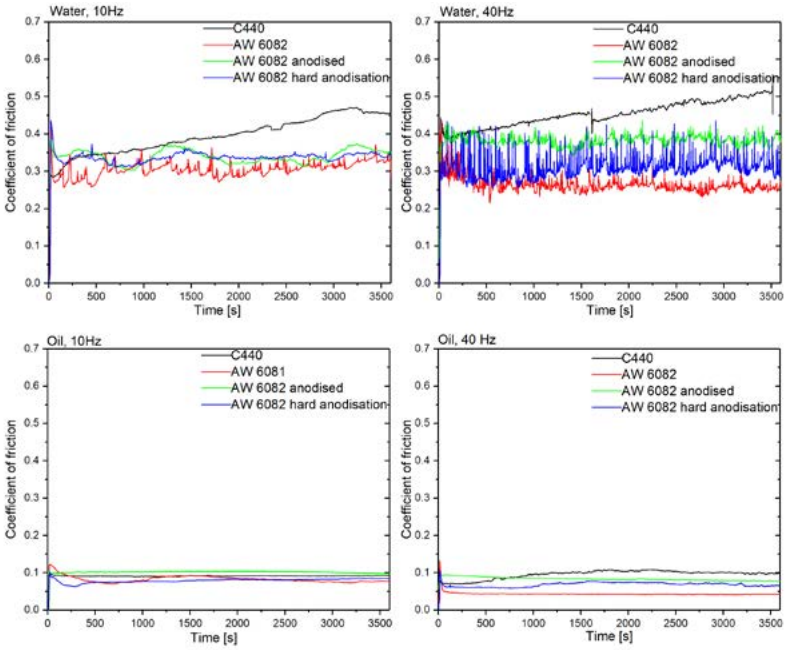

Figure 2. Evolution of the coefficient of friction during the reciprocal tests of of aluminium alloys pins against MS1 in water and hydraulic oil, at two different sliding speeds

The coefficient of friction measured in the water doesn't show typical running in, it rather has unusable value for all aluminium alloys. The fluctuations observed in case of water lubricated conditions indicate, that water incorporates some instabilities into the sliding contact. At lower frequency these instabilities are the most prominent for nature aluminium alloy, and tend to become smoothed after anodisation. At higher frequency these instabilities are simillar for nature alloy and standard anodisation, but more intense for hard anodized sample. In case of standard AISI 440-C these instabilities are not evident, although coefficient of friction is linearly increasing during the observed period of time at both frequences (up to 34 %) and has higher value compared to tested all aluminium alloys. If we compare these results to the measurements in ISO VG46 hydraulic oil, the coefficient of friction reaches a stable value almost immediately for all aluminium alloys similarly to AISI 440-C, at both frequencies (with in the first 2500 cycles).

3.2. Coefficient of friction

Figure 3 represents average values of measured steady coefficient of friction for all tested samples in both water and hydraulic oil, at both frequences.

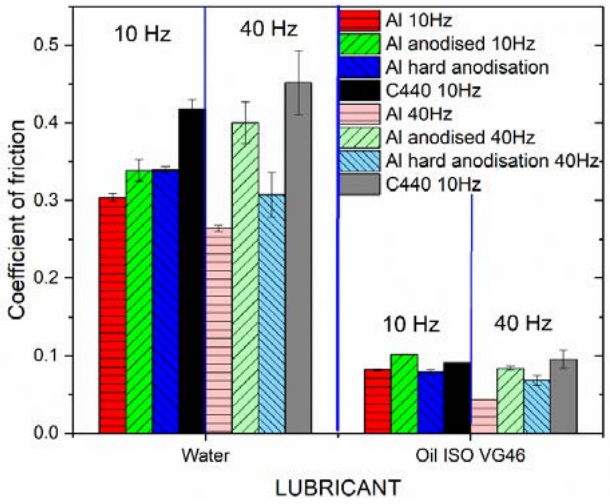

Figure 3. Average coefficient of friction during the reciprocal tests of aluminium alloys pins against MS1 in hydraulic oil and water at two different sliding speeds

When water was used as lubricant, at lower frequency, comperable values of coefficient of friction were measured for natrure aluminium alloy (around ~ 0.3), followed by anodised and hard anodised aluminium (~ 0.33), and considerably higher value was measured for AISI 440-C (~ 0.39). At higher frequency, nature and hard anodized aluminium alloy coefficient of friction even decresed (value around ~ 0.28 and 0.3 respectively). In water all aluminium alloys give good response compared to standard stainless steel, and from that point of view could be potentially good materials for water hydraulics. When we account for fluctuations in measured values seen in aluminium alloys, anodisation it is expected to enable smoother working conditions even in water.

Lower values of coefficient of friction were observed in hydraulic oil, for all tested samples compared to water lubricated conditions. The coefficient of friction decreased in oil around 4.5 times for all aluminium alloys and AISI 440-C, at both frequences. However even in oil, nature aluminium alloy showed lowest measured coefficient of fiction with values comparable to measured values for both anodised aluminium and AISI 440-C, all around ~ 0.09. At higher frequency, slight decrese was observed for nature aluminium alloy.

3.3. Specific wear

Based on repeated measurements in water and hydraulic oil at two sliding frequences, Figure 4 represents average values of calculated specific wear from analyzed pictures of wear tracs, of all tested pin samples for each material.

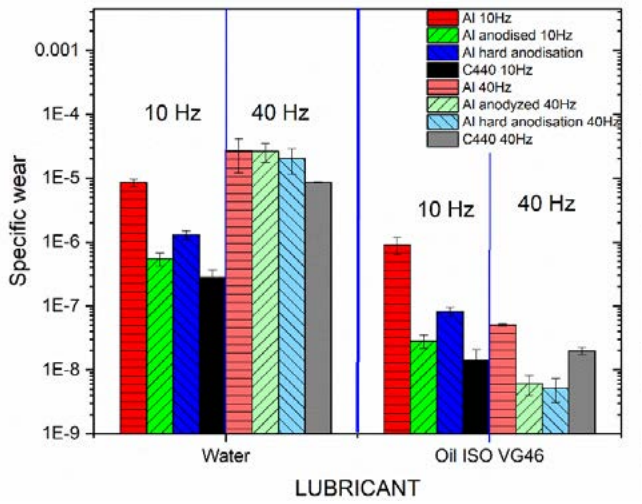

Figure 4. Average specific wear of aluminium alloys pins after sliding against MS1 in water and hydraulic oil, at two different sliding speeds

In water, the lowest measured specific wear was for AISI 440-C (~2.8 × 10^{-7} mm^3/Nm), fairly followed by anodised aluminium (~5.4×10^{-7} mm^3/Nm). Evidently anodization improved wear resistance of nature aluminium alloy (~ 8.6 × 10^{-8} mm^3/Nm), even comparted to hard anodization (~1.3 × 10^{-6} mm^3/Nm). However, at higher frequency difference between tested materials is lower. From all aluminium alloys (~2.3 × 10^{-5} mm^3/Nm) to AISI 440-C (~8.6 × 10^{-6} mm^3/Nm).

In hydraulic oil, we can see that both all aluminium alloys and AISI 440-C showed lower specific wear, compared to water lubricated conditions at both frequences. Smaller decrease was found at lower frequency (from 2 times for anodized aluminium up to 157 times for hard anodized aluminium alloy) compared to higher frequency (around 500 times for nature aluminium and AISI 440-C, up to around 4000 times for both anodized alloys). Again anodized aluminium alloy (~8.2 × 10^{-8} mm^3/Nm) fairly followed AISI 440-C (~1.4 × 10^{-8} mm^3/Nm) at lower frequency, with even better results at higher frequency (~6.1 × 10^{-9} mm^3/Nm and ~2 × 10^{-8} mm^3/Nm respectively).

Based on the measurements, we can conclude that the best results were accomplished by AISI 440-C followed by anodised aluminium, under harsh water lubricated conditions. In hydraulic oil, anodization improved aluminium properties to put it even in front of the AISI 440-C (for tested frequences and loads). Both anodization and hard anodization process improved tribological properties of nature aluminium alloy, however hard anodization did not significantly change properties compared to standard anodization, especially at lower frequences.

3.4. Comparison with HFC 46 as lubricant

The results of the same tribological tests in hidrol HFC 46, when nature aluminium and anodized aluminium alloy pins slide against MS1 at two different frequencies, are presented of Figure 5 and 6.

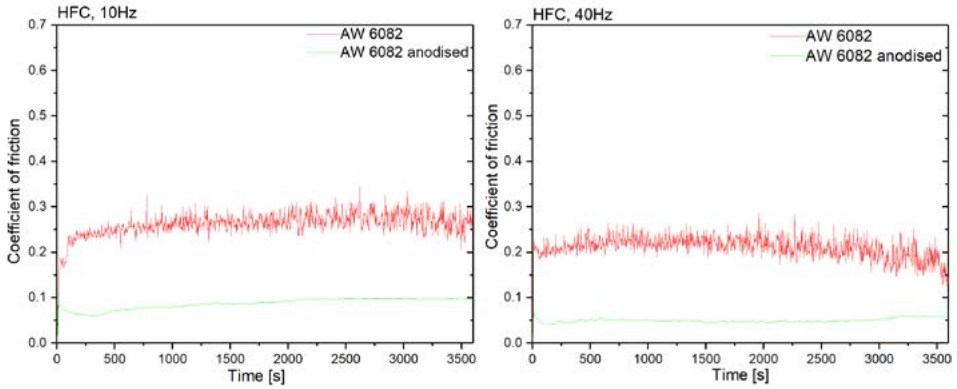

Figure 5. Evolution of the coefficient of friction during the reciprocal tests of aluminium alloys pins against MS1 at two different sliding speeds in HFC 46

From the results it is evident that anodization improves tribological properties of nature aluminium, and sliding frequency does not impact significantly measured properties (at sampled range 10 – 40 Hz). Measured coefficient of friction is smoother and more stable after anodization, at both frequencies (Figure 5), while average value of the coefficient of friction decreases 3.25 times at 10 Hz, up to 4.2 times at 40 Hz after anodization (Figure 6a). Specific wear also decreases after anodization, around 800 times at 10 Hz, up to 3000 times at higher frequency (Figure 6b). Specific wear of nature aluminium (~3.4 × 10^{-4} mm^3/Nm) is lower but not significantly affected by higher frequency (~2.4 × 10^{-4} mm^3/Nm).

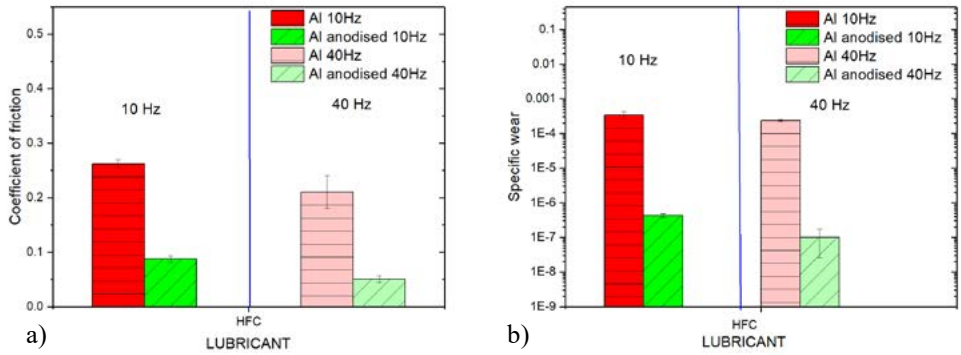

Figure 6. Average a) coefficient of friction b) specific wear of aluminium alloys pins after sliding against MS1 at two different sliding speeds in HFC 46

If we compare these results to the measurements in water and hydraulic oil, nature aluminium alloy responds similarly in water and HFC 46, with comparable values of coefficient of friction at both frequencies, and specific wear lower but comparable to the values in water. But after anodisation, measured coefficient of friction becomes comarable to the values measured in hydraulic oil, at both frequences. Also specific wear of anodised aluminum is one order (at 10 Hz) up to three orderes (at 40 Hz) lower compared to eater lubricated conditions, beeing cloaser to the values measured in hydraulic oil ISO VG46.

3.5. Surface analyses

After the tests, wear tracks of both pin and disc in sliding contact, were analyzed with digital microscope (Figure 7 and Figure 8). From the pictures it is clear, that the most significant wear and material removal area is evident in water at higher sliding speed, for all materials. Also, for the nature aluminium pins the stretches in the sliding direction are the most intensive at both sliding speeds, thick and prominent, suggesting abrasion as main wear mechanism.

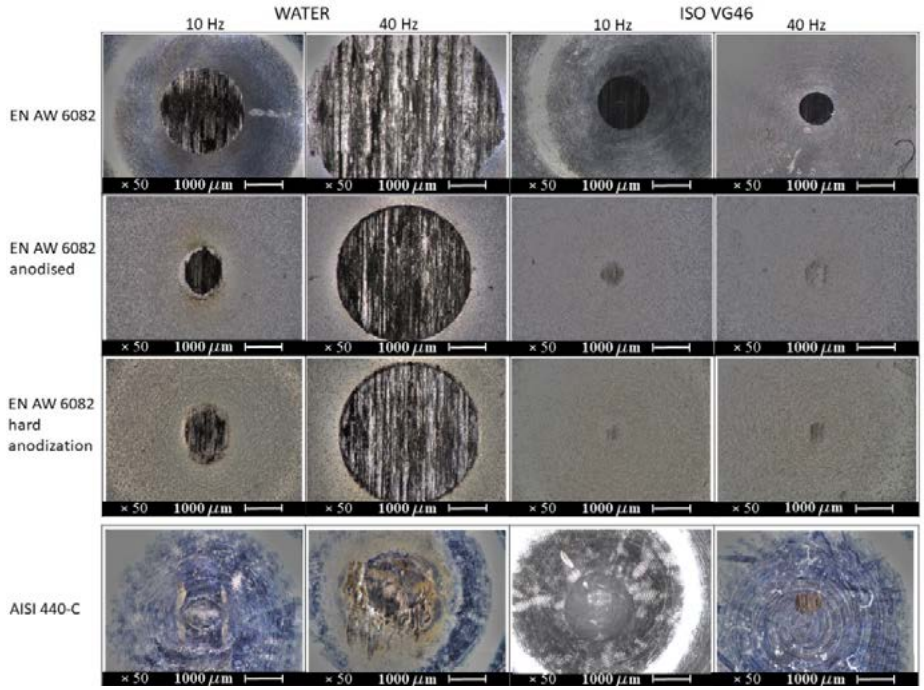

Figure 7. Digital micrographs of aluminium alloys pins after sliding against MS1 in water and hydraulic oil, at two different sliding speeds (magnification, ×50)

Aluminium alloy samples after both anodization and hard anodization suggest relatively smaller wear area, with area comparable to AISI 440-C, but different wear mechanism present. There were irregularities, that probably present peeled anodised protective layer in water, thus suggesting adhesive wear followed by two body abrasion. These adhesive debris and intensive delamination unevenly distributed over abrasive grooves were even more prominent at the four times higher sliding speed (increasing from 0.05 to 0.2 m/s). In case of AISI 440-C only some slight, rare unevenly distributed abrasive scratches were present.

The difference between nature and anodised aluminum is even more significant in hydraulic oil. Nature aluminum alloy shows stratches in sliding direction, less intense and thinner than in water, but comparable at both sliding speeds. In case of anodized and hard anodized aluminium in oil, only some irregular mocroploughings and pores are presents, even with smaller coverage area at higher sliding speed. These microplughings and microcracings are even less intense and with smaller coverage area in both anodized aluminium alloys comaperd to AISI 440-C.

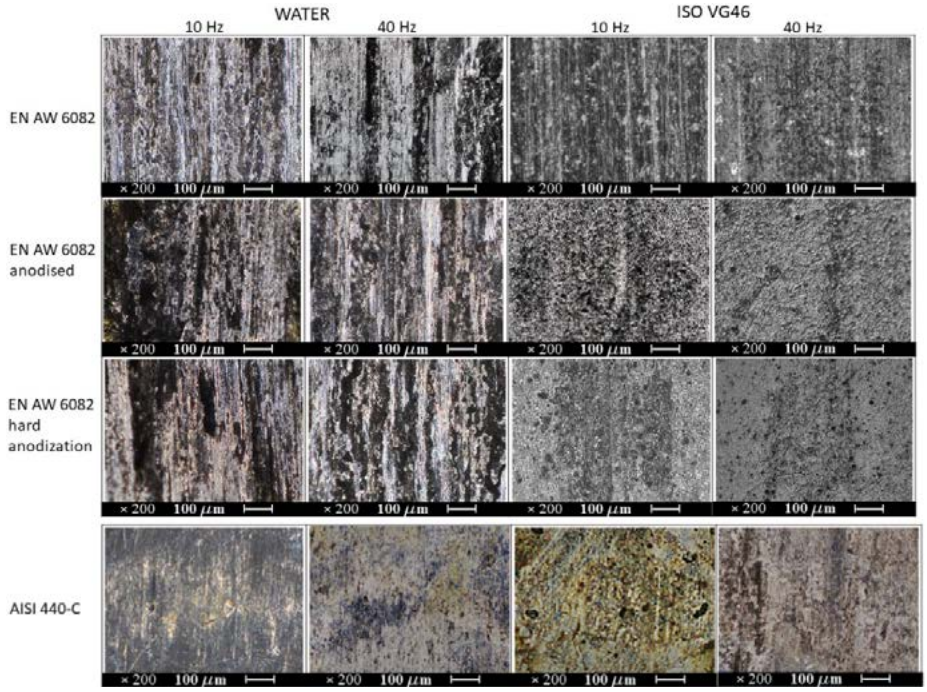

Figure 8. Digital micrographs of aluminium alloys pins after sliding against MS1 in water and hydraulic oil, at two different sliding speeds (magnification ×200)

The difference between nature and anodised aluminum is even more significant in HFC 46 (Figure 9), where the wear tracks of nature aluminum are comparable to the tracks seen in water at higher frequency. However, after anodisation wear track are comparable to the measurements in hydraulic oil, at both frequences. In case of nature aluminium alloy beside prominent intensive abrasive stratecs a lot of irregular embaded adhesive debris is pressent at both sliding speeds, with large wear area even compared to water lubricated conditions.

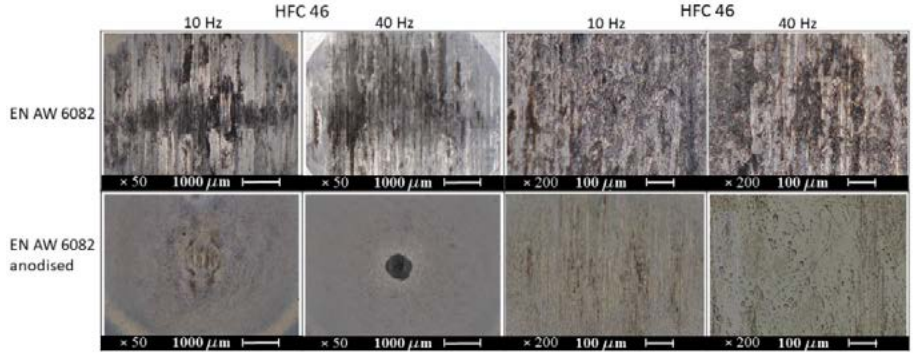

Figure 9. Digital micrographs of aluminium alloys pins after sliding against MS1 in HFC 46, at two different sliding speeds (magnification ×50 and ×200)

On contarry, in case of anodized aluminium alloy in HFC 46 relativelly small wear area was present at both slidin speeds, with some slight scratches at lower sliding speed and more

microplugings and pores at higher sliding speed. However all observed material changes are comparable to the wear tracks seen in case of hydraulic oil (Figure 7 - 8).

After the tribological tests the surfaces of MS1 discs were also analysed (Figure 10 - 12). The anodization (both standard and hard) improved tribological properties, and decreased contact area compared to nature aluminium, the effect is even greater in oil at both sliding frequencies (Figure 10).

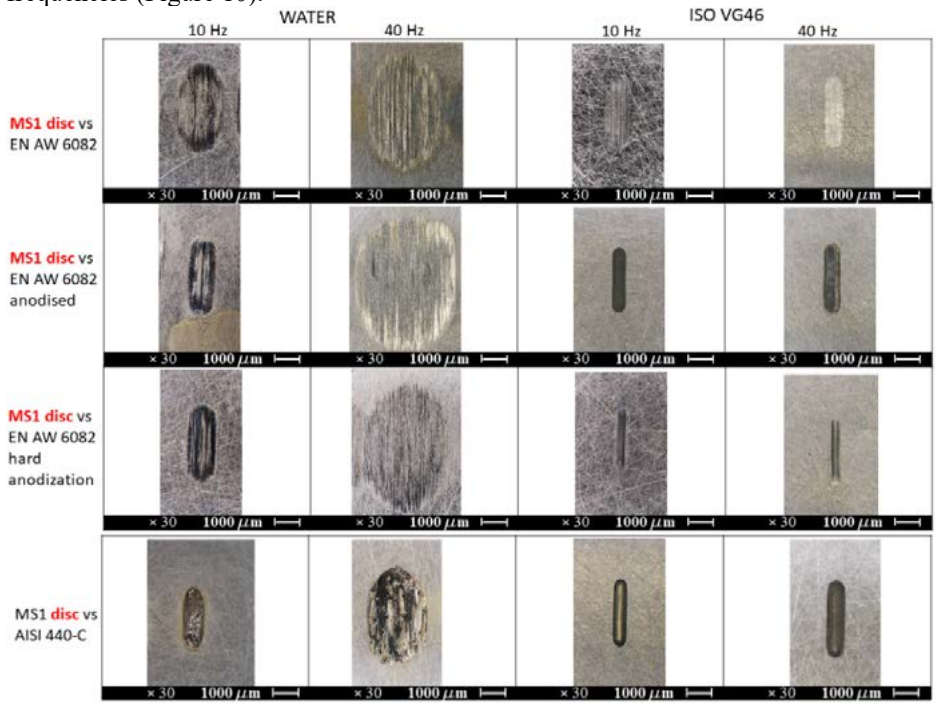

Figure 10. Digital micrographs of MS1 discs after sliding against aluminium alloys pins in water and hydraulic oil, at two different sliding speeds (magnification ×30)

The wear track widths at the lower sliding speed were generally comparable across most materials (~1070–1400 µm), with the exception of natural aluminium, with significantly wider track (~2300 µm) However, at higher sliding speed in water wear tracks become more prominent and intense for all tested materials *(~3500 µm)*. Under oil lubrication, the narrowest wear tracks were produced by hard-anodized aluminium pins at both sliding speeds (~350–450 µm). These were followed by C440 and conventionally anodized aluminium pins, which generated wear tracks of roughly 600–800 µm. In contrast, natural aluminium pins produced wider tracks, reaching ~1300 µm. The impact of higher sliding speed on MS1, is not significant in oil.

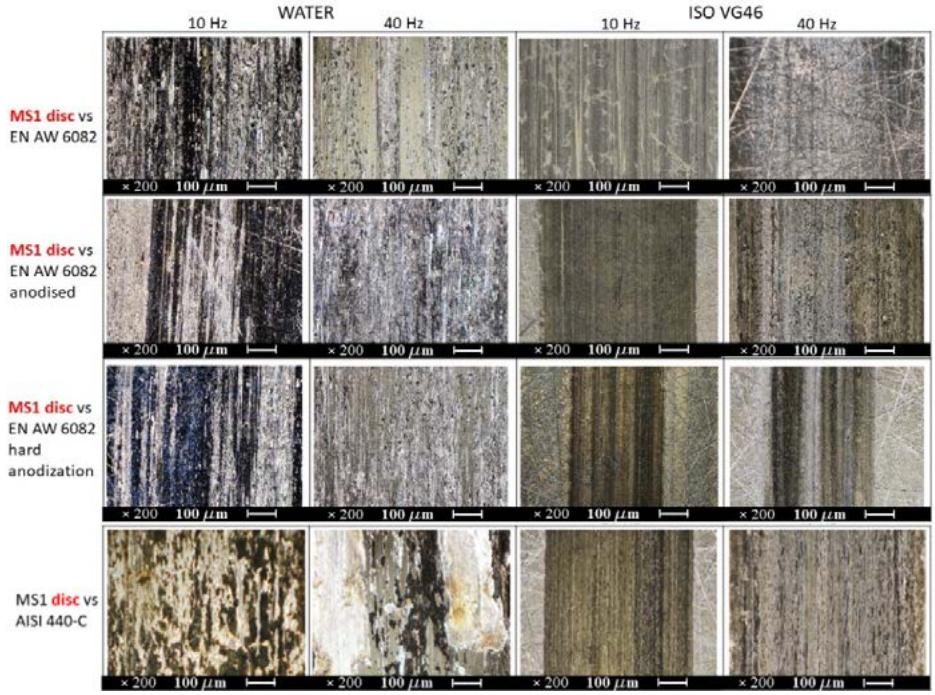

Figure 11. Digital micrographs of MS1 discs after sliding against aluminium alloys pins in water and hydraulic oil, at two different sliding speeds (magnification ×200)

At higher magnification (Figure 11) scratches and micro ploughing in sliding direction can be observed in all aluminium alloys in both water and hydraulic oil. Only the density and track width is much lower after anodization. In case of AISI 440C steel, intense delamination and adhesion is present especially at higher sliding speed. In case of HFC 46 (Figure 12), scratches are present in sliding direction, however the most significant difference is in the coverage area of the wear track between nature and anodized aluminium alloy.

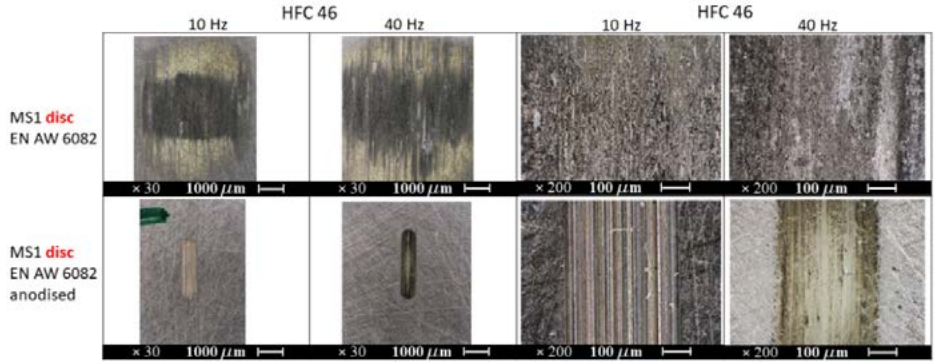

Figure 12. Digital micrographs of MS1 discs after sliding against aluminium alloys pins in HFC, at two different sliding speeds (magnification ×30, ×200)

4. CONCLUSIONS

In this study, the tribological properties of 3D-printed maraging steel were tested and analysed after sliding against three different versions of aluminium alloy AW 6082 at two different sliding speeds. The tests were conducted in water and compared to standard testing conditions in hydraulic oil ISO VG 46, as well as to sliding against the typical material used in hydraulic valves, nitride AISI 440C. A partial comparison was also made to the commercial water based lubricantHFC 46. The results of the tribological tests were used to analyse the influence of the surface treatment of the aluminium alloy and the effect of sliding speed when sliding against MS1, for potential material pairs in water hydraulics.

Sliding speed had no significant effect on the tribological performance of the tested materials in oil. Conventional anodization notably enhanced the surface properties of the aluminium alloy, achieving values comparable to those of AISI 440C steel. In contrast, under water lubrication, sliding speed emerged as a critical factor. At lower speeds, anodization substantially improved the specific wear resistance of the aluminium alloy, yielding results similar to those observed in steel. However, at higher sliding speeds, severe wear occurred on all aluminium specimens, although anodized samples still exhibited better performance than untreated ones.

The coefficient of friction in water was generally lower for the aluminium alloys compared to AISI 440C steel. While anodization did not significantly reduce the friction coefficient, it effectively stabilized the frictional response, producing smoother curves and more consistent sliding behaviour at both speeds.

Overall, the findings suggest that anodized aluminium alloys can be effectively employed in sliding contact with maraging steel, even under pure water lubrication, provided that the operational sliding speed is carefully controlled. Preliminary tests conducted in HFC 46 fluid further indicate that anodized aluminium in contact with MS1 steel demonstrates tribological performance comparable to that in hydraulic oil. This material pairing therefore holds promise for applications in standard hydraulic systems, offering a potential lightweight alternative to conventional steel components.

Ana Trajkovski received the PhD in Mechanical Engineering from University of Ljubljana in 2015. She is currently working as teaching assistant at the Department of Tribology and maintenance systems, Laboratory for Fluid Power and Controls, Faculty of Mechanical Engineering, University of Ljubljana. Her research areas include inovative materials and lubricants for sustainable hydraulics, smart control design and optimization of hydraulic components, water hydraulics. She has written many scientific papers and collaborated in many national and international conferences and research projects.

Jan Bartolj received the M.Sc. degree in Mechanical Engineering from University of Ljubljana in 2024. He is currently working as teaching assistant at the Department of Tribology and maintenance systems, Laboratory for Fluid Power and Controls, Faculty of Mechanical Engineering, University of Ljubljana. His research areas include optimisation of hydraulic components, additive manufacturing in hydraulics and water hydraulics.

Nejc Novak received the PhD in Mechanical Engineering from University of Ljubljana in 2025. He is currently working as researcher at the Department of Tribology and maintenance systems, Laboratory for Fluid Power and Controls, Faculty of Mechanical Engineering, University of Ljubljana. His research areas include analyses of hydraulic components wear mechanisms and lifetime, hydraulic fluid properties and filtration.

Jan Pustavrh received the M.Sc. in Mechanical Engineering from University of Ljubljana in 2022. He is currently working as researcher at the Department of Tribology and maintenance systems, Laboratory for Fluid Power and Controls, Faculty of Mechanical Engineering, University of Ljubljana. His research areas include design and control of multi-axis servo hydraulic systems, smart control and design of hydraulic components.

Mitjan Kalin is full professor and the head of the Department of Tribology and maintenance systems, at the Faculty of Mechanical Engineering, University of Ljubljana. He has written more than 200 international peer-review papers, gave more than 80 invited lectures at international conferences and is project leader of more than 50 major projects. His main

research areas are in wear and friction mechanisms of advanced materials, green lubrication technologies and nanoscale interface phenomena. In particular, he is recognised in academia and industry as a pioneer in boundary lubrication and tribochemistry of diamond-like carbon (DLC) coatings. Prof. Dr. Kalin was elected as a member of Slovenian Academy of Engineering, a Member of the International Academy of Engineering, and in 2024 to European academy of science and arts. He received a 2025 ASME Mayo D. Hersey Award, one of the highest academic recognitions in tribology.

Franc Majdič received the PhD in Mechanical Engineering from University of Ljubljana in 2010. Hi is currently working as assoc. professor at the Department of Tribology and maintenance systems, at the Faculty of Mechanical Engineering, University of Ljubljana and is the head of the Laboratory of Fluid power and controls. His research areas include water hydraulics, hydraulic components development and testing. He has written many scientific papers and collaborated in many international conferences. He is a project leader of more than 50 industrial and research projects and collaborated in several industrial patents.

Performance evaluation of a wear test rig for positive displacement pumps

Pascal Moor[1], Maximilian M. G. Kuhr[1], Christopher Albrecht[2], Peter F. Pelz[1]

[1] Chair of Fluid Systems – TU Darmstadt, pascal.moor@tu-darmstadt.de

Abstract.

The operation with abrasive particles is not recommended for most types of rotating displacement pumps. For these pumps, the scientific knowledge of the wear behaviour and the influence of the many parameters on the wear behaviour is sparse. This is especially true for multi-screw pumps. Therefore, the chair of fluid systems has developed a test rig for scientific research of the wear in rotating displacement pumps with a focus on repeatability of the test parameters. The practical challenges in achieving such a setup and the results of the commissioning of the test rig are shared in this paper in order to aid likeminded researchers in their development of a suitable test setup.

Keywords. wear, abrasion, test rig, displacement pumps, screw pumps.

1. INTRODUCTION

In order to cater to the industrial markets and remain relevant within globally competitive markets, component and system manufacturers need to meet all three dimensions of quality to their customers satisfaction, namely effort, availability and acceptability [1]. If the manufacturers fail to do so, they lose the ability to develop new markets and even have to face being pushed out of existing markets. Many types of positive displacement pump have historically only been used for non-abrasive applications. With the expansion of markets however, the pump manufacturers increasingly face applications with abrasive particles suspended in the pumped fluids. These applications pose a significant challenge for the manufacturers and operators of the pumps. From a manufacturer's perspective, only strict adherence to the cleanliness requirements allows for optimal life expectancy, while from the operator's perspective, these levels of cleanliness are difficult or impossible to achieve in many applications. Especially for pumps in continuous production processes with particle-laden products e.g., in the chemical or food industries, the abrasiveness poses a constant challenge due to high wear rates in the pumps, thus limiting service life.

For such applications, pumps based on soft sealing partners, such as membrane pumps or lobe pumps are often chosen. These soft sealing mechanisms however limit the maximum efficiency that can be achieved per pumping stage even in optimal operation. Furthermore, the pressure levels that can be achieved with soft sealing mechanisms are limited [2]. For

All Open Access articles are peer-reviewed, distributed under the Creative Commons Attribution-Non Commercial 4.0 International

diaphragm pumps, pump handbooks give a pressure limit of 17 bar for standard applications [3]. Hard sealing mechanisms as present in gear, vane, screw and lobe pumps allow for higher pressure levels, are however more susceptible to wear, when critical abrasive particles are present. The particles most critical are abrasive particles in a size close to the respective gap height, since these particles are likely to be entrained into the sealing gap by the relative motion of the sealing partners [4]. The sealing gaps are widened by wear, thus increasing internal leakage and reducing volumetric efficiency [5].

Wear to the sealing gaps can be described as a superposition of abrasive and erosive wear [4]. Abrasive wear, especially by means of three-body abrasion results from particles slightly larger than the gap height being drawn and rolled through the gaps when relative motion of the sealing partners is present. Erosive wear is caused by the flow through the sealing gaps, driven by the pressure difference. Abrasive particles smaller than the gap height are carried along by the leakage flow across the sealing gaps and cause erosion to the sealing partners. This mechanism does not require relative motion of the sealing partners [6].

The scientific literature does not offer adequate insight into the wear behaviour for many of the aforementioned pump types with hard sealing mechanisms when operated with abrasive particles. Wear in general cannot be characterised as a component's property, but is always dependent on the composition of the system that the components operate in. Schmidt [7] showed in her work on the wear behaviour in two-spindle screw pumps, that a correlation between the wear behaviour observed in standardised tribometer tests cannot be drawn to predict the wear behaviour in the field tests of the pumps. She performed a small series of experiments in an effort to analyse the wear behaviour. The tests were performed with water and 2 %-mass quartz-sand with a particle size of 40 – 150 µm (mean: 86 µm) at a pressure difference of 14 bar. The pressure was developed along the 3.3 chambers. With her work she showed the importance of performing wear experiments as close to the real application as possible, in order to not loose relevance to the real-world application.

Even when testing whole pumps, but removed from the real-world application, the pumps may show different wear behaviour when compared to real world applications, as was shown by the preliminary work for ISO/DIS 9632 [8] shows. Here pumps with similar real world wear behaviour showed different wear behaviour in the controlled test environment. This highlights the importance of well documented test rig setups for the repeatable experimental investigation of rotating displacement pumps.

The research paper that is presented here, covers the commissioning of a test rig, that has been developed in order to perform experimental research on the wear in pumps with hard sealing mechanism, as discussed above. The development of the test rig setup has been discussed in the scientific community at the screw machines conference in 2024 [9]. The presenting authors of this research paper aim at making their path to a newly developed test rig setup transparent. The test rig needs to offer a repeatable test environment. Due to logistical limitations and a lack in practical experience regarding the behaviour of such a test rig, strict control of all parameters for every experiment cannot be achieved. The repeatability with regards to the test results therefore relies on a combination of controlled parameters and monitoring of other parameters in a well-documented test environment, as will be elaborated on within this paper.

2. DESIGN AND COMMISSIONING OF THE TEST RIG

In order to achieve a test environment that allows for repeatable test parameters and offers the wide variability of adjustable parameters, the test rig has been designed with special focus on the conditioning of the suspension and on minimising dead-volumes in the pipelines. The test rig is comprised of two circuits, which are fed by a common suspension tank. The main circuit includes the measurement environment for the test pumps. The filtering circuit aids in the conditioning of the suspension. The conceptual design of the test rig is shown in figure 2.1. and explained below. Many of the design decisions could be evaluated during the commissioning phase.

2.1. Conceptional Design of the Test Rig

For the main circuit, the pipelines are kept short, while also considering the critical bend radius for the hoses and minimising the transitions in cross-sectional area. The suction side of the pump is connected to the tank, which is used for the preparation of the suspension and the temperature control. The mass flow as well as the density of the suspension is measured by a Coriolis-type flow meter located in the suction line. The difference in fluid temperature and in pressure are measured across the pump. Pump speed and torque are measured by a torque measuring shaft, which is coupled to a safety clutch that disconnects the pump from the motor in the event of a pump jamming. By means of these measurements, the operating point of the pumps can continually be monitored and changes to the pump behaviour caused by accumulative wear can be detected.

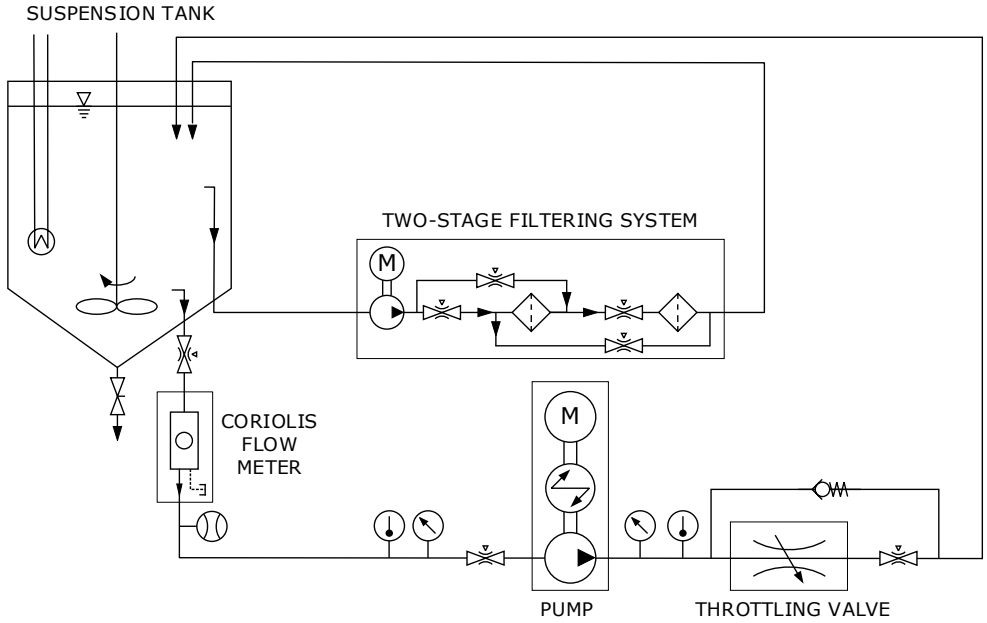

Figure 2.1. Hydraulic schematic of the test rig setup for wear analysis on pumps. [9]

In order to adjust the operating point of the pump, an adjustable pinch valve is used as a throttle. The valve, as shown in figure 2.2, is mechanically actuated and restricts the flow by pinching a flexible sleeve. After passing the throttle, the suspension can flow back to the

suspension tank. The outlet of the return line into the tank is oriented against the direction of flow in the tank caused by the mixer, in order to aid the mixing by disturbing the flow. The suction inlet is oriented in a way that the pump draws in the suspension against the direction of flow caused by the mixer.

Figure 2.2. Mechanically actuated pinch valve. [10]

The filtering section needs to allow for ease of assembly and maintenance. Therefore, a routing was chosen that allows for the sections that need to be drained, to remain small and with a low point at the filters. The filtering unit is comprised of a pump and two filters that are operated in series. The suspension is first pumped through a coarse filter in order to separate the large particles, that are still sharp and most relevant for the wear in the sealing gaps. For the fine filter, a 5 µm filter was chosen, instead of the 10 µm filter that was discussed in the previous paper in order to aid the oil cleanliness.

The experimental tests focus on the wear to the spindles and liner, thus for each test a new set of spindles and liner will be used. This pump assembly will then be operated at one operating point for each respective test. The operating point is defined by rotational speed, pressure, oil viscosity, particle concentration, particle size distribution and particle type. Each of these parameters can be set independently. The requirements and limitations that had to be faced in the design of the test rig, as well as the components that were chosen for the construction of the test rig are covered in depth by the previous research paper [9]. Based on the conceptual design, the test rig has been built up and first commissioning tests were able to be performed, offering first insights into the behaviour of the test rig and additional challenges that have to be faced.

2.2. Test Procedure

The test procedure consists of a fluid pre-conditioning cycle, the wear test, and a detailed cleaning cycle to provide a reproducible and uncontaminated environment for the next tests. Within the previous publication, this test procedure has not been shared yet and is therefore discussed below.

The pre-conditioning cycle of the fluid is split up in two phases. First the fluid is brought up to temperature, while the particles remain in a sedimented state. In order to aid the homogenous temperature distribution throughout the test rig, the pump is operated at slow speed to allow heating not only the fluid in the suspension tank but also in the pipeline assembly. Additionally, the mixer is operated at slow speed in order to avoid hot zones near the heating element. Care must be taken, to not bring the particles into suspension, that have

settled at the bottom of the tank since the previous test. When the desired test temperature of 40 °C is reached, the temperature is held at a constant level for the subsequent wear test. After the temperature pre-conditioning phase, the pump speed as well as the operating pressure are increased up to the operating point of the pump. Once the operating point has been reached, the mixer speed is increased in order to bring the particles into suspension, the wear test of the pump has started. The particle concentration in the suction line of the pump can continuously be monitored by means of the suspension density.

After the predefined test time the test pump is to be stopped, marking the end of the wear test. Now, the mixer and temperature control are turned off. Therefore, the pipelines are filled with particle-laden suspension. The particles remain in the pipelines and have a chance to settle at any given place in the test rig. This sediment needs to be removed from the pipelines in order to avoid introducing unsteady particle concentrations into the pumps during subsequent tests. Since disassembly of the test rig is not feasible in between all tests, the particles need to be flushed out of the pipeline, while in place. In-situ flushing of pipelines is common practice, especially in food industries or pharma applications, often called Cleaning-in-Place (CiP) [11]. By means of often turbulent flow of a cleaning aid, the pipes are flushed and sediments removed from the system [11]. Flushing the measuring section of the wear test rig in a similar way prohibits itself for two reasons. Firstly, the pipeline diameters of the test rig have specifically been chosen large in order to reduce erosive wear to the pipeline components by reduction of the flow velocity. Thus, turbulent flow can only be achieved with very high volume flows, which cannot be reasonably provided by the size of pump that would fit the available space or budget. Secondly, the particles shall remain in the suspension tank during the flushing cycle, in order to reduce effort in the test preparation and aftercare. Solutions with a suction side filter in the tank were not considered, since the size required to provide sufficient filter capacity would not fit the available space. Instead, the suspension is given time for sedimentation. Clean fluid for flushing is thus made available by allowing the particles to settle at the bottom of the tank. In order to not agitate the particles that have already settled at the bottom of the tank, the flushing cycle can only operate with low volume flow.

Instead of turbulent flushing, a concept based on mechanical agitation of the particles in the pipelines was chosen. A pipe cleaning spiral, fitted with a nylon brush, allows to agitate the particles, bringing them back into suspension. The suspended particles are then carried back to the tank by a low volume flow. In order to provide the necessary volume flow, a secondary flushing pump is used, that can be mounted in place of the test pump. With the flushing pump in operation, the cleaning spiral is inserted into the suction port in the tank and fed into the pipeline until the brush reaches the suction port of the pump. Thereby the sediments from the pipeline assembly can be flushed back to the tank while minimising disturbance to the sedimented particles in the tank.

This flushing concept is only possible thanks to the specific design of the pipeline assembly, which is based on the guidelines for food industries. Namely by avoiding dead spaces as well as sharp bends and aiming for smooth transition of diameters, it is possible for the brush and cleaning spiral to move freely through the pipes. Thanks to the design of the suction port of the secondary flushing pump, there is no risk of catching parts of the cleaning spiral or the brush in the moving parts of the pump. For changing the particle type, the return lines can be flushed accordingly by inserting the brush into the return line.

3. PERFORMANCE EVALUATION

The measures described above all focus on producing a repeatable test environment. The following paragraphs will show the performance of the systems and allow for an evaluation with regards to the repeatability of the test parameters.

3.1. Temperature Pre-Conditioning

The operating temperature for the test rig is 40 °C. The temperature is controlled to within ± 2 °C by a 9 kW heating element and two tube coil heat exchangers in the suspension tank. The temperature control allows for the test fluid to be preheated to 40 °C before starting the tests. For the preheating of the measuring section, the test pump is operated at slow speed, in order to not agitate the settled particles in the tank. The wear test is initiated by increasing pump speed and pressure to set the operating point and ramping up the mixer speed in order to bring the particles into suspension. Dependent on the environmental conditions at the time of the test and the operating point, the hydraulic losses may be great enough to keep the test rig at 40 °C or even heat up the test fluid. The temperature controller therefore adjusts the volume flow of coolant through the tube coil heat exchanger, thus allowing for continuous control of the temperature. Figure 3.1 shows the temperature in the tank and at the pump inlet during the pre-conditioning, confirming, that the temperature pre-conditioning cycle ensures repeatable test parameters, allowing for a consistent oil viscosity and density to be considered for the wear tests.

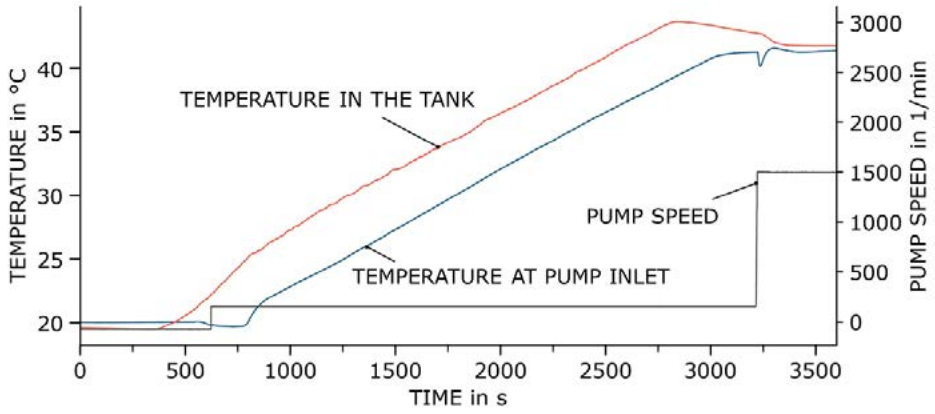

Figure 3.1. Fluid temperature pre-conditioning cycle and run-up of the pump.

3.2. Particle Concentration

The temperature pre-conditioning cycle discussed above must not introduce a critical amount of abrasive particles into the measuring pump. Additionally, the particle concentration introduced into the pump during the run-up of the pump and the mixer needs to be evaluated. The introductory paragraphs mention, that not all parameters can be controlled within the test rig. The particle concentration that is introduced into the pump is the most important parameter that can only indirectly be influenced by changes to the mass of particles in the tank and the run-up phase. Therefore, it is very important to monitor and document the particle concentration during all states and consider the findings when drawing conclusions from the measurement results.

Preliminary tests have shown, that with respect to the cleanliness achievable by the flushing cycles and the accuracy achievable in the measurement of the particle concentration, the temperature pre-conditioning cycle can be considered to not contribute to introducing particles into the measuring section. Fluid samples taken near the pump inlet in the tank after the pre-conditioning phase show, that no critical amount of particles was brought into suspension.

Figure 3.2 shows a pre-conditioning cycle after the oil has been heated to 40 °C with the pump and the mixer operated at slow speed, in order to provide uniform heating throughout the measuring section and the tank. Then, the pump is run-up to 1500 1/min in order to set the operating point, before the mixer speed is increased, in order to bring the particles into suspension. The density drops slightly below the expected reference value of 0.852 ± 0.002 kg/l during the temperature pre-conditioning cycle. The reference value was obtained using a Lauda TD3 tensiometer at a temperature of 40 °C. Once the pump has reached its operating speed of 1500 1/min, the density approaches the reference density, indicating that the pump does not stir up a critical amount of abrasive particles in the suspension tank.

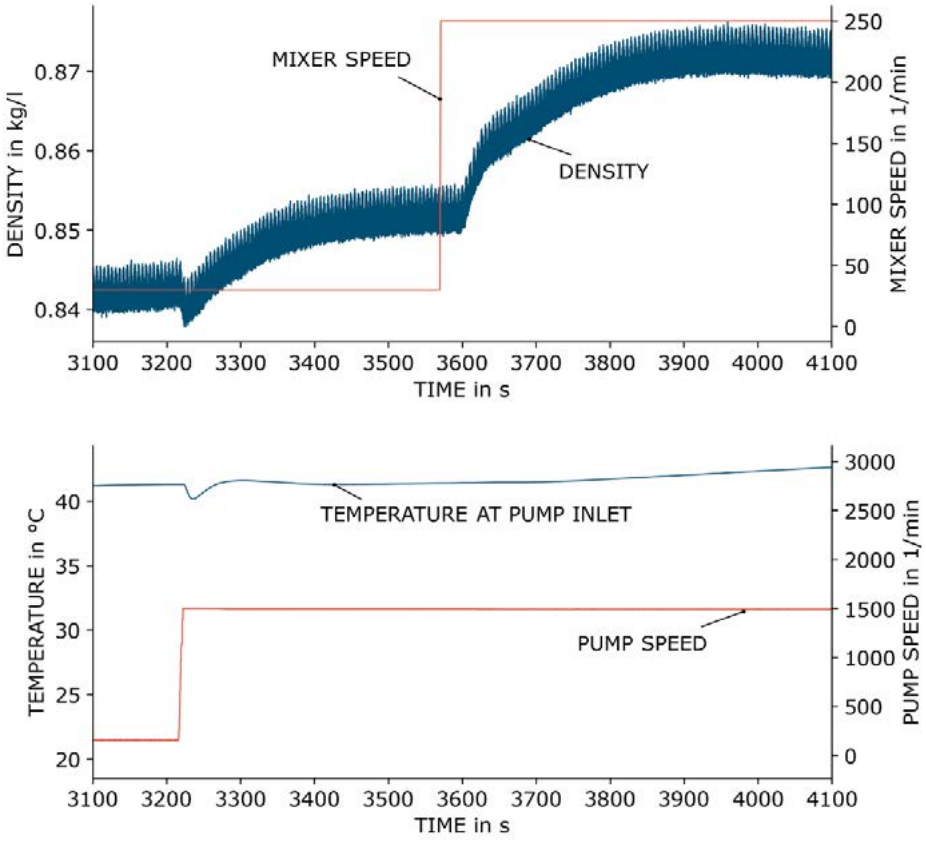

Figure 3.2. Suspension density and temperature at the pump inlet during pre-conditioning.

The density of clean oil at the same pump speed is shown in figure 3.3. Checking against the measurement in clean oil confirms, that for the run-up of the pump to 1500 1/min is safe to assume, that no critical amount of particles are stirred up from the bottom of the tank.

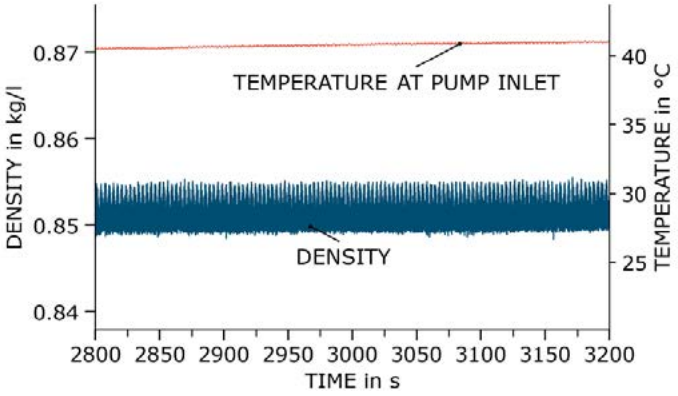

Figure 3.3. Clean oil density and temperature at the pump inlet.

Additionally, a fluid sample was taken from the tank, after the pump was run-up to 1500 1/min. After sufficient time for sedimentation of the sample, it could be confirmed, that no significant amount of particles was present in the oil. Thereby, both the temperature conditioning as well as the run-up cycle of the pump fulfil the requirements necessary for a repeatable test environment. This can also be confirmed by means of a sight glass in the suction line before the pump. Additionally, the fact that test pumps operated within these conditions did not show any signs of wear and upon disassembly did not show any signs of binding. Binding of the spindles within the liner due to particles within the small clearances has been observed with all pumps that were operated at test concentrations. The pre-conditioning phase can thus be considered to allow for sufficiently clean oil at the start of the tests, ensuring the repeatability of the tests.

After setting the operating point, the mixer speed is increased, in order to bring the particles into suspension. Figure 3.2 shows that the density increases. From the density, the particle concentration can be calculated. The supplier of the glass granule particles used for the commissioning tests, gives a range of 2.0 … 2.6 kg/l for the particle density. [12] Assuming a particle density of 2.2 ± 0.2 kg/l and an oil density of reference value of 0.852 ± 0.002 kg/l, a particle concentration of 1.53 % by mass can be calculated with a spread of +0.42 %, -0.31 %, matching the nominal particle concentration of 1.5 % by mass.

3.3. Flushing Cycle

Without clean pipelines at the start of a test, all other efforts to ensure a repeatable test environment are in vain. Unknown particle agglomerations, especially on the suction side may detach undetected and enter the pump. Thereby, the wear in the pump would no longer be able to be traced to known parameters. Since the density measurement only gives information about the density of the flow through the sensor, a manual inspection of the achievable cleanliness in the pipes has to be performed. The design of the test rig is such that critical dead volumes are minimised. Therefore, the remaining critical sections are the sharp transitions in diameter at the hose fittings and the step down in diameter at the pump

inlet. These critical sections were checked by disassembly and showed, that no particle agglomerations were to be found.

Additionally, the density measurements of clean oil in the test rig at an ambient temperature of 21 ± 1 °C were compared to the density after flushing at the same temperature. The density in clean oil was 0.868 ± 0.004 kg/l, while the density after flushing was 0.870 ± 0.004 kg/l. Thus, the flushing cycle offers sufficient cleanliness for the tests.

3.4. Cavitation

The commissioning test showed, that at high volume flows and high pressure drops ($\Delta p > 8$ bar), cavitation could be noticed. The cavitation presented as vibrations within the hydraulic hoses, that were transferred back to the test pump. The origin could be traced to the pinch valve. The high pressure drop at the pinch valve that is used to set the operating pressure of the pump, leads to cavitation within the pinch valve, which transmits the vibrations to the hose assembly of the test rig. These high system vibrations highlighted an issue in the mounting solution for the Coriolis-type flow meter, since vibrations from the return hose were able to be transmitted into the mount of the flow meter. The flow meter, which operates in a frequency range of $400 \ldots 600$ Hz thus gave inconsistent measurements for the density of the suspension. Therefore, the flow meter was mounted more rigidly and isolated from transmission of vibrations. Thereby the negative effect on the measurements was omitted. Further, in order to reduce vibrations within the test rig and reduce cavitation erosion to the pinch valve, concepts for further throttling were developed and will be added to the test section.

4. CONCLUSIONS AND OUTLOOK

Based on the results of the preliminary and commissioning tests, the test rig can be set up for the parameter studies to analyse the wear behaviour in screw pumps. Final adjustments to the throttling of the measuring section and to the filtering section can be performed. The performance of the test rig will continuously be monitored, and future changes documented in order to avoid the propagation of systemic changes to the experimental findings. The tests that will be performed, aim at the starting phase of wear in screw pumps in order to enhance the knowledge of critical parameters and better understand safe vs. critical operating points.

The experiences in the design and commissioning process of the test rig are further discussed below in order to aid future researchers by providing a condensed lessons learned. Future experiences in the operation and upkeep of the test-rig are intended to be shared as well.

Some practical findings to keep in mind during the design of a similar wear test rig, that became important during the commissioning tests are summarized below.

In order to reduce particle agglomerations within the pipeline system, smooth transitions are to be chosen, when variations to the inner diameter of pipes and connectors cannot be avoided. Adhering to that principle made the flushing concept described above possible. However, it can be noted that the step at the transition from the hydraulic hose to the barbed hose fitting leads to increased settling of particles at that transition. Therefore, for applications with particle suspensions it is recommendable to design the leading edge with sufficient taper.

Wear will not only affect the measuring section, but the filtering unit as well. Cumulative wear will lead to a decrease in volume flow, thus reducing the filtering rate. This reduction in the filtering rate can currently not be characterised since the filtering section is not equipped with a flow sensor. For ensuring consistent filtering, it is recommendable to add a flow sensor to the filtering section.

The suspension tank has been chosen with a focus on adaptability and dead volume free design. Therefore, a cylindrical tank from the food industries has been chosen that is equipped with a dished bottom and total drain. The tank has been equipped with two tube coil heat exchangers that are nested. These are oriented concentric to the central mixer and mounted to the wall of the tank. The mounting hardware serves double duty. They affix the coils in the tank and at the same time act as baffles preventing the formation of a vortex as a result of the centrally mounted mixer. Some of the mounts break through the fluid-air interface, thus allowing air entrapment into the flow around the mounts at high flow rates of the pump. The influence on the experimental results is expected to be minor, since the air bubbles remain close to the surface and are few in number. Nevertheless, it is advisable to avoid disturbing the fluid air interface to mitigate air entrapment.

Further focus needs to be put on the wear to the test rig itself. While it is designed with low wear rates to the components in mind, the test rig needs to be checked for wear periodically. Especially the throttling components, that are subject both to cavitation and highly erosive conditions need to be checked frequently. A standardised, sacrificial wear body may be added to the outlet of the pipeline assembly in order to pose as an indicator for cumulating wear in the test rig components.

Abstract.

Axial piston pumps in electrified, variable-speed duty cycles increasingly operate at low speed and start–stop conditions where hydrodynamic lubrication margins are reduced, making the cylinder block/valve plate interface especially wear-critical. In this study, a previously optimized bronze meso-structured (sinusoidal) valve plate is re-evaluated under thermal steady-state conditions on the TU Dresden test rig at 40 °C and 60 °C inlet temperature, including very low-speed operation. The bronze design retains its efficiency benefit across both temperatures and shows no measurable additional wear, with surface changes remaining below 1 µm. Motivated by this wear-free behavior, a lead-free steel/steel material pairing is pursued. A new steel wave pattern is obtained by repeating the THED simulation optimization for the updated material pairing and was consequently manufactured and tested. Experimental results show strong efficiency improvements compared to reference and bronze configurations, but also reveal that at elevated temperature short contact events can rapidly escalate into failure. The findings confirm that meso-structured valve plates can be designed predictively for a given material system, additional research is needed to combine them with steel/steel pairings.

Keywords. Surface-structure, lead-free material pairing, electrification, axial piston pumps, valve plate, THED gap simulation.

1. INTRODUCTION

Positive displacement machines remain key components in fluid power systems due to their high power density and suitability for high-pressure operation. Axial piston pumps are widely used because of their high efficiency, variable displacement capability, and compactness as well as robustness in most heavy duty industrial applications. The ongoing shift toward electrified drivetrains has altered operating profiles. Frequent start-stop events, extended partial-load phases, and operation at low shaft speeds are increasingly required, while simultaneously high efficiency and reduced noise are expected. Under such conditions, the hydrodynamic lubrication margins of the major tribological interfaces are reduced and mixed lubrication or local contact is more likely to occur, particularly at the cylinder block/valve plate interface, which is spring pre-loaded for high speed performance, further increasing bearing loads at low-speed conditions.

In parallel, regulatory and sustainability-driven constraints have intensified the transition toward lead-free materials. In conventional pump designs, lead-containing alloys and coatings have been used to support run-in and to tolerate occasional metal-to-metal contact during early life and adverse operating points. It has been shown that surface shaping and meso-structuring can be applied to actively manipulate the lubricant film, increase hydrodynamic support, and reduce both friction and leakage losses, especially in low-speed regimes. Previous research has demonstrated efficiency gains from wave-shaped hydrostatic bearings as well as a significant reduction in wear [1], [2], [3], [4].

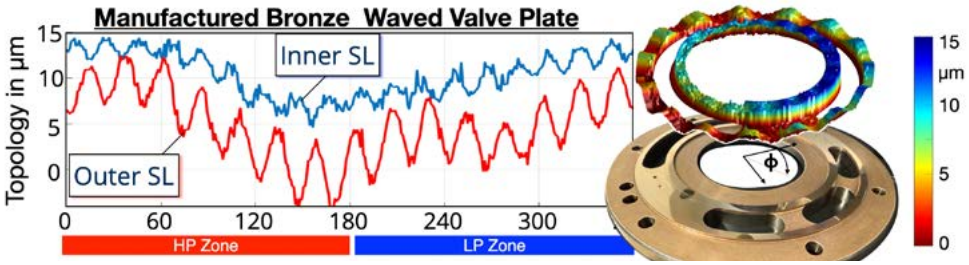

Figure 1.1. Manufactured and tested waved bronze valve plate [5].

In prior work, a meso-structured valve plate was designed using a thermo-elastohydrodynamic gap model in Caspar FSTI and was validated experimentally on an industrial test bench. A strong reduction in power losses (η_{total} +7%) at low speed was measured while high efficiency at nominal operating points was retained (η_{total} >90%). Importantly, the wave

structure remained intact after testing, and the run-in behavior typical of conventional designs was substantially reduced to remain below 1 µm total wear [5].

The present contribution extends the prior work in two directions. First, repeated measurements of the bronze meso-structured valve plate were performed under thermal steady-state conditions on the TU Dresden test rig at 40 °C and 60 °C inlet temperature, including very low-speed operation (<10 rpm), to confirm performance and wear behavior under controlled thermal boundary conditions. Second, the demonstrated low-wear behavior was used to motivate a next material step toward steel/steel pairings to avoid leaded materials and to reduce dependence on costly bronze/brass materials. Since the deformation behavior and lubrication conditions differ substantially with material pairing, a new micro-structure was designed by repeating the simulation optimization for steel/steel.

2. RESEARCH GOAL

The goal of this work is to validate and extend meso-structured valve plate technology for variable-speed axial piston pumps in a way that supports lead-free and cost-effective material strategies. Two specific objectives were pursued:

1. **Confirm improved thermal stability of the waved valve plate**: Simulation results indicated that the meso-structured valve plate experiences a superior thermal response when experiencing hotter fluid temperatures. In the industrial tests the fluid temperature was not maintained steady, not allowing for a definitive validation of this claim. Hence, these tests were repeated on a research test-rig at **40°C and 60°C inlet temperatures**, allowing for full thermal stability.
2. **Material transition and redesign for steel/steel**: Based on the wear-free behavior of the bronze design, a transition toward a **steel/steel** pairing was to be evaluated as a next step toward lead-free and cost-relevant pump development. Due to differences in material properties a new wave pattern had to be designed using the same simulation method as published previously [5], but with an updated material pairing. Prototype manufacturing and testing were to be performed to identify performance potential and limiting failure mechanisms.

3. TEST RIG AND MEASUREMENT METHODOLOGY

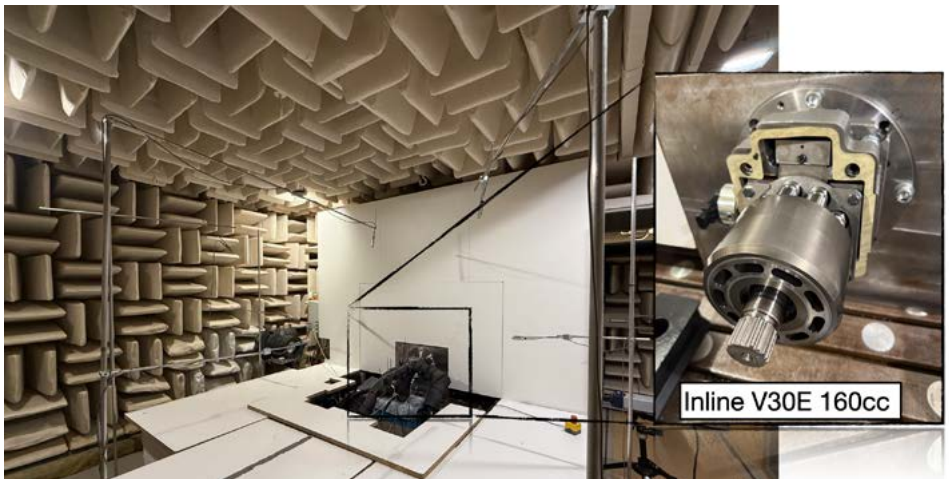

Figure 3.2. Test rig and 160cc test pump

The measurements for this work were performed in the pump test rig of the Institute of Fluid-Mechatronical Systems. This 250 kW test rig doubles as the anechoic sound measurement room, which is shown in Figure 3.2.

The pump used for this research is an V30E 160cc pump from the company Inline Hydraulik (also branded as HAWE), which is a high pressure industrial open circuit variable axial piston pump.

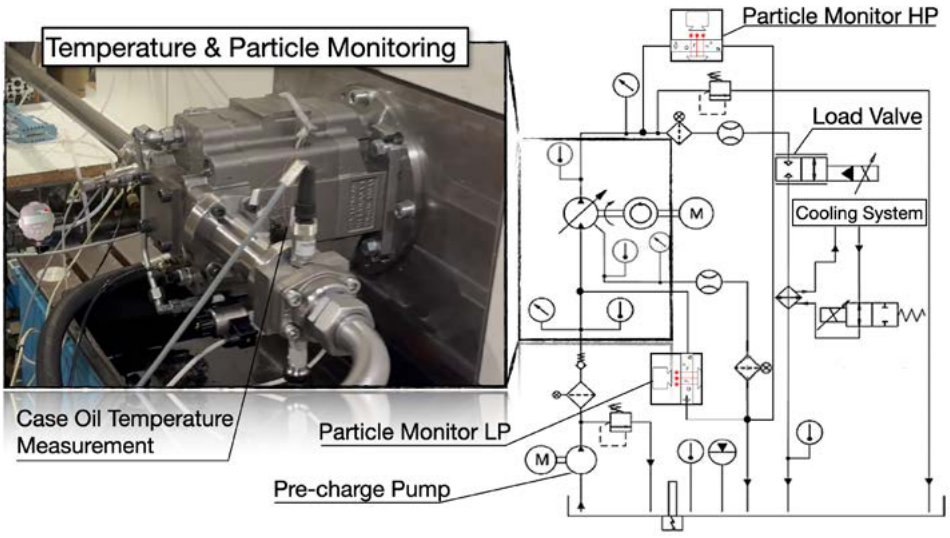

Figure 3.3. Schematic and sensor setup

The test rig features a 200 kW cooling system, capable of controlling the fluid temperature within ±1 K. In addition to the standard protocol for efficiency measurements such as pressure, temperature, flow and torque sensors, additional particle sensors as well as thermocouples were placed in strategic places (see Figure 3.3) to monitor pump performance and detect failures.

The measurement series were performed in the following order:

1. Reference measurements with a new pump (Ref1 - Kit1)
2. Repeat measurements of the used waved bronze valve plate (Bronze WVP- Kit1)
3. Unhardened waved steel valve plate (Steel WVP (S) - Kit1)
4. Hardened wave steel valve plate with a used rotating kit (Steel WVP (H) - Kit2)

The reason for the change in rotating kits, was that the unhardened steel wave had a significant failure contaminating the pump with metal particles. Hence, a rotating kit that was previously used for other measurements was used. Reference measurements were available for this replacement rotating kit, which will be compared to the Steel WVP (H) measurements only.

For each series the following measurement runs were performed:

Run1: Full operating span at 40˚C inlet
Run2: Full operating span at 60˚C inlet
Run3: Low Speed Tests
Run4: Repeat of full operating span at 40˚C inlet

Total test time: 25-30 hours.

4. PRIOR WORK AND STEADY MEASUREMENTS OF BRONZE VALVE PLATE

This paper is a continuation of the previously published meso-structured bronze valve plate [5]. This section will summarize the achievement of this paper and build upon them to lead up to the final results of the meso-structured bronze valve plate at steady state conditions.
Prior work on meso-/micro-structuring of lubricated interfaces in axial piston pumps has shown that tailored surface topographies can actively manipulate the fluid film to increase hydrodynamic load support and reduce both viscous

friction (hydromechanical) and leakage-related (volumetric) losses, especially under low-speed conditions where mixed lubrication is more likely.

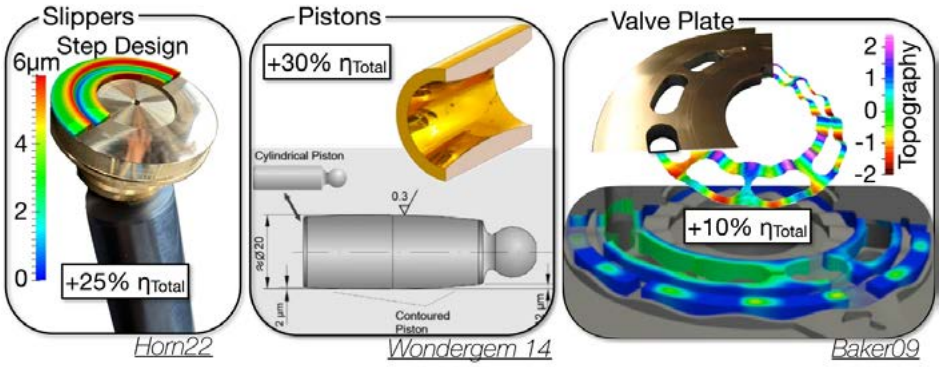

Figure 4.4. Previous published meso-structures in axial piston pumps

Across the three dominant loss-contributing interfaces—piston/cylinder, slipper/swash plate, and cylinder block/valve plate—different structure concepts and optimization targets have been published in the past and are visualized in Figure 4.4 [1], [2], [6]. The common outcome is improved low-speed efficiency with strongly reduced run-in wear when the structure is properly adapted to the interface physics. In particular, wave- or step-like meso-geometries were shown to provide measurable efficiency benefits at low speed while limiting wear to minor peak smoothing rather than bulk material removal.

Building on these findings, the present work focuses on the cylinder block/valve plate interface using the previously optimized waved bronze valve plate [5], and re-evaluates its performance under controlled *thermal steady-state* boundary conditions to remove the temperature transients inherent to the earlier industrial testing campaign.

4.1. Meso-Structured Waved Bronze Valve Plate at Steady State Conditions

Figure 4.5 summarizes the key efficiency benefit of the waved bronze valve plate at 25% displacement, showing the improvement in total efficiency (left) and the corresponding gain in hydromechanical efficiency (right) relative to the reference. The data indicate that most of the total-efficiency benefit originates from hydromechanical loss reduction, consistent with the intended mechanism of the wave structure in supporting the lubricating film. The four operating conditions used for the original design optimization are

superimposed and serve as fixed reference points for later power-loss breakdowns. The choice of 25% displacement is deliberate, since valve-plate-related losses contribute a larger fraction of total losses in this regime; therefore, a ~6 percentage-point total efficiency increase (in this case from 75% to 81%) is practically meaningful.

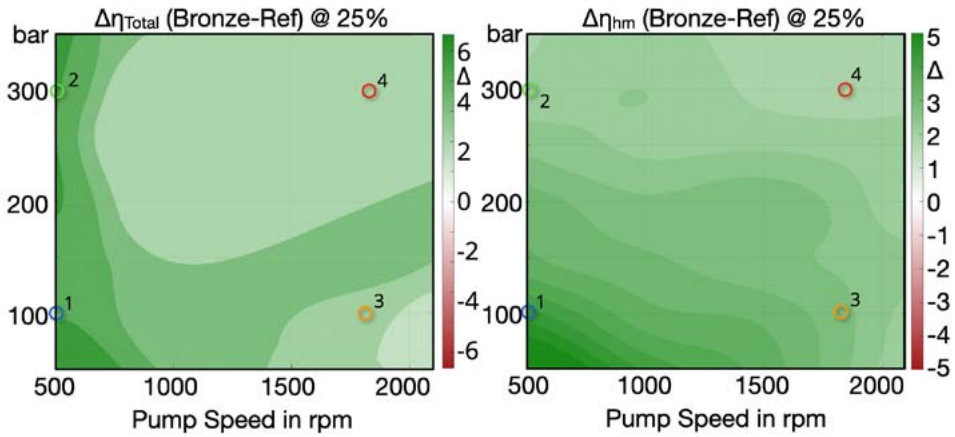

Figure 4.5. Improvement of the total and hm efficiency using a waved valve plate design in comparison to the reference at 25%

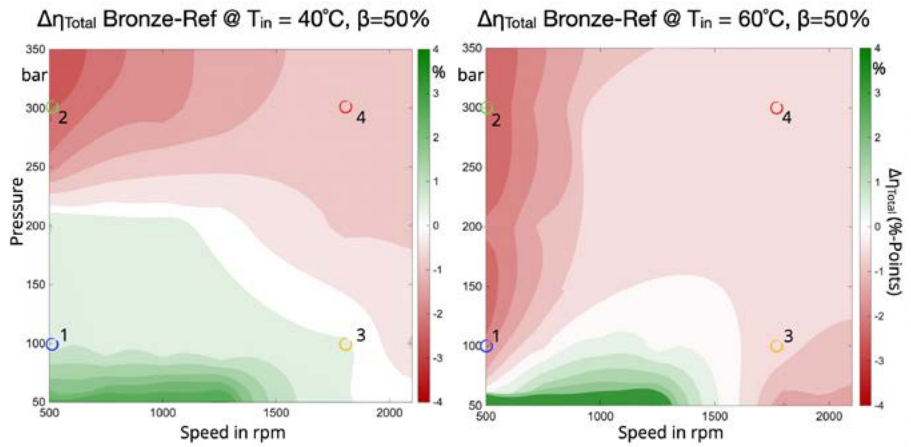

Figure 4.6. Difference between the measured total efficiency at 50% displacement for 40˚ and 60˚C inlet temperature between the meso-structured bronze VP and the reference.

Figure 4.6 provides the measured total-efficiency difference between the waved bronze and reference valve plates at 50% displacement for two inlet temperatures. The map indicates up to ~4 percentage-point improvements

primarily at low speed and low pressure, while the majority of the operating range remains close to unchanged (approximately ±1 percentage point). A localized efficiency reduction is visible in the low-speed/high-pressure region, and the overall efficiency level decreases with increased inlet temperature, most notably at higher pressures.
To connect the efficiency trends to energy terms, Figure 4.7 shows a stacked power-loss breakdown at the four design operating conditions for the reference and waved bronze valve plates at 40°C and 60°C inlet temperature. While total losses increase at 60°C for both configurations, the waved bronze valve plate shows a smaller loss increase than the reference (~15% lower increase), supporting the simulation-based expectation that the meso-structure provides improved thermal robustness of the valve-plate interface under hotter fluid conditions.

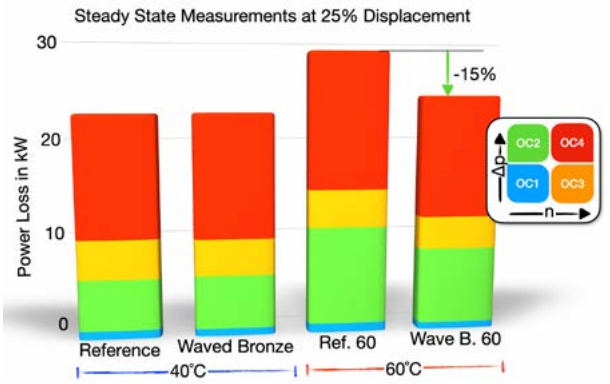

Figure 4.7. Measured efficiency improvement at 60˚C and 25% displacement across 4 main operating conditions.

This trend is further corroborated in Figure 4.8, where simulation and measurement are compared using a normalized representation: since the THED model predicts valve-plate interface losses rather than full-pump losses, values are normalized to the summed power loss at 40°C. The temperature-induced loss trend is captured well across most operating points, including a particularly strong agreement at low-speed conditions (OC1 and OC2). Deviations remain at higher-load points (notably OC3/OC4), but the agreement in both direction and magnitude is sufficient to validate the main thermal sensitivity trend relevant to variable-speed duty cycles.

In summary, the waved bronze valve plate demonstrates repeatable efficiency benefits under thermal steady-state conditions and shows a

reduced loss sensitivity to elevated inlet temperature; however, the most critical requirement for long-term applicability is that the small-amplitude structure remains intact, which is assessed next via detailed wear measurements.

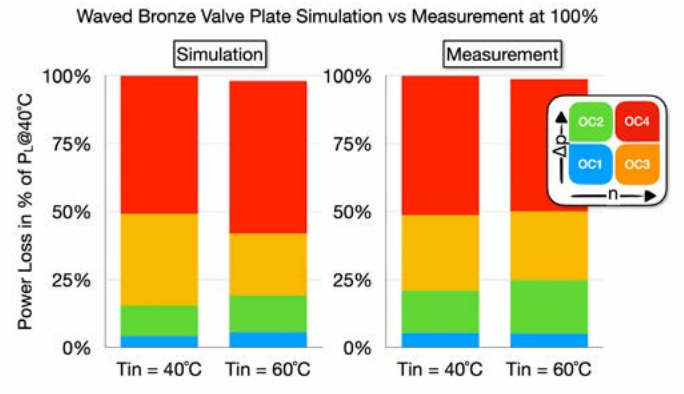

Figure 4.8. Comparison of predicted vs measured power losses at full displacement for 4 operating conditions at 40˚C and 60˚C normalized to the total power loss at 40˚C.

4.2. Evaluation of Surface Wear After Steady State Measurements

As the wave amplitudes are on the order of micrometers, even small amounts of wear can eliminate the functional hydrodynamic effect; therefore, *structure survivability* is a primary success criterion alongside efficiency. with no meaningful additional wear detected during the steady-state series.

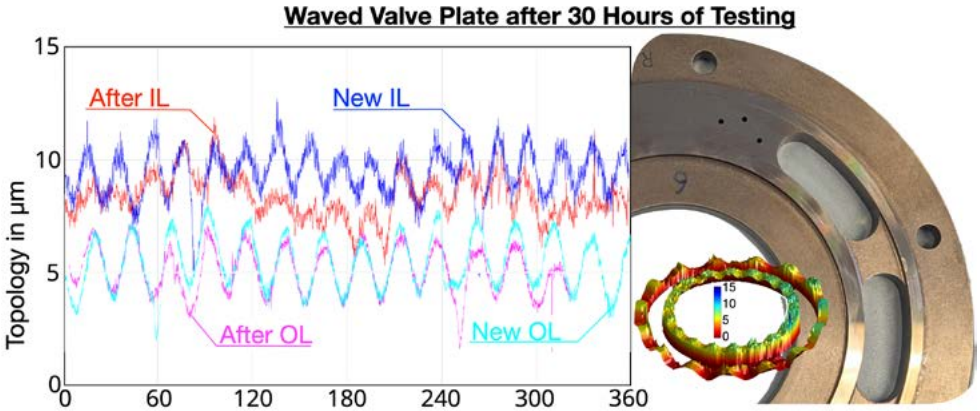

Figure 4.9. Meso-structured bronze waved valve plate new and after testing (IL = Inner sealing land; OL = Outer sealing land).

Figure 4.9 shows the waved bronze valve plate after the combined test exposure (industrial dynamic testing plus the additional steady-state campaign, totaling ~30 h). The 3D topography measurement confirms that the wave pattern remains clearly present across the sealing lands. The inner (IL) and outer (OL) sealing-land profiles, compared between the new condition and after testing, show only minor changes; while slight plastic deformation is visible—primarily at the IL—the wave form remains intact, and total material change stays below 1 µm. Importantly, the valve plate was measured after the industrial tests and again after the steady-state campaign,

The wear contrast to the reference valve plate is highlighted in Figure 4.10. Note that the color scales differ: the reference plate exhibits material loss up to approximately 5 µm at the inner sealing land and additional localized losses on the outer land, whereas the waved bronze valve plate primarily shows limited peak smoothing at the IL with the OL wave pattern largely preserved with material loss under 2 µm. Darker regions on the OL are predominantly attributable to plastic deformation rather than removal of the wave geometry, as can be seen in the surface profile in Figure 4.9.

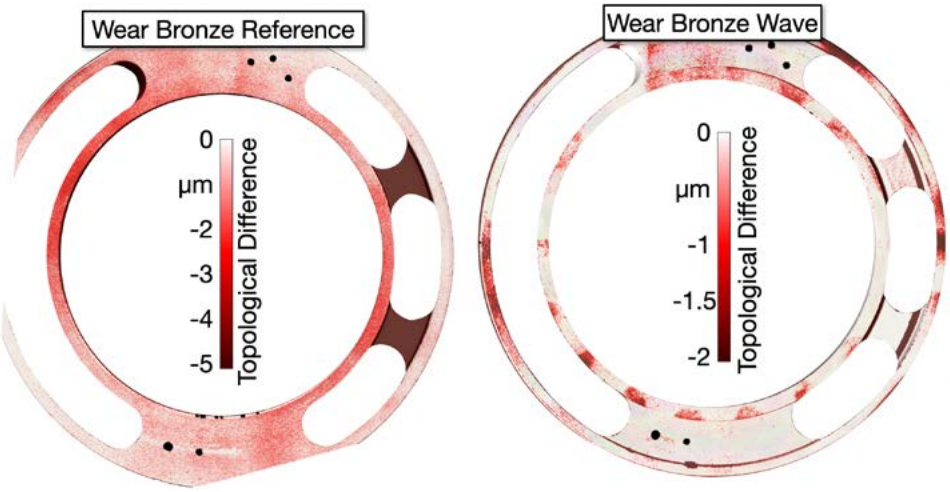

Figure 4.10. Material loss of both vale plates after industrial and steady state testing as compared to the new state.

In summary, the waved bronze concept not only improves partial load efficiency but also suppresses run-in wear to the micrometer level, motivating the hypothesis that a lead-free, cost-relevant steel/steel pairing could be feasible—provided the wave geometry is re-optimized for the

fundamentally different material and deformation behavior; the following section therefore describes the simulation-based redesign workflow for steel/steel.

5. STEEL/STEEL SIMULATION AND OPTIMIZATION

The valve plate design simulations were performed within the Caspar FSTI framework, which is a powerful simulation software tailored for gap design in axial piston pumps [7]. The used model of the pump was described in detail here [5], [8], [9], [10] and validated using temperature measurements of the cylinder block [8], [9], [11].

The meso-structured wave geometry discussed in Section 4 was originally designed for the bronze WVP configuration used in the previous study. Importantly, this component is not a monolithic bronze part, but a bi-metal configuration in which the valve plate body is predominantly steel with a bronze bearing layer (~0.5mm). This material pairing influences the thermo-elastic deformation response of the valve plate: the two materials exhibit different thermal expansion behavior and stiffness, such that the resulting thermal crowning and local gap shape can differ significantly from a full steel/steel pairing. Consequently, a wave pattern that is optimal for the bi-metal configuration cannot be assumed to remain optimal—or even stable—when transferred to a monolithic steel valve plate.

To evaluate whether the bronze-derived wave concept can be transferred with minimal redesign, two parametric studies were performed on a full steel valve plate by varying only the sealing-land radii (i.e., the hydrostatic bearing area), while keeping the kidney geometry unchanged. The inner sealing land diameter was varied from d_{GapIn} = 87.5 to 89 mm and the outer sealing land diameter from d_{GapOut} = 125.5 to 128 mm, and the four previously introduced design operating conditions (OC1–OC4) were simulated in a full DOE. In the first study, a *positive-wave* pattern (IL+1µm with +5µm offset; OL+3µm) was used, as this was the optimal design found for the bronze VP [5]. The positive wave is essentially the full wave without the negative amplitude. In a second study the full-wave pattern (IL±1 µm with +5µm offset; OL±3 µm, see Figure 1.1) was also analyzed on the steel VP. This full wave pattern reflects the realized waved bronze VP, which was chosen due to manufacturing limitations.

Figure 5.11 summarizes the results at T_{in}=35˚C as power-loss maps over the design-of-experiments domain for each operating condition. The color scale

indicates the magnitude of predicted power losses (note that the scale differs between OCs), while grey regions denote non-converged simulations. Non-convergence occurred primarily when contact was predicted or when the cylinder block lifted off, both indicating an unstable design for the tested geometry. The results demonstrate that the majority of radius combinations fail in at least one operating condition. Only a single candidate (Des20) converged in all four OCs; however, the lowest-loss region is shifted toward smaller values of d_{GapIn} and d_{GapOut} where designs such as Des72 approached favorable loss levels but still failed to converge in OC4. As a reference the bronze WVP had 88.5mm and 127.4 mm as d_{GapIn} and d_{GapOut} respectively. Nevertheless, both Des72 and Des20 showed problems at 60˚C inlet, a temperature when the full wave pattern was superior.

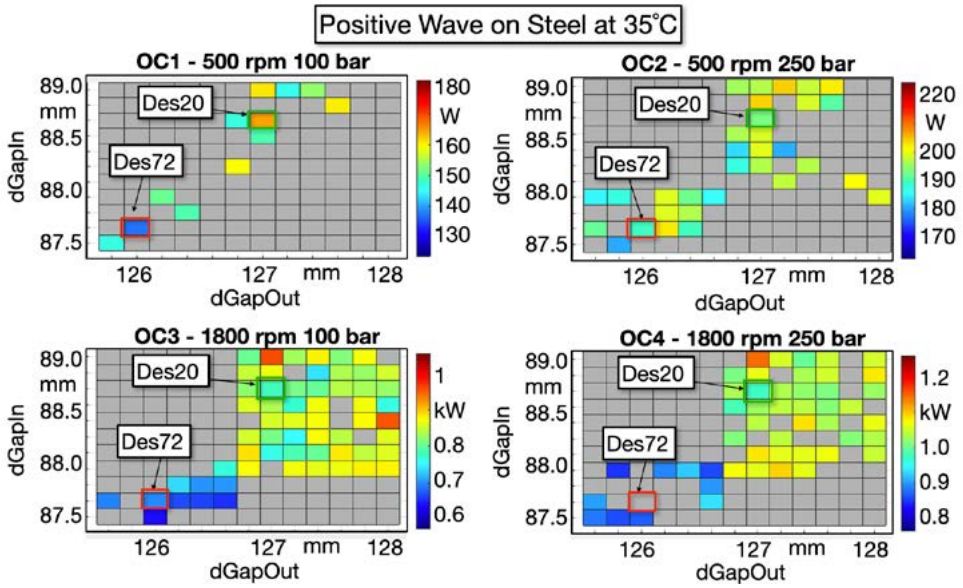

Figure 5.11. Powerlosses with variation of the sealing land width on a steel VP for a positive wave design adapted from the waved bronze VP

The results of the full wave pattern at T_{in}=35˚C are shown in Figure 5.12. While the loss levels were, on average, reduced compared with the positive-wave sweep, the same fundamental limitation remained: only one design converged across all four OCs, and the best-performing low-loss candidate (Des33) still failed in OC4. This indicated that the stability margin of the hydrostatic balance in steel/steel is highly sensitive and that “best loss” and “robust across OCs” do not coincide when only the sealing-land radii are varied. Des 33 converged in all OCs at 60˚C inlet temperature, making it the base for further amplitude studies.

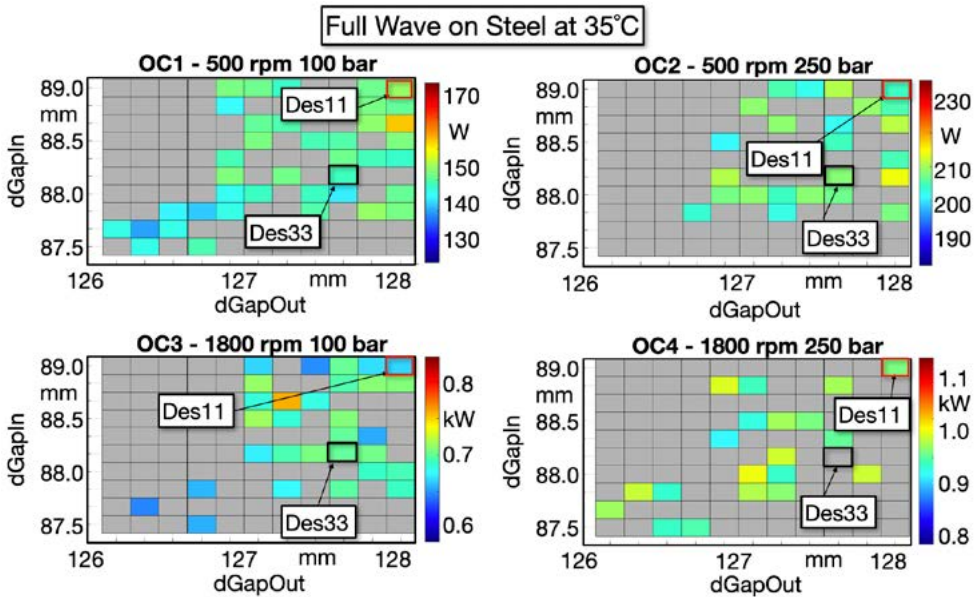

Figure 5.12. Powerlosses with variation of the sealing land width on a full steel VP for a full wave design adapted from the waved bronze VP

Since the bronze steady-state measurements in Section 4 revealed a strong temperature dependence, both geometrical studies were repeated at an elevated inlet temperature of $T_{in} = 60°C$. The outcome was a qualitative change in behavior: the formerly robust positive-wave candidate (Des20) failed at higher temperature (already in OC3), whereas Des33 became stable and exhibited very low predicted losses at elevated temperature.

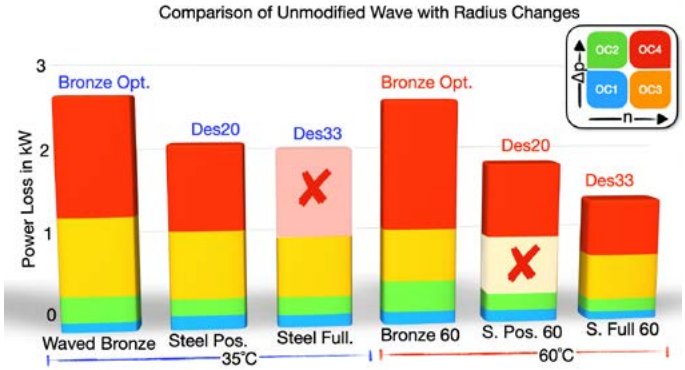

Figure 5.13. Direct adaption of full and positive wave from bronze design to a steel VP adjusting the sealing land width only.

Figure 5.13 condenses these findings by comparing stacked valve-plate power losses over the four operating conditions for essentially the same wave

pattern, only (differentiating between positive and full wave) for the bronze and steel VP at inlet temperatures of 35°C and 60°C. While the steel VP can, in principle, achieve lower valve-plate losses than the bronze design at both temperatures, none of the directly transferred configurations provided a single radius choice that remained stable and convergent across all four operating conditions and both inlet temperatures. In other words, the transfer produced attractive "point solutions," but no robust design envelope.

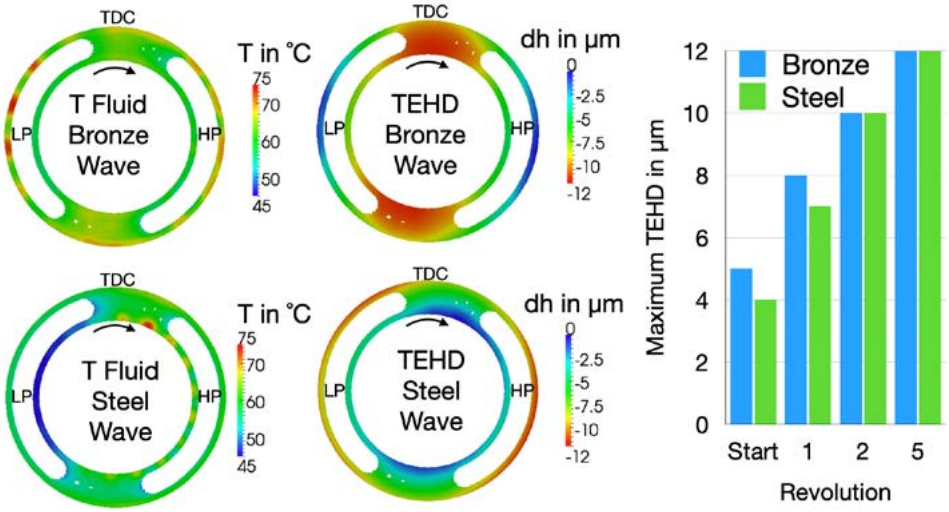

Figure 5.14. Thermal deformation effect on the fluid film between bronze and steel waved valve plate at OC4 (1800 rpm, 300bar, 100%)

The underlying cause of this temperature-dependent instability is the fundamentally different thermo-elastic deformation pattern of the full steel VP compared with the bi-metal bronze configuration. This is illustrated in Figure 5.14 for OC4, where the simulated fluid-film temperature distribution (left) and the gap-height change caused by thermo-hydrostatic-elastic deformation (THED contribution shown in the middle) are shown for both material systems. Although the *magnitude* of thermal deformation is comparable, the *spatial distribution* differs drastically: the bi-metal configuration produces a deformation pattern that creates a low spot in regions between the HP and LP kidney around TDC/BDC, whereas the full steel VP experiences the highest points in these critical areas. Because the wave pattern is designed to interact constructively with the thermo-elastic deformations, this shift explains why a geometry optimized for the bi-metal plate can become unstable when applied to steel/steel—particularly at OC4, where thermal gradients and pressure loading are most severe.

On the right side of the figure is the maximum THED of the valve plate with the simulation revolution. The simulation framework calculates the thermal conditions after each completed revolution and updates the thermal boundary conditions; thus, each revolution is associated with a modified thermal deformation field. When a design completes the first 3 revolutions and then fails, it is usually due to thermal deformations. This will be relevant later in this section.

As the direct adaptation of the bronze wave pattern onto the steel VP was shown to be unwise, a new wave optimization was performed. Due to time constraints, the optimization scope was restricted to a full-wave concept with the same phase and frequency as the bronze design, while varying predominantly the wave amplitudes and offsets. This restriction was motivated by prior sensitivity results indicating that amplitude is typically the dominant parameter, while phase and frequency have secondary influence for the bronze configuration.

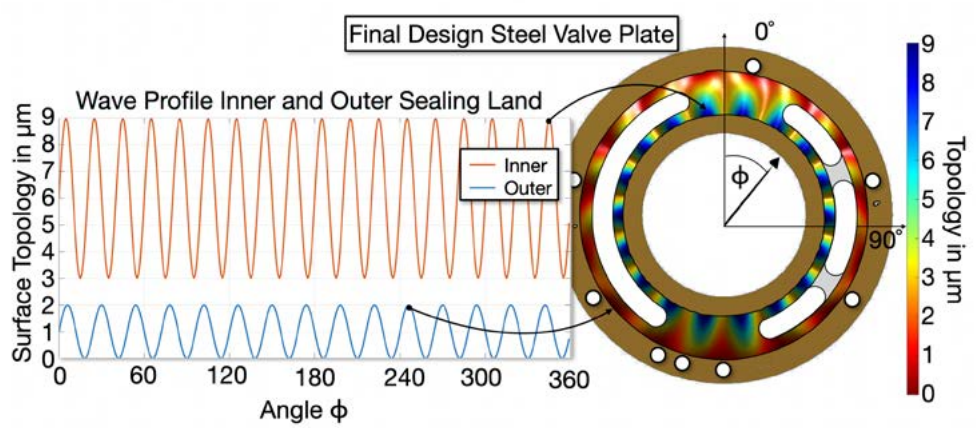

Figure 5.15. Final manufactured design for the steel valve plate with a full wave design and adapted sealing land width.

The resulting optimized steel design is shown in Figure 5.15 and differs significantly from the optimized bronze wave plate: whereas the bi-metal bronze plate used a larger outer-land amplitude (±3 µm) and a smaller inner-land amplitude (±1 µm) with a 7 µm offset, the optimized steel design essentially inverts this distribution by placing the dominant waviness on the inner sealing land (±3 with a 6 µm offset) and reducing the outer-land amplitude to ± 1µm. In addition, the steel design extends structuring across the full sealing-land circumference, including transition regions around TDC and BDC.

The performance predicted performance of this design is shown in Figure 5.16 in form of stacked power loss bars. The found design is predicted to substantially reduce power losses by more than 30% at 35°C inlet and 35% at 60°C inlet, when compared to the already well performing bronze wave design. This demonstrates the strong potential of steel/steel when the wave is designed for the correct thermo-elastic response. However, even with the redesigned wave pattern, a fully robust solution for OC4 at elevated temperature was not achieved within the limited optimization scope.

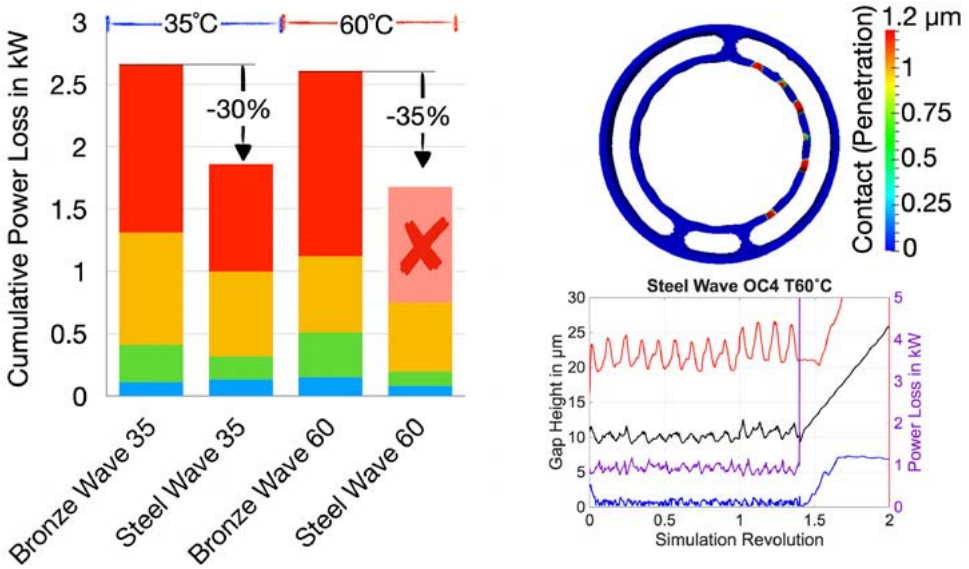

Figure 5.16. Final design steel valve plate after re-running full optimization (left). Right: Simulation result for OC4 Steel Wave 60, with predicted wear at the inner sealing land.

As shown on the right side of Figure 5.16 the steel design shows contact on the inner sealing land at OC4 at 60˚C inlet temperature. The graph on the bottom right of the figure confirms, that this is primarily due to a thermal deformation problem, as the first revolution delivered very good power losses of under 1 kW for this interface. For comparison, the standard valve plate produces about 2.4 kW power losses at this condition. However, after the simulation entered the second revolution the simulation predicted contact and crashed at the end of the high-pressure stroke. For this reason, the OC4 "result" should be interpreted as an initial-revolution indicator rather than a validated steady-state prediction, indicating that this design might experience problems at high speed, high pressure and high temperature.

Despite this remaining limitation, the significantly improved power losses and the stable behavior at 35°C across the majority of the operating domain motivated fabrication of the optimized steel valve plate to experimentally validate the low-temperature performance and to identify the limiting failure mechanisms in a controlled measurement campaign. A complete optimization over phase, frequency, amplitude distribution, offsets, and sealing-land geometry is expected to enable convergence across all operating conditions and both inlet temperatures; however, this extended design space was outside the available project timeframe. The following section therefore describes the manufacturing approach and the experimental validation of the optimized steel valve plate concept.

6. MANUFACTURING AND SURFACE MEASUREMENTS

Manufacturing of the steel meso-structured valve plates was carried out at Fraunhofer IWU (Chemnitz). IWU previously produced the step-structured slippers and the waved bronze valve plate discussed in Section 4 using precision turning, where the micro-topography is generated via a piezo-actuated tool path. For the present steel design, a laser-based structuring route was selected instead. Steel is well suited for ultrashort-pulse ablation, and the laser process offers (i) high geometric fidelity for shallow µm-scale features, (ii) flexible patterning without dedicated tooling, and (iii) robust repeatability for complex wave layouts. The applied laser setup with the resulting wave like structure is shown in Figure 6.17. It uses an femtosecond ultrashort-pulse TruMicro 2030 laser (average power: 20 W, wave length: 1030 nm, pulse rate: 300 fs–20 ps).

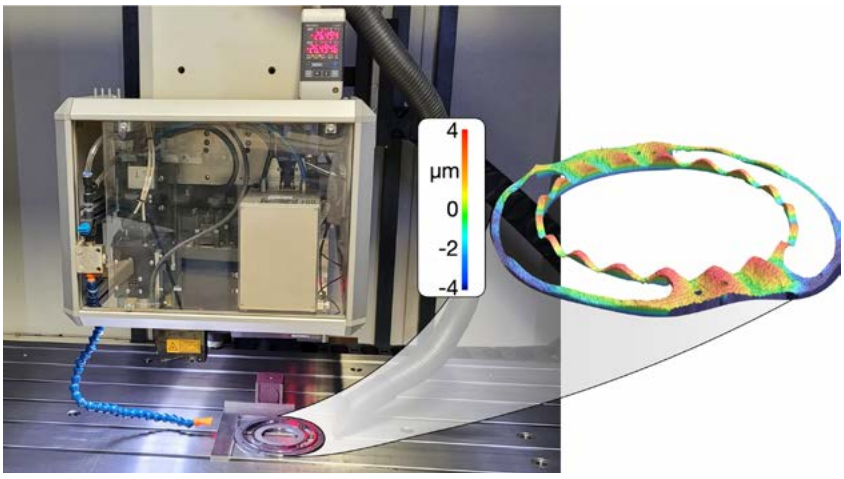

Figure 6.17. Laser structuring at the Fraunhofer IWU

A total of four steel valve plates were manufactured: two in an unhardened steel condition and two as hardened parts. The unhardened variant was intended to provide a more forgiving material response against the hardened cylinder block surface during possible mixed-lubrication events occurring at start-up or brief moments of dynamic changes. However, this assumption did not hold across the full operating envelope. In subsequent testing, the unhardened valve plates exhibited limitations at high-pressure conditions, whereas the hardened valve plates demonstrated clearly improved robustness at elevated pressures. The premature failure at high pressures motivated the focus on hardened steel valve plates for the high-pressure validation steps.
The manufactured valve plate and a superimposed 3D surface measurement are shown in Figure 6.18. The measured surface profiles on the inner land (IL) and outer land (OL) indicate that the realized wave amplitudes deviate moderately from the nominal targets: the OL is approximately ±1.5 µm (target ±1 µm), while the IL is approximately ±2.5 µm (target ±3 µm with offset). This deviation is likely influenced by the pre-existing flatness error of the valve plate prior to structuring (≈3.4 µm), which cannot be fully compensated by the laser structuring process. Nevertheless, the achieved geometry was considered acceptable, since the amplitudes remain within the tolerance band for which the simulations indicated robust performance.
Despite this deviation, the overall structure—frequency, phase relation, and relative amplitude concept—was realized consistently. The wave topographies are not visually apparent to the naked eye; instead, the structured region primarily becomes noticeable through characteristic color effects from light diffraction/reflection on the textured surface as captured in the photograph on the right.

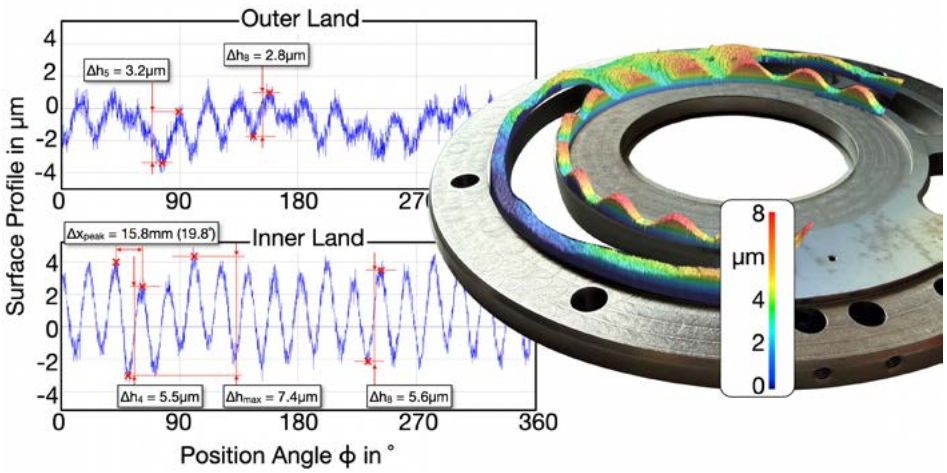

Figure 6.18. Manufactured waved full steel valve plate with surface scan.

With the steel valve plates manufactured and geometrically verified, the next section presents the experimental results for the steel/steel pairing, including performance mapping, temperature/particle monitoring, and the observed failure mechanisms under high-pressure and elevated-temperature conditions.

7. EXPERIMENTAL RESULTS: STEEL/STEEL VALVE PLATES (UNHARDENED THEN HARDENED)

Both variants of the meso-structured full-steel valve plate described in Section 6 (unhardened and hardened) were tested in the same measurement procedure described in section 3, using identical instrumentation for pressure, flow, torque, temperature and particle monitoring. The results are presented in two parts.

In Section 7.1, the unhardened steel waved valve plate (Steel WVP (S)) is directly compared against the waved bronze valve plate and the reference valve plate using **Rotating Kit 1**, for which complete reference measurements (Ref1) were available at both 40˚C and 60˚C inlet temperatures and including the low-speed measurements. Unfortunately, the unhardened steel plate failed prematurely, severely damaging the cylinder block and contaminating the pump with metallic debris, which necessitated a hardware change. Consequently, Section 7.2 focuses on the hardened steel valve plate measurements performed with a **replacement rotating kit (Kit 2)**. For Kit 2, a reference data set was available from other projects [12], but not for 60 °C and not for the ultra-low-speed conditions; furthermore, Kit 2 had already seen significant prior operation and therefore exhibits lower baseline efficiency than the new Kit 1. For this reason, the hardened steel results are evaluated primarily relative to Reference Kit 2 (Ref2) in terms of efficiency.

7.1. Rotating Kit 1 – Unhardened Steel Valve Plate

The unhardened steel wave valve plate was tested over the operating range 250–2100 rpm and 50–250 bar at 40˚C inlet temperature, before the test campaign was interrupted by a premature failure that occurred at 1800 rpm and 250 bar. Up to the onset of failure, Steel WVP (S) showed a remarkably strong efficiency potential and, in large parts of the map, outperformed both the new reference valve plate and the waved bronze valve plate—showing significant improvements even at full displacement.

Figure 7.19 summarizes this efficiency by showing the total efficiency difference of the Steel WVP (S) relative to Ref1 (left) and relative to the waved bronze valve plate (Bronze WVP) (right). The steel WVP yields

pronounced gains at low speed and low-to-medium pressures, reaching +10 percentage points over the reference and up to +16 percentage points over the bronze configuration at 250 rpm and high pressure (250 bar).

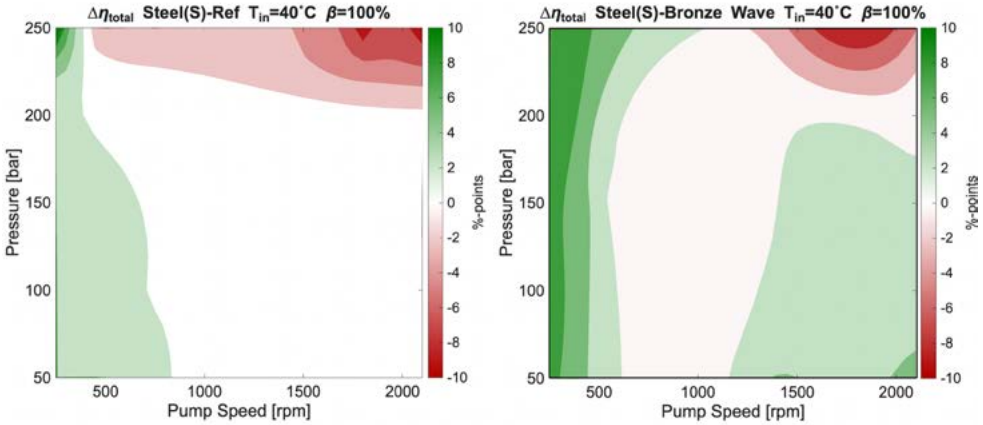

Figure 7.19. Efficiency difference between the unhardened steel WVP, the reference Kit1 and the bronze WVP at 40˚C inlet and 100% displacement

In the low-pressure region the advantage persists up to roughly 750 rpm, after which the performance approaches the reference level. At higher pressures, the efficiency initially remains improved but then degrades rapidly as the operating point approaches the failure region; immediately before failure, a strong drop is observed at high speed and 250 bar. Despite the failure, the magnitude of the low-speed improvement is significant. Increasing the total efficiency from 61% to 76% at 250 rpm, 250 bar and full displacement represents a substantial step toward electrification-relevant operating conditions, and the improvement over the already optimized waved bronze valve plate at low speed and high pressure indicates that the steel-specific wave interaction and thermal-mechanical behavior can produce different—and in parts more favorable—trends than the bronze-based design.

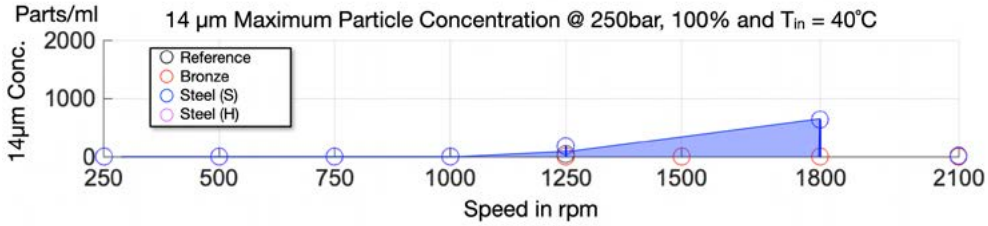

Figure 7.20. Maximum 14µm particle production at 250bar and 40˚C

Figure 7.20 shows the maximum concentration of 14 µm particles in the HP line at 250 bar and T_{in} = 40 °C for all tested valve plates. While Ref1 and the bronze WVP remain at low particle levels, Steel WVP (S) begins producing large particles already at 1250 rpm, and the particle concentration increases dramatically until the full failure at 1800 rpm. Notably the Steel WVP (H) did not produce any particles at this temperature and pressure. The resulting damage state is documented in Figure 7.21, where both the valve plate and the cylinder block exhibit severe wear, with grooves exceeding 0.5 mm in depth.

Figure 7.21. Failure of the unhardened steel valve plate after reaching 1800rpm and 250 bar at 40˚C.

This outcome highlights an important characteristic of steel/steel pairings: they are highly unforgiving once mixed lubrication and local contact occur. The meso-structure operates at the micrometer scale and is therefore sensitive to early damage. Moreover, the steel valve plate geometry was intentionally adapted (reduced sealing land width) to compensate for the additional hydrodynamic lift of the wave. Once wear occurs it removes or damages the meso-wave structure. After losing the additional hydrodynamic lift and the interface became critically underbalanced, accelerating contact, heat generation, and material removal. Post-test inspection further indicated plastic deformation of the unhardened plate, indicating that the high pressure loading deformed the VP, which is an effect that the simulation model cannot capture as only elastic deformation is considered.
These findings motivated the second steel configuration: a hardened wave valve plate intended to provide higher resistance against pressure-driven deformation and to improve robustness under the high-pressure operating

points. The following Section 7.2 therefore evaluates the hardened steel wave valve plate using Rotating Kit 2 and compares its efficiency performance to the corresponding reference for that kit.

7.2. Rotating Kit2 – Hardened Steel Valve Plate

The hardened steel waved valve plate (Steel WVP (H)) was tested with rotating kit 2 and is therefore evaluated exclusively against the corresponding reference measurement of kit 2 (Ref2). Figure 7.22 summarizes the resulting efficiency differences at 100% and 50% displacement. The largest gains occur at low pressure and in the operating regions that are most relevant for variable-speed duty cycles: at 100% displacement the total efficiency increases by more than 7 percentage points around 1000 rpm (from 80% to 87%), while at 50% displacement improvements of roughly 5 percentage points are observed at high speed (at 1800–2100 rpm from 70% to 75%). Importantly, these benefits are achieved with only minor efficiency drawbacks at high pressure and low-speed, where the efficiency decreases by approximately one percentage point.

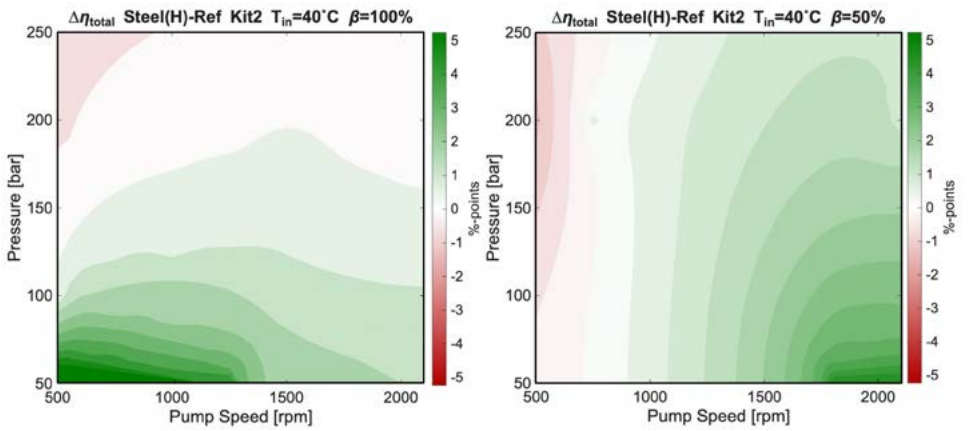

Figure 7.22. Efficiency difference between the hardened steel WVP and the reference for rotating kit 2 at 100% and 50 % displacement at 40˚C inlet.

The simulation-based performance trend is thereby validated and is further reflected in the operating-condition power-loss evaluation shown in Figure 7.23. In the design phase (Figure 5.16), the thermo-elastohydrodynamic optimization predicted a substantial reduction of valve-plate interface losses, primarily at OC3 and OC4 at 40 °C inlet temperature; the predicted relative reduction of interface losses corresponds to an absolute reduction on the order of 0.7 kW. Experimentally, a reduction of 1.1 kW

(~4%) is obtained when summing OC1–OC4 at 100% displacement. At 50% displacement the reduction increases to 3.6 kW (~17%). These results confirm that meso-structures can deliver a measurable reduction in losses even in a steel/steel pairing and across a wide speed range—an essential prerequisite for electrification-ready pump concepts where the machine is frequently operated in various speed domains.

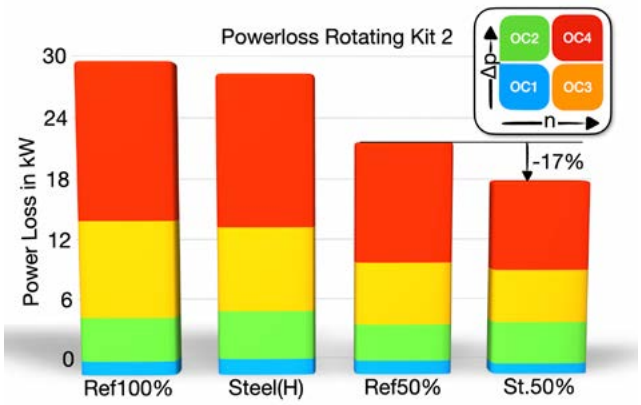

Figure 7.23. Efficiency improvements of the hardened steel VP at 100 and 50% at 40˚C inlet temperature for OC1-4.

Besides efficiency, the key system-level metric for electrified drives is torque demand, because required motor size, peak current capability, and thermal load scale directly with torque.

Figure 7.24 therefore compares torque losses at 50 bar and 200 bar. Due to the premature failure of the first steel valve plate and the lack of low-speed reference measurements for Kit 2, the comparison necessarily combines data from both rotating kits. As expected, Kit 1 exhibits lower torque losses overall, consistent with its higher efficiency baseline. Nevertheless, Steel WVP (H) (Kit2) shows very pronounced torque-loss reductions: at 50 bar and 20 rpm, the torque loss is reduced by approximately 66% (more than 10 Nm). By extrapolating the trend onto Kit1 (red dashed line), a further reduction is likely, amounting to 80% torque reduction when comparing the same rotating kit with each other. At 200 bar, the torque-loss reduction amounts to more than 30% at 250 rpm and remains around 20% over a broad speed range, which directly translates into a substantially reduced e-motor torque requirement and therefore offers a clear pathway to smaller and lower-cost electric drive systems.

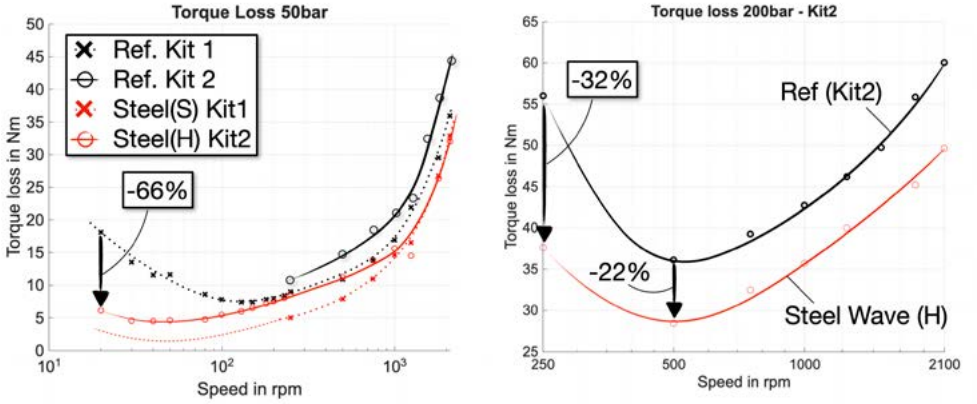

Figure 7.24. Improved low speed torque loss at 50 bar and 200bar for both rotating kits.

Up to this point, the hardened steel WVP confirms the simulation predictions and demonstrates strong potential. However, the results also confirm the key limitation of steel/steel pairings: once contact occurs under high temperature and elevated speed, wear becomes rapidly self-accelerating.

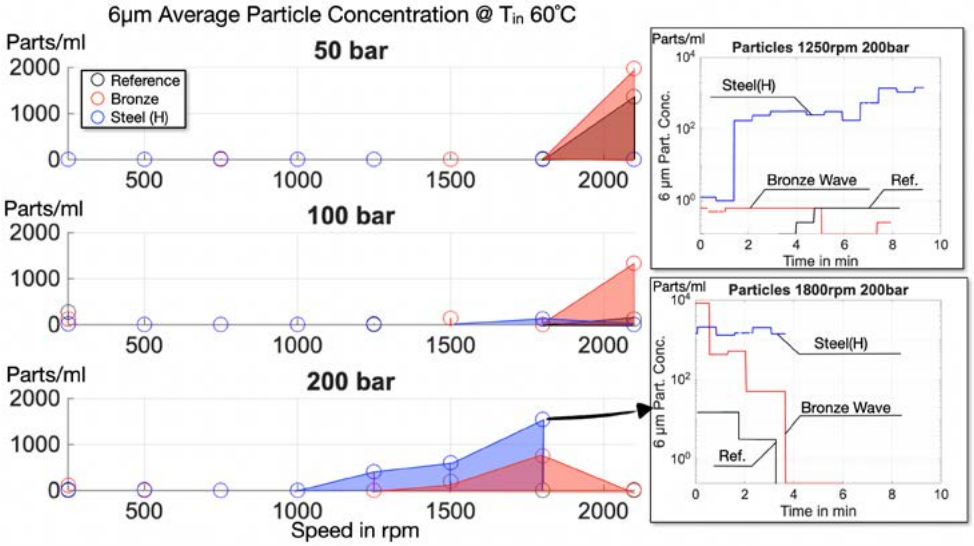

Figure 7.25. Average particle generation at 60˚C inlet temperature with zoom-ins at 1250 rpm and 1800 rpm at 200 bar.

Figure 7.25 shows the average 6 µm particle concentration in the HP-line for 60°C inlet temperature over the tested speed and pressure range. The 6 µm

class is chosen because it provides two practically relevant insights. First, it acts as an early warning indicator for impending failure in steel/steel interfaces: at 1250 rpm and 200 bar the particle concentration begins to rise and remains elevated over time even though the pump is still operating with acceptable efficiency. Continuing operation leads to further escalation, and at the final operating point (1800 rpm, 200 bar) the concentration increases strongly (note the logarithmic y-axis scaling), accompanied by the emergence of larger particles, which triggered the shutdown event. Second, the same measurement highlights the robustness of bronze-based pairings during short contact events: both the reference and the bronze valve plate can show elevated particle production at high speed and high temperature (e.g., the bronze waved valve plate at 1800 rpm and 200 bar), but the particle generation typically decays back toward zero, consistent with a gentle run-in mechanism. In contrast, steel/steel contact tends to remove micrometer-scale material and generate larger fragments, leaving grooves that promote further contact and accelerate damage. Post-test inspection of Steel WVP (H) showed severe grooving and wear depths on the order of several hundred micrometers, similar to the unhardened case, indicating that once the surface structure is damaged the interface can no longer act as a controlled hydrostatic/hydrodynamic bearing. If the VP would have had a similarly forgiving tribological material pairing, then the VP would have likely survived.

8. DISCUSSION

Across both rotating kits, the experiments demonstrate that meso-structured valve plates can be designed to significantly improve efficiency and reduce torque losses in operating regions that dominate variable-speed duty cycles. The steel designs, in particular, show that a hard/hard pairing does not inherently prevent performance benefits. On the contrary, the steel material allowed for a design of an even superior wave pattern, improving efficiency by more than 10% and torque loss by 60-80%, which directly supports electrification-driven requirements for compact and efficient motor-pump units.

At the same time, the measurements expose the central robustness challenge. While bronze-based systems can tolerate brief metal-to-metal contact through a forgiving run-in mechanism with limited wear volume, steel/steel contact can rapidly transition into severe, self-amplifying wear. Particle monitoring—especially in the 6 µm class—proved to be a sensitive early indicator of such failure onset, but preventing the underlying contact remains the primary requirement for a viable steel/steel implementation.

The simulation model predicted wear at high inlet temperature and elevated pressure, which the measurement confirmed. Previous designs optimized with the Caspar FSTI suite also indicated brief wear periods, something that a soft/hard material pairing usually accepted. However, the study has shown when designing a hard/hard pairing with meso-structures, contact needs to be avoided in all operating conditions, even when just brief. With a more time and exploring a larger design space, the author is confident that a suitable design can be found.

9. CONCLUSIONS AND OUTLOOK

This study confirms that meso-structured valve plates can improve the performance of axial piston pumps operated under electrification-relevant, variable-speed conditions. The structured bronze valve plate maintains the previously reported benefits and exhibits negligible wear, even when operated at steady-state thermal boundary conditions.

Extending the same design to steel/steel interfaces was not feasible, as the bi-metal bronze valve plate experiences different thermal expansion as a full steel one. Hence, a complete redesign had to be performed, yielding very different sealing land structures. The steel wave valve plate demonstrated even larger improvements in efficiency and torque demand, indicating that meso-structures can support lead-free and cost-relevant material strategies.

However, the steel/steel results also highlight that robustness, not peak efficiency, is the limiting factor. Once contact occurs at elevated temperature and speed, steel/steel interfaces can rapidly generate large wear volumes, destroy the micro-structure, and lose the hydrodynamic and hydrostatic balancing on which the design is based. Future work should therefore focus on mechanisms that allow short contact events without catastrophic damage, while simultaneously exploring a larger design space to avoid contact even at the most extreme conditions.

When combining these measured findings of over 80% torque reduction and 10-30% efficiency improvements, with the similarly impressive meso-structured slippers published in previous research [4], it becomes clear, that pump designs can be significantly improved when combining surface structures to all hydrostatic bearings. With these additions, meso-structuring offers a high-potential pathway to electrification-ready, lead-free axial piston pump designs that combine efficiency gains with reliable long-term durability.

ACKNOWLEDGEMENTS

Abstract

With the shift towards electrification and the advancement of quieter internal combustion engines, the noise produced by axial piston pumps has gained increased attention. While fluid-borne noise emissions resulting from pulsating flow and airborne noise emissions through the housing of hydraulic pumps are well researched, studies on structure-borne noise emissions–transmitted to adjacent structures via the pump's mechanical mounting–are rare. One method to describe these emissions is through blocked forces, which allow for a receiver-independent characterization of structure-borne noise sources. In this publication, the excitation characteristics of an axial piston pump are analyzed based on blocked forces, which can be projected onto one or several points at the interface using the so-called virtual point transformation. The extent to which the pump's description differs when using one or two virtual points is investigated. The structure-borne noise excitation caused by the pump is examined during a speed run-up, allowing for the identification of dominant excitation degrees of freedom. It is indicated that for the axial piston pump under investigation, a source description utilizing a single virtual point is sufficient.

Keywords. Axial Piston Pumps, Structure Borne Noise, Blocked Forces, Virtual Point Transformation

1. INTRODUCTION

In addition to the airborne noise (ABN) directly emitted from the pump housing, hydraulic pumps also emit fluid-borne (FBN) and structure-borne noise (SBN) through the connection points into the overall system. Previous studies [1], [2], [3], [4], [5] indicate that these noise contributions have a significant impact on the overall sound power level of hydraulic systems. Fiebig [1] even states that hydraulic systems typically exhibit sound power levels that are 4 to 12 dB(A) higher than those of the pumps themselves, concluding that it is

All Open Access articles are peer-reviewed, distributed under the Creative Commons Attribution-Non Commercial 4.0 International

unlikely that the ABN from the pumps housing constitutes the main sound power sources in such hydraulic systems.
While the excitation due to pressure pulsation is well-researched [6], [7] and established methods and standards [8], [9] for its determination exist, the SBN transmitted through the pump mounting points into the system remains largely unexplored. Fiebig's investigation [1] shows that this type of excitation can be a major cause of noise in hydraulic systems. In his study the dynamic forces generated by the pump are transmitted as SBN to the electric motor via the pump mounts. The motor and other large components act as noise radiators, converting this SBN energy into ABN. Therefore, knowing the pump emitted SBN at the interface also opens up various optimization potentials, such as optimizing the matching of excitation characteristics and system behavior through finite element simulation or designing decoupling elements between the pump and motor, as well as between the motor and the motor base.
A promising method to experimentally determine the SBN excitation at the pump mounting points independently of the receiver system is the "In situ Blocked Force Method" described in the ISO20270 standard [10], where the so-called blocked forces are used to characterize SBN sources. In [11], it has been demonstrated that this method can be successfully applied to an axial piston pump, thereby enabling the assessment of the SBN emission of hydraulic pumps.
In the following study, the source characterization based on experimentally determined blocked forces is further investigated. Therefore, the source description of an axial piston pump using one or two virtual contact points is compared. Furthermore, it is examined which excitation degree of freedom (DoF) are the most dominant for the investigated pump.

The publication is structured as follows: First, the theoretical foundations of the “Virtual Point Transformation” and “Component-based Transfer Path Analysis” are introduced. This is followed by a method for aggregating virtual point forces and torques into a single force and torque quantity. These concepts are then applied to an axial piston pump, and the results of the different methods are presented. Finally, the key insights are summarized, and an outlook on future work is provided.

2. METHODS

A fundamental prerequisite for analyzing SBN excitation from a hydraulic pump is the determination of quantities that describe the pump-induced SBN at the interface to a receiving system. Consequently, the following section introduces various concepts of transfer path analysis and source characterization.

2.1. Virtual Point Transformation

A critical aspect in the description of SBN sources is the definition of the interface between the source and the receiver system. Particularly when the excitation of a source is to be combined with the behavior of a passive receiver, the coupling points must be clearly defined. However, this is often not the case for quantities determined through measurement techniques, as source excitation and receiver behavior are measured in different ways or using different measurement setups.
One way to overcome this is the so-called Virtual Point Transformation (VPT). The concept was first introduced by van der Seijs et al. [12] and aims to project interface quantities (interface DoF) onto a set of interface displacement modes (IDMs), thereby enabling a clear

definition of the interface. When IDMs correspond to the six DoF (3 translational and 3 rotational) of a virtual point (VP), they are also known as rigid interface modes or virtual point DoF. A detailed description of the mathematical framework of the VPT is beyond the scope of this publication and has already been thoroughly described in various studies [12], [13], [14].

As the designation of the VP DoF as rigid interface modes implies, the classical VPT is based on the rigid body assumption. This means that the motions or forces projected onto a VP via VPT are assumed to behave as those of a rigid body. This condition can only be satisfied within a limited frequency range, depending on the structural dynamic behavior of the interface. In particular, the geometry and material properties of the interface significantly influence this range. If the rigid body condition is not fulfilled, the interface can no longer be fully described by the VP.

If a single VP is insufficient to describe the interface, as it is often the case for systems with multiple mounting points or flange-like contacts [15], [16], multiple VPs can be employed to represent the interface. The rigid body condition must then be satisfied only for each individual VP, thereby typically enabling the description of the source SBN excitation up to higher frequencies.

For the axial piston pump investigated, featuring a two-bolt mounting flange according to DIN ISO 3019-1 [17], two VPT setups were examined: one with a single VP (1VP setup) located at the center of the interface, and another with two VPs positioned at the mounting points (2VP setup). Figure 1 schematically illustrates both setups along with their respective interface DoF. While the 1VP setup requires only six DoF to describe the interface, the 2VP setup necessitates twelve DoF.

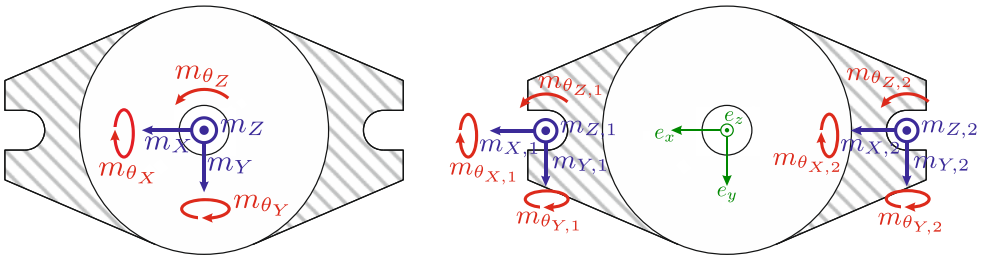

Figure 1: Schematic illustration of VPT setups for the axial piston pump. Left: 1VP setup with six DoF. Right: 2VP setup with twelve DoF.

2.2. Component-based Transfer Path Analysis

The primary objective of Transfer Path Analysis (TPA) is to identify the contributions of various noise sources and transmission paths to the overall noise level. A key step in TPA is source characterization, which aims to define a set of interface quantities that accurately describe the source's excitation at the interface with the passive receiving structure. Various interface quantities can be utilized for this purpose; however, for analyzing the source excitation itself, receiver-independent interface quantities are particularly valuable. When such quantities are used to describe the source, the TPA approach is referred to as component-based TPA (cTPA).[18]

The three most common methods of cTPA are illustrated in Figure 2. The “Free Velocity” method represents the extreme case where the source operates under freely vibrating conditions. In this scenario, the velocities measured at the interface $\mathbf{u}_2^{\text{free}}$ are independent of

the receiver and thus represent a pure characteristic of the source. However, this method is unsuitable for hydraulic pumps, as a motor is required to drive the pump. The other extreme case is the "Direct Blocked Force" method, which assumes that the receiver connected to the source is infinitely stiff. Under this assumption, the forces measured at the interface, known as blocked forces $\mathbf{f}_2^{\mathrm{eq}}$, are independent of the receiver. Nonetheless, this method presents practical challenges, as detailed in [11].

A method that avoids such extreme boundary conditions is the "In Situ Blocked Force" method, which was first introduced by Moorhouse et al. [19]. Moorhouse et al. demonstrated that the blocked forces can also be determined in systems that are not infinitely stiff by applying a matrix inversion procedure. By means of this two-stage approach, the influence of the receiving system can be removed, enabling the determination of the receiver-independent blocked forces. This approach allows for the determination of blocked forces *in situ*, meaning within the typical application and is adaptable to various SBN sources. Consequently, it has gained prominence in recent years, particularly in the automotive industry, and has been standardized in ISO 20270 [10]. A detailed description of its application to an axial piston pump is provided in [11], [13].

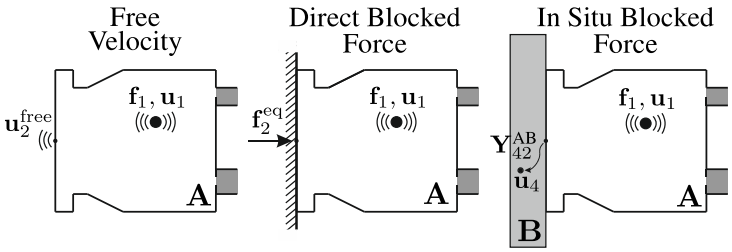

Figure 2: Common methods of source characterization in cTPA

The in situ blocked force method is based on the formula:

$$\mathbf{f}_2^{\mathrm{eq}} = (\mathbf{Y}_{42}^{\mathrm{AB}})^{+}\mathbf{u}_4 \tag{1}$$

which states that the blocked forces $\mathbf{f}_2^{\mathrm{eq}}$ can be determined by multiplying the vibration responses at the so-called indicator sensors $\mathbf{u}_4$ with the inverted transfer behavior $\mathbf{Y}_{42}^{\mathrm{AB}}$ from the interface to the indicators in the coupled state (denoted by $(\cdot)^{\mathrm{AB}}$). The symbol $(\cdot)^{+}$ denotes the pseudoinverse, as the transfer matrix $\mathbf{Y}_{42}^{\mathrm{AB}}$ is typically not a square matrix. From Equation 1, it follows that the method consists of two main steps:

Step 1**:** Determination of the transfer behavior $\mathbf{Y}_{42}^{\mathrm{AB}}$ from the interface to the indicators. This is typically achieved by exciting close to the interface using an impulse hammer or a shaker and measuring the vibration response at the indicators, usually with accelerometers.

Step 2: The source is in operation and the vibrations at the indicators $\mathbf{u}_4$ are measured. Using Equation 1, the blocked forces can then be calculated.

It is crucial to note that the blocked forces are determined exactly at the locations where the interface was excited with the impact hammer in Step 1. Because, in the in-situ blocked force method, the source and receiver are mechanically coupled, these excitation points are not located directly on the interface but rather in its vicinity, typically on the receiver structure. Consequently, the spatial positions of the blocked forces depend on the receiver

geometry in the region around the interface, and the resulting blocked forces are therefore not completely receiver independent.
This receiver-dependency can be eliminated by transforming the blocked forces into VP coordinates, which are uniquely defined by the source itself. However, instead of transforming the blocked forces $\mathbf{f}_2^{\mathrm{eq}}$ into VP blocked forces and torques $\mathbf{m}_2^{\mathrm{eq}}$ after performing the in-situ blocked force TPA, it is also possible to transform the transfer matrix $\mathbf{Y}_{42}^{\mathrm{AB}}$ beforehand. The measured matrix is usually denoted $\mathbf{Y}_{42,\mathrm{uf}}^{\mathrm{AB}}$, where the subscripts $(\cdot)_{\mathrm{u}}$ and $(\cdot)_{\mathrm{f}}$ are added to indicate that this corresponds to the original form of the matrix. The transformed matrix is denoted $\mathbf{Y}_{42,\mathrm{um}}^{\mathrm{AB}}$, as only the forces are transformed into VP coordinates, whereas the measured motions at the indicator sensors are not transformed. This has the benefit that by transforming only the forces into VP coordinates, the number of force DoF is reduced, while the number of motion DoF remains constant. This results in a higher overdetermination of $\mathbf{Y}_{42,\mathrm{um}}^{\mathrm{AB}}$ compared to $\mathbf{Y}_{42,\mathrm{uf}}^{\mathrm{AB}}$, leading to a more stable matrix inversion. In the ISO 20270 standard an overdetermination by a factor between 2 and 3 is suggested. By applying the VPT exclusively to the forces, the recommended overdetermination factor can be achieved with smaller number of sensors to capture the vibrations $\mathbf{u}_4$.
It is important to note, that both matrices, $\mathbf{Y}_{42,\mathrm{uf}}^{\mathrm{AB}}$ and $\mathbf{Y}_{42,\mathrm{um}}^{\mathrm{AB}}$, represent the transfer behavior $\mathbf{Y}_{42}^{\mathrm{AB}}$ schematically shown in Figure 2. However, $\mathbf{Y}_{42,\mathrm{uf}}^{\mathrm{AB}}$ uses the original physical excitation points of the impact hammer or shaker, whereas $\mathbf{Y}_{42,\mathrm{um}}^{\mathrm{AB}}$ uses the VP DoF.
Using this, the relation for the in situ blocked force TPA becomes

$$\mathbf{m}_2^{\mathrm{eq}} = (\mathbf{Y}_{42,\mathrm{um}}^{\mathrm{AB}})^{+}\mathbf{u}_4, \tag{2}$$

which allows for the determination of the blocked forces directly in the VP coordinates.
An additional benefit of the in situ blocked force method is that it allows for direct validation of the source description through the blocked forces. This validation step is referred to as On-Board Validation (OBV). For this purpose, additional validation sensors $\mathbf{u}_3$ are located on the receiver, which are not used for determining the blocked forces. The transfer behavior $\mathbf{Y}_{32,\mathrm{uf}}^{\mathrm{AB}}$ can be directly determined during the measurement of $\mathbf{Y}_{42,\mathrm{uf}}^{\mathrm{AB}}$, resulting in minimal additional effort. After the blocked forces have been determined using Equation 2, the movement at the validation points $\mathbf{u}_3$ can be predicted using the blocked forces through the relationship

$$\mathbf{u}_3^{pred.} = \mathbf{Y}_{32,\mathrm{um}}^{\mathrm{AB}}\mathbf{m}_2^{\mathrm{eq}}. \tag{3}$$

These predicted motions can then be compared with the directly measured signals $\mathbf{u}_3^{meas.}$, providing an initial validation of the blocked forces. If the blocked forces are unable to describe the excitation by the source, or if numerical errors occur during the inversion of the matrix $\mathbf{Y}_{42,\mathrm{um}}^{\mathrm{AB}}$, this will be evident in the OBV.

2.3. Aggregation of Blocked Forces and Blocked Torques Using Vector Norms

As already explained in [13], blocked forces and torques can be summarized using the vector norm, which is particularly useful when the goal is a straightforward evaluation of a SBN source. Here, the aggregation of blocked forces and torques is specifically used to analyze whether the source description with two VPs is advantageous or if a single VP is sufficient. For the single VP case, the procedure is identical to that in [13], and the force or torque vector norm is determined as follows:

$$\|\mathbf{F}_{1VP}\| = \sqrt{{F_x}^2 + {F_y}^2 + {F_z}^2} \tag{4}$$

$$\|\mathbf{M}_{1VP}\| = \sqrt{{M_x}^2 + {M_y}^2 + {M_z}^2} \tag{5}$$

In contrast, the 2VP setup introduces additional complexity because not all six force and torque components can be directly combined using vector norms without distinguishing between the two VPs. Moreover, the coupling between the two VPs must be taken into account: unlike in the single-VP case—where only one VP emits vibration power—the two-VP setup also involves power exchange between the VPs.

In general, for SBN sources described by multiple contact points or VPs, two special cases may occur. The first case arises when the VPs are not coupled, i.e., they behave completely independently. This condition is analogous to neglecting transfer-mobilities between coupling points in a power-based approaches. Previous investigations have shown that this simplification can be valid, for example, in systems with multiple point contacts that are connected to the receiver via resilient mounts [20]. In such cases, it is reasonable to treat the two VPs as separate sources. However, if the primary goal is to minimize the number of evaluation quantities, energetic aggregation of all force and torque components of the two VPs can also be considered. However, for the investigated axial piston pump, this first case is likely less relevant. Instead, it can be assumed that the pump's steel flange behaves like a rigid body over a broad frequency range, leading to strong coupling between the two VPs in the 2VP setup.

The second special case, which is therefore more plausible for the investigated axial piston pump, is that the VPs of a SBN source behave like points of a rigid body. In this case, the forces and torques of the two VPs can be geometrically combined into a total force and a total torque as follows:

$$\mathbf{F}_{2VP} = \mathbf{F}_{VP1} + \mathbf{F}_{VP2} \tag{6}$$

$$\mathbf{M}_{2VP} = \mathbf{M}_{VP1} + \mathbf{M}_{VP2} + \mathbf{r}_{VP1} \times \mathbf{F}_{VP1} + \mathbf{r}_{VP2} \times \mathbf{F}_{VP2} \tag{7}$$

Assuming rigid-body behavior is fully satisfied, these quantities are coherently combined in phase. Subsequently, the vector norms of the resulting force vector $\|\mathbf{F}_{2VP}\|$ and the resulting torque vector $\|\mathbf{M}_{2VP}\|$ can be calculated similarly to the 1VP setup. A key point is that the total torque in Equation 7 introduces terms of the form $\mathbf{r} \times \mathbf{F}$, which represent torques arising from the rigid coupling of the VPs [21]. The vectors $\mathbf{r}$ denote the relative vectors from a reference point to each respective VP. For later comparison with the single VP setup, the position of the sole VP in the 1VP setup can be chosen as the reference point. Provided that the interface behaves as a rigid body, the norms $\|\mathbf{F}_{1VP}\|$, $\|\mathbf{M}_{1VP}\|$, and $\|\mathbf{F}_{2VP}\|$, $\|\mathbf{M}_{2VP}\|$, should then be identical. However, it is evident that this method of combining forces and torques of the 2VP setup negates the primary advantage of describing the source with two VPs, which is to require the rigid body condition to be fulfilled for only one VP.

When neither of the two special cases—independence between the individual virtual points or fulfilment of the rigid-body condition—is met, a straightforward aggregation of the SBN excitation on a force or torque level is not possible. Instead, extended approaches, such as power-based methods, must be applied [22].

For the following investigation of the axial piston pump, the aggregation of the 2VP setup

under the assumption of rigid-body conditions is used to assess whether a description with two VPs is necessary, or if a single VP is sufficient.

3. RESULTS

In the following section, the results of the concepts introduced earlier will be presented, with a particular focus on comparing the 1VP and 2VP setups. It is important to note that all transfer functions, also called Frequency Response Functions (FRFs), were obtained through excitation with a shaker. This excitation method allowed for a sufficient signal-to-noise ratio to be achieved starting from 140 Hz. Consequently, all subsequent frequency-dependent quantities will be presented only for frequencies greater than 140 Hz. This lower frequency limit is sufficient to characterize the SBN of 9-piston axial piston pumps at rotational speeds of approximately 1000 rpm and higher, as the first harmonic at 1000 rpm occurs at 150 Hz. The upper considered frequency is 5 kHz, as this frequency is cited in the literature as the upper threshold for acoustic analysis of axial piston pumps [23].
All the results shown in the following were obtained with the support of the open-source Python package pyFBS [24], [25].

3.1. Virtual Point Transformation Quality

A straightforward method for analyzing the quality of the VPT is through the "Consistency" criterion. This metric assesses how accurately the measured forces or motions can be represented by the corresponding VP forces and motions. To determine the consistency, the measured transfer matrix is first transformed into VP coordinates and then mapped back to the original coordinates using the inverse VPT. If the rigid-body condition is fully satisfied, the reconstructed transfer matrix will match the originally measured matrix. However, if the rigid-body condition is violated, the reconstructed matrix will only contain the rigid-body motion, while the flexible dynamics are filtered out. Comparing the original and reconstructed matrices therefore serves as a quality indicator for how well the rigid-body assumption is fulfilled.
A detailed description of the consistency calculation is omitted here, as it would require a full introduction to the VPT, which is beyond the scope of this publication. The procedure is explained in [15], where it is also shown how, based on the original and reconstructed matrices, a single scalar value can be derived for impacts and sensors, using the vector norm. These values are referred to as overall sensor consistency and overall impact consistency, respectively.
In the following, the focus is on impact consistency, as the VPT is applied solely to the forces, as previously mentioned. The overall impact consistency for the 1VP and 2VP setups is illustrated in Figure 3. As demonstrated, the impact consistency for both setups remains approximately 100 % up to around 4.3 kHz. Beyond this frequency, the impact consistency of the 1VP setup declines sharply, whereas that of the 2VP setup remains high. According to these results, it can be concluded that the rigid body condition is satisfied for the 1VP setup only up to 4.3 kHz. For frequencies exceeding 4.3 kHz, the utilization of two VPs in the interface description provides a distinct advantage in impact consistency.
However, the determination of consistency is based solely on the measured transfer matrices and the geometric properties of the VPT. It does not allow for an assessment of whether the rigid body condition is also met during operation.

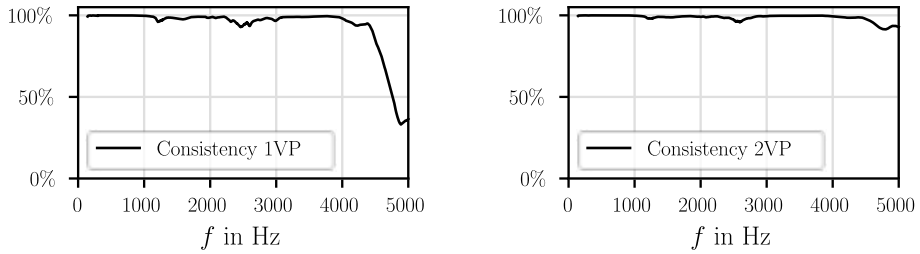

Figure 3: Overall impact consistency. Left: 1VP setup. Right: 2VP setup.

3.2. Results Stationary Operating Point

In the next step, the SBN excitation of an axial piston pump at a stationary operating point will be examined. Specifically, the operating point at $n = 2000$ rpm, $p = 200$ bar, and the maximum displacement volume $V_d = V_{d,max}$ will be considered. The pump investigated in the following study is suitable for use in a 6-ton mini excavator.

Figure 4 presents the results of the OBV for the 1VP and 2VP setups. In each case, the velocity measured directly at the validation sensors $\mathbf{u}_3^{meas.}$ is compared with the velocities predicted based on the blocked forces $\mathbf{u}_3^{pred.}$. The displayed velocity represents the vector norm of the three sensor channels of a triaxial accelerometer. A reference value of $v_{ref} = 10^{-6}$ m/s is used to calculate the dB value. Circles and crosses at the peaks of the harmonics were used to highlight the agreement at those frequencies.

It can be observed that both setups yield very similar results up to the 8th harmonic, i.e., 2.4 kHz, and that the direct measurements agree closely with the predictions within this frequency range. For the 1VP setup, the predictions become less accurate at certain higher harmonics, whereas for the 2VP setup, the predictions and measurements show good agreement, except at the 11th harmonic. Overall, it can be concluded that for both setups, the blocked forces and torques are capable of describing the SBN excitation of the axial piston pump, with the 2VP setup providing slightly better results for frequencies above 2.4 kHz.

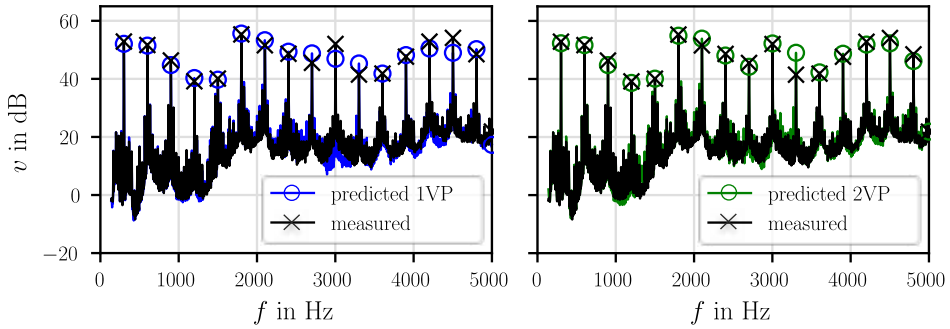

Figure 4: OBV for a stationary operating point. Left: 1VP setup. Right: 2VP setup.

The OBV method enables evaluation of whether interface quantities can describe the excitation caused by a SBN source. The primary objective of this study, however, is to quantitatively investigate the SBN excitation caused by the axial piston pump. Therefore, in the following the blocked forces and torques will be examined. Figure 5 presents the

aggregated blocked forces $\|\mathbf{F}\|$ and blocked torques $\|\mathbf{M}\|$ at the same operating point as the OBV, for both VP setups. For the calculation of the dB values a reference value of $F_{ref} = 10^{-6}$ N is used for forces and $M_{ref} = 10^{-6}$ Nm for Torques.
Before comparing the curves, it is important to first comprehend the differences in the vector norms between the two setups. In the 1VP setup, rigid-body behavior of the entire interface is assumed from the outset, and blocked forces and torques are determined under this assumption. The vector norms are then simply computed using Equations 4 and 5. In contrast, for the 2VP setup, blocked forces and torques are calculated under the condition that rigid-body behavior is satisfied for each VP individually, but not necessarily for the entire interface. The rigid-body assumption between the two VPs—and thus for the full interface—is only imposed later, when the forces and torques from the two VPs are aggregated using Equations 6 and 7.
Consequently, if $\|\mathbf{F}\|$ and $\|\mathbf{M}\|$ of the 1VP and 2VP setups agree, the rigid-body assumption must hold true during the aggregation of the 2VP setup via the vector norms, and thus also for the entire interface. Alternatively, if rigid-body assumption does not hold true, applying Equations (6) and (7) would be expected to produce discrepancies between $\|\mathbf{F}_{1VP}\|$ and $\|\mathbf{F}_{2VP}\|$ as well as $\|\mathbf{M}_{1VP}\|$ and $\|\mathbf{M}_{2VP}\|$. Therefore, the comparison of the vector norms between the two setups serves as a qualitative indicator of whether the rigid-body assumption is satisfied during operation.

Figure 5 shows that both $\|\mathbf{F}\|$ and $\|\mathbf{M}\|$ agree almost perfectly between the setups, with only minor deviations. This confirms what was already suggested by the evaluation of the impact consistency, namely that the interface behaves like a rigid body over a wide frequency range. However, it is interesting to note that while the consistency for the 1VP setup declines beyond 4.3 kHz, the determined vector norms still show good agreement at higher frequencies. This is likely because the consistency criterion is significantly more sensitive to violations of the rigid-body condition than the qualitative comparison of the norms. Yet, for the analysis of SBN excitation, the blocked forces and torques are of primary relevance, and these agree well for both setups. As a result, the considerably more complex interface description using two virtual points is not necessary, particularly as the dominant harmonics lie in the low-frequency range, where agreement is strongest.

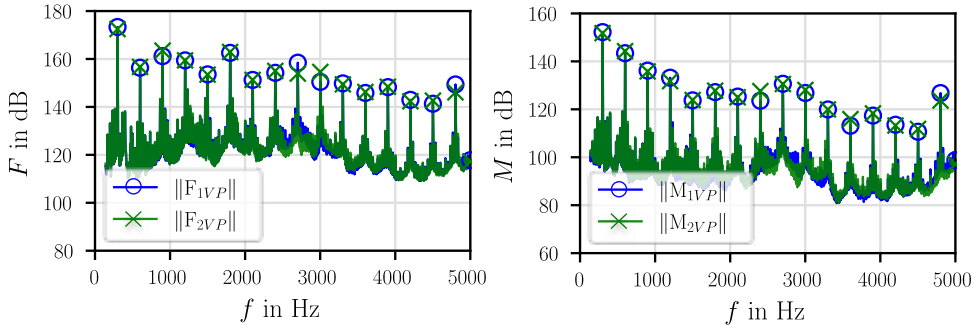

Figure 5: Comparison of SBN excitation for the 1VP and 2VP setup for a stationary operating point. Left: Norm blocked forces $\|\mathbf{F}\|$. Right: Norm blocked torques $\|\mathbf{M}\|$

3.3. Results Run-Up

As the final part of the analysis, the excitation of the SBN caused by the axial pistons during a speed run-up at a pressure of $p = 200\,\text{bar}$ and maximum displacement volume $V_d = V_{d,max}$ is examined. For each discrete speed step, a distinct excitation spectrum is obtained. Since analyzing each individual spectrum in detail would not be efficient, the spectra are consolidated by calculating the root-mean-square (RMS) value of each spectrum. The entire frequency range from 140 to 5000 Hz is considered in this calculation. However, as shown in Figure 5, it is expected that the resulting RMS value is primarily determined by the dominant low-frequency harmonics.

The corresponding blocked forces and blocked torques in each spatial direction are presented in Figure 6. Specifically, both the forces and torques of the 1VP setup $F_{i,1VP}$, $M_{i,1VP}$ and the total forces and torques per coordinate direction for the 2VP setup $\sum F_{i,2VP}$ $\sum M_{i,2VP}$ are shown. These results match almost perfectly, except for minor deviations in the torque around the z-axis, confirming the findings of the previous analysis.

For torques, the sum of the 2VP torques is additionally plotted with dotted lines, excluding the $\mathbf{r} \times \mathbf{F}$ terms of Equation 7. As expected, this omission has no effect on the torque in the x-direction $\sum M_{X,2VP}$, because the two VPs in the 2VP setup are displaced only along the x-direction (see Figure 1). However, for the other two directions, the torque is significantly underestimated when the $\mathbf{r} \times \mathbf{F}$ terms are omitted. This highlights the strong coupling between the two VPs and emphasizes that these terms must generally be taken into account when aggregating the torques of SBN sources described with multiple connection points.

Each plot also shows the vector norm of the 1VP forces $\|\mathbf{F}_{1VP}\|$ and torques $\|\mathbf{M}_{1VP}\|$. The vector norms of the 2VP setup are not shown, as they are nearly identical. This representation makes the dominant force or torque contribution at each rotational speed immediately visible, aiding in root-cause analysis and the development of countermeasures at critical operating points. If a critical operating point is identified, a detailed spectral analysis can help to determine harmonics responsible for strong SBN excitation.

For the axial piston pump under investigation, a key observation is that the force excitation is primarily dominated by the force in the y-direction, while the force in the z-direction contributes minimally to the overall excitation. Analysis of torque excitation revealed that all three rotational DoF significantly contribute to the overall excitation, depending on the rotational speed. For example, at 1500 rpm, the excitation is predominantly governed by torque around the z-axis, corresponding to axial torque excitation.

4. CONCLUSION AND OUTLOOK

To analyze the SBN excitation generated by an axial piston pump, the concepts of VPT and the in-situ blocked force TPA were introduced. For the investigated pump, a key objective was to compare the interface description of the pump using one versus two VPs.

Theoretical considerations indicate that that aggregating the interface forces and torques of multiple VPs using the vector norm is reasonable only when the VPs are largely independent or when the rigid-body assumption holds. In the latter case, however, it may be more appropriate to model the interface with a single VP from the outset.

This was also the case for the examined axial piston pump. When investigating the difference between the 1VP and 2VP setups, it was found that the coupling between the two VPs in the 2VP setup was very strong. Within the investigated frequency range, their interaction could be approximated as rigid body coupling. Consequently, representing the source with two VPs is unnecessary, and a single-VP representation in the center of the interface is more appropriate. However, it is important to note that this conclusion applies specifically to the pump under investigation and to the analysis of SBN excitation. As the OBV results show, describing an SBN source with multiple VPs can be advantageous—or even necessary—especially at higher frequencies.

Based on the blocked forces determined for a single VP, the SBN excitation of the pump can be analyzed for the individual DoF of the VP, enabling the identification and investigation of critical operating points. For the examined pump force excitation is predominantly in the y-direction, with minimal excitation in the z-direction. In contrast, for torque excitation, all directions contribute to the overall excitation, depending on the rotational speed of the pump.
A limitation of the applied approach is that forces and torques are evaluated separately and cannot be combined directly due to their differing physical units. A solution to this is provided by power-based approaches. By combining forces and torques with the corresponding velocities and angular velocities, power quantities for each DoF can be derived. This would allow for direct comparison between translational and rotational excitation.
Another promising direction is to study excitation in conjunction with a specific target system. Such an analysis would make it possible to evaluate which excitation DoF has the greatest influence on a specific target, like a microphone at the diver's ear, providing a more application-oriented understanding of the SBN.

From 2022 to 2023, he was a researcher at the Institute of Mobile Machines (Mobima) at KIT. Since 2023, he has been pursuing a Ph.D. at Mobima in cooperation with Bosch Rexroth AG. His research focuses on developing a method for evaluating the structure-borne noise emissions of axial piston pumps.

Marcus Geimer received his Diploma degree in mechanical engineering from the RWTH Aachen University, Aachen, Germany in 1990. In 1995, he received his Ph.D. from the Institute of Hydraulics and Pneumatics, today named Institute for Fluid Power Drives and Systems, RWTH Aachen University. He started his industrial career in 1995 in the field of construction at the company Krupp Berco Bautechnik GmbH, Essen (Germany). There, he was the leader of the research group for hydraulic breakers. In 2000, he changed to Bucher Hydraulics Gmbh, Klettgau (Germany), where he led the construction and customer development for mobile hydraulics. Since 2005, he is a full professor and director at the Institute of Mobile Machines (Mobima), at the Karlsruhe Institute of Technology KIT, Germany. Hydraulic and electric drives for the traction drive as well as for the working functions and controls for mobile machines are main research areas of the institute.

Review of Single-Sided and Double-Sided Axial Piston Machine Characteristics

Thomas Heeger, Liselott Ericson

Linköping University, Department of Management and Engineering, Division of Fluid and Mechatronic Systems, Linköping, Sweden, liselott.ericson@liu.se

Abstract.

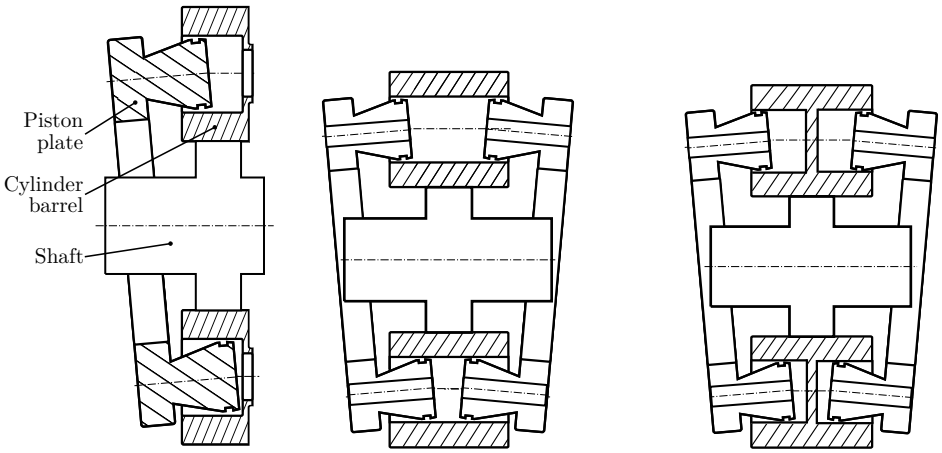
Most conventional axial piston machines have a single rotating group. However, double-sided machines with another set of pistons can have the same displacement with different properties. Double-sided machines can counteract forces and moments between each side and therefore reduce structure-borne noise and bearing loads. Further, there are different setups of double-sided machines, with a main difference being if there is a phase shift between the sides. This paper qualitatively compares the properties of different machine setups.

Keywords. Axial piston pump, fluid power, pump design, double-sided machine.

1. INTRODUCTION

There are various types of positive displacement machines. One machine type which is very popular in mobile machinery is the axial piston machine type. For this machine type, there are different options available on the market. One significant difference can be how the rotating group is set up. Many machines on the market have one set of pistons (e.g., [1, 2]), which will be referred to as single-sided machines in this paper. However, several sets of rotating pistons can be driven on the same shaft and are available on the market, e.g., double row machines with two sets of pistons on different diameters (e.g., [3]), machines using modular back to back designs (e.g., [4]) where each set of pistons has its own housing, or tightly integrated machines where a mirrored design of two sets of pistons shares the same housing and the same inlet and outlet [5].

Some advantages of using two sets of pistons have been presented in the literature. For example, Innas BV presented their floating cup machine with two sets of pistons (e.g., [6]), and mentions the benefit of increasing the number of pistons, and the compensation of axial forces due to the mirrored design. This results in reduced bearing loads and is expected to reduce structure-borne noise. The high number of pistons also reduces both kinematic and compressible flow pulsations and thus reduces fluid-borne noise. Similarly, the Vickers MPEV3-040-2 aerospace motorpump included two inline machines driven in opposite directions by individual electric motors, which cancels both radial and axial piston forces. This results in reduced yoke and bearing loads. Further, the two inline machines shared one displacement controller [7]. Mehta [8] used a tandem pump with an angular between the mirrored sets of pistons to reduce the torque ripple by 75%. Danes and Vacca [9] aimed for destructive interference of the flow of a tandem pump in order to reduce fluid-borne noise. For low harmonics, measurements



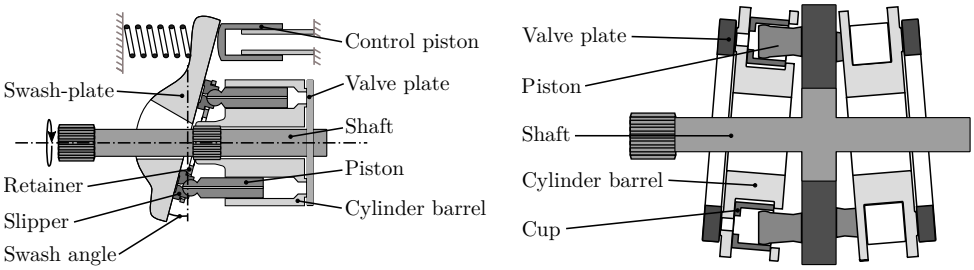
All Open Access articles are peer-reviewed, distributed under the Creative Commons Attribution-Non Commercial 4.0 International

showed significant reductions of sound pressure levels, whereas, contrary to the expectation from simulation, this was not the case for higher harmonics. Ericson and Heeger discussed using mirrored pump designs to achieve discretely variable by idling one pump half [10] or continuously variable displacement by rotating the valve plates [11].

1.1. *Machine Configurations*

Figure 1.1 sketches different axial piston machine configurations on the example of floating piston machines. Figure 1.1a shows a single-sided set up, whereas Figures 1.1b and 1.1c show double-sided machines with mirrored rotating groups. In Figure 1.1b, pistons from each side share a displacement chamber, whereas in Figure 1.1c, the cylinder barrel provides a separate displacement chamber for each piston. Note that further configurations are feasible, e.g., by using multiple cylinder barrels, but are not in scope of this paper.

Figure 1.1 shows floating piston machines, but the same machine configurations are applicable also for floating cup machines or conventional slipper type machines as sketched in Figure 1.2. As bent-axis machines do not provide a through-drive possibility [12], double-sided machines are not applicable for them.



(a) Single-sided machine.

(b) Double-sided machine with connected sides.

(c) Double-sided machine with separated sides.

Figure 1.1: Schematic of different floating piston machine versions [10, 13].

(a) Sketch of main components of a slipper-type machine.

(b) Sketch of main components of a floating cup machine of mirrored design. Note the angular offset between the machine halves.

Figure 1.2: Schematic of axial piston machines [13].

1.2. *Research Gap*

Each of the aforementioned references was focusing on some specific design aspects. This paper aims to provide a wider comparison of pumps with one set of pistons with the two types of mirrored pump designs. The discussed aspects include flow, force, moment, and torque ripples; bearing loads; barrel tipping; aspect ratios; piston count.

1.3. *Limitations*

The simulations in Section 9 assume a inlet pressure of 3 bar and therefore cannot indicate differences in self-suction speed of the different machines. The pressure relief grooves in the study were manually tuned and therefore a comparison of commutation behaviour is not fully objective.

1.4. *Paper Outline*

Section 2 summarises background on flows, forces, and moments in axial piston machines. Based on this, Sections 3 to 8 qualitatively discuss the properties of the machine setups shown in Figure 1.1. Section 9 presents a lumped-parameter simulation study for specific designs. Finally, Section 10 summarises the properties for the different setups and shows conclusions.

2. Background on Flows, Forces, and Moments in Axial Piston Machines

The flow, force, and moment contributors in axial piston machines are crucial to understand their noise behaviour and bearing loads. Manring [14] and Ivantysyn and Ivantysynova [15] provided detailed information on this topic and Heeger et al. [16] summarised and visualised the noise contributors. The following section repeats this background information. Figure 2.1 sketches an exemplary sketch of nine pistons and valve plate kidneys.

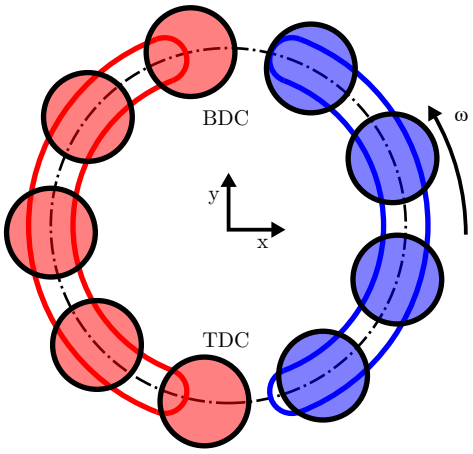


Figure 2.1: Sketch of nine pistons and valve plate kidneys. The sketch includes the location of bottom dead centre (BDC), top dead centre (TDC), as well as the coordinate system and direction of rotation.

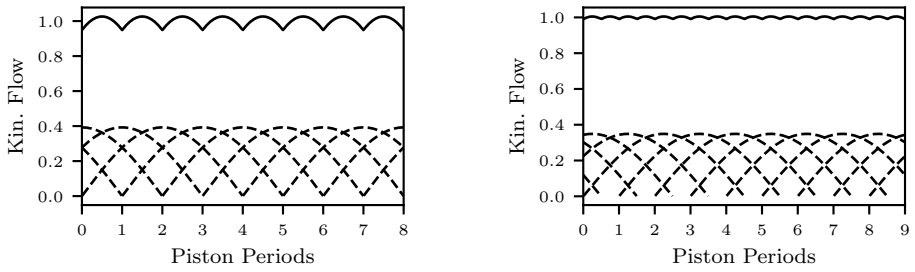
In stationary operation, the same events are in principle repeated for each piston. In a simulation environment, neglecting e.g., manufacturing tolerances, the events are even exactly repeated for each piston and therefore piston periods are used to visualise the machine's behaviour. A piston period represents the time it takes between two pistons passing the same



location, and the figures show the results for two consecutive piston periods. Note that the time of one piston period depends both on the machine's speed and piston count.

2.1. *Flow Ripples*

The overall flow ripple is the sum of the kinematic and the compressible flow ripples.

2.1.1. *Kinematic Flow Ripples*

In axial piston machines, the piston velocity and therefore the flow of one displacement chamber follow a sine shape. As the number of displacement chambers is finite, the total delivered flow is not constant and kinematic flow ripples as shown in Figure 2.2 occur.

(a) Machine with 8 pistons.

(b) Machine with 9 pistons.

Figure 2.2: Exemplary kinematic flow ripples. Dashed: contributions of the individual pistons, solid: total kinematic flow. The figures are normalised with the average total kinematic flow.

The kinematic flow ripple behaves differently for machines with odd and even piston counts z. For even piston counts, the chambers connect and disconnect from the ports in pairs, whereas for odd piston counts, there is half a piston period phase shift between the events of connecting and disconnecting. Consequently, odd piston counts yield lower peak-to-peak kinematic flow ripples but higher frequencies [15]. Conventionally, 7 or 9 pistons are used [14].

2.1.2. *Compressible Flow Ripples*

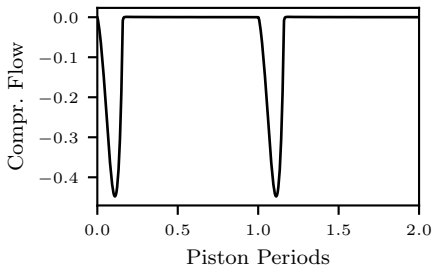
Pressure equalisation (and the fluid's compressibility) cause compressible flow during commutation. In mobile working machines, the compressible flow ripples are usually larger than the kinematic ones [17]. Without any commutation features, using so-called zero-lapped valve plates, very large compressible flow ripples as shown in Figure 2.3 occur. Various commutation features can reduce the compressible flow ripple amplitude, and reviews are provided e.g., by Johansson [17] and Heeger et al. [18]. The frequency of the compressible flow is not affected by whether the piston count is odd or even.

Increasing piston counts can decrease the compressible flow ripple, as the stroke and dead volume of each displacement chamber are reduced, thus reducing the compressible flow required for pressure equalisation.

2.2. *Force, Moment and Torque Ripples*

2.2.1. *Axial Force Ripples*

The axial force of a piston depends on its pressure level. A varying count of pressurised pistons therefore causes axial force ripples. When neglecting commutation effects, even piston counts do not have an axial force ripple, as the chambers connect and disconnect in pairs. Odd piston counts however do have force ripples in the magnitude of the force of one piston. Figure 2.4



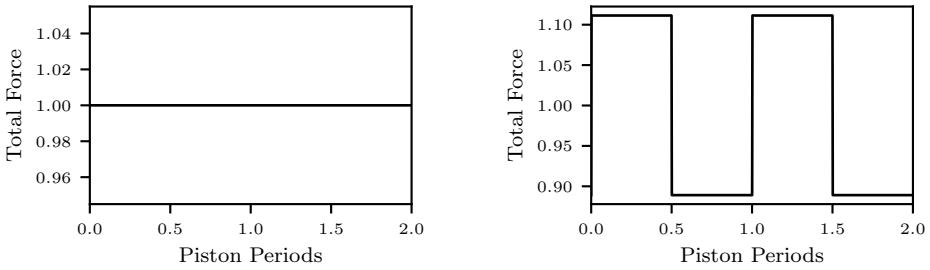


Figure 2.3: Compressible flow ripple for a zero-lapped valve plate, normalised with the average total kinematic flow.

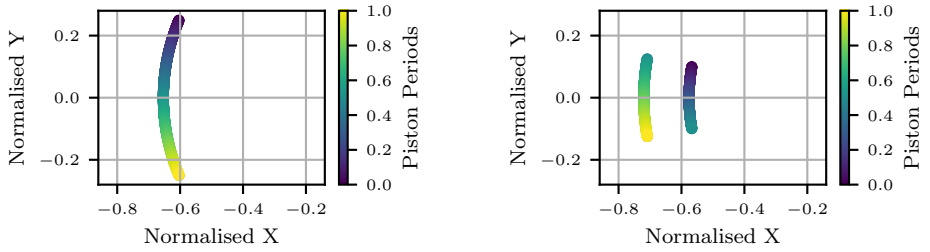
shows the piston force ripple, neglecting commutation effects. Johansson [17] considers the axial force as the main source of structure-borne noise.



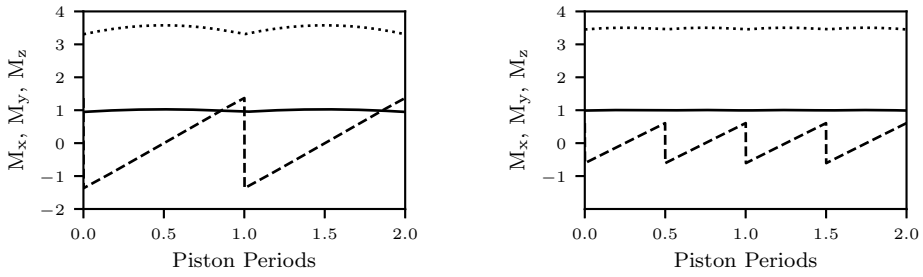
(a) Machine with 8 pistons.

(b) Machine with 9 pistons.

Figure 2.4: Exemplary normalised piston force ripples.

2.2.2. *Bending Moment and Drive Torque Ripples*

A varying count of pressurised pistons and the varying piston positions cause bending moment ripples, which also contribute to structure-borne noise. Figure 2.5 shows the position of the force resultants for one piston period 2.5.



(a) Machine with 8 pistons.

(b) Machine with 9 pistons.

Figure 2.5: Exemplary location of resultant of piston forces, neglecting commutation effect. Normalised with the radius of cylinder barrel bore location.

Bending moments occur around the x- and the y-axis (refer to Figure 2.5 for the axis definition) and cause loads on the bearings. The moment around the z-axis is the drive torque. Figure 2.6 shows bending moment ripples and drive torque ripples.

(a) Machine with 8 pistons.

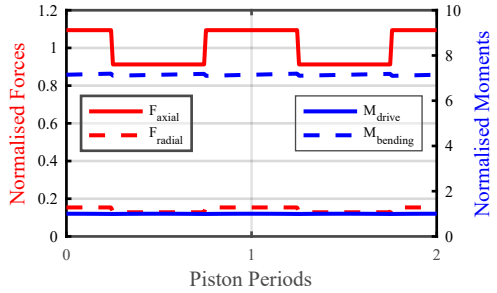
(b) Machine with 9 pistons.

Figure 2.6: Exemplary bending moment ripples (M_x - dashed, M_y - dotted) and drive torque ripples (M_z - solid line), normalised in relation to the average drive torque.

The bending moment ripple is increased for even piston counts, as the location of the resultant piston forces varies more. The ripple around the x-axis is larger than around the y-axis, as the normalised x-position is larger than the normalised y-position when the pistons enter / leave a port. Further, the x-moment has a varying sign and can therefore release geometric plays.

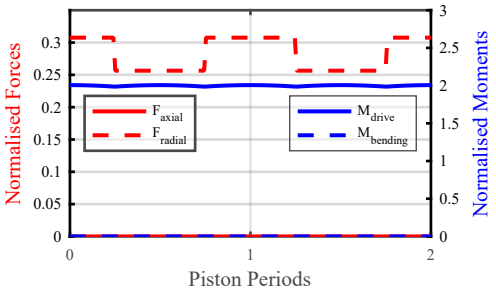
3. Bearing Loads and Barrel Tipping

In single-sided machines, the axial piston forces load a bearing. For double-sided machines, the axial forces from each side counteract each other. In case of the double-sided machine with connected sides, the forces and moments of each side are identical, leading to low bearing loads. For double-sided machines with a phase shift between the sides, the axial piston force is of alternating sign and of the magnitude of the force of one piston. Figure 3.1 visualises the resulting forces and moments for the three considered machine setups and a machine with 11 pistons. The origin for the moment calculation is in the intersection of the shaft axis and the mirroring plane to create the mirrored pumps. Moments are normalised by the average drive torque required to drive a single-sided pump [10].



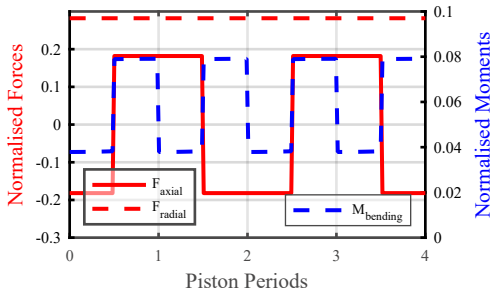
Mirroring a rotating group obviously doubles the displacement, the radial forces, and the drive torque, but reduces axial forces and bending moments. Note that for comparing single-sided and double-sided machines of the same displacement, the dimensions can be scaled according to the scaling laws presented by Achten [19].

3.1. *Bearing Loads*



In case of a single-sided machine, the bearings are loaded with axial and radial forces and bending moments as shown in Figure 3.1a. As Figure 3.1b shows, the axial forces and bending moments from each machine side counteract each other in double-sided machines with connected sides. Therefore, the bearing are in principle only loaded with radial forces. If a double-sided machine with an angular offset between the two sides is used, the bearings are loaded with alternating forces with the magnitude equivalent to one pressurised piston as shown in Figure 3.1c.

3.2. *Barrel Tipping*



Achten et al. [20] investigate barrel tipping in single-sided floating cup and slipper-type machines, and show that hydrostatic, centrifugal, friction, spring, and reaction forces affect the cylinder barrel and therefore its tipping moment. In double-sided machines without an angular offset between the machine sides, the tipping moments from both machine sides counteract

(a) Normalised forces and moments for a single-sided machine.

(b) Normalised forces and moments for a mirrored machine with connected machine sides.

(c) Normalised forces and moments for a mirrored machine with independent machine sides and an offset of half a period between both sides. Due to the offset between the machine sides, there are twice as many piston periods per revolution.

Figure 3.1: Forces and bending loads on the bearings for different machine configurations. The double-sided machine in this figure have twice the displacement of the single-sided machine [10].

each other, thus providing higher robustness against barrel tipping. If there is an angular offset between the machine sides, the moments from each side are not fully compensated, but the resulting oscillating moments on the barrel are of lower magnitude than in single-sided machines.

4. Flow Ripple

4.1. *Interference of Flow from Double-sided Machines*

Danes and Vacca [9] aimed for destructive interference of the flow of a tandem pump in order to reduce fluid-borne noise. The considered tandem pump consisted of two pumps with nine pistons each. Simulation results showed that a phase shift of half a period eliminates the odd pressure ripple harmonics, whereas a phase shift of a quarter period eliminates harmonics of the order $2 + 4n$. Further, the pressure ripples for the tandem machine were lower than for a simulated single-sided machine of the same displacement, independent of the phase shift applied to the tandem machine halves. For the first and third harmonic, measurements showed significant reductions of sound pressure levels when using a phase shift of half a period between the pump halves, whereas, contrary to the expectation from simulation, this was not the case for higher harmonics. Danes and Vacca give insufficient symmetry in their experiment as a potential cause for this.

4.2. *Dead Volume*

Larger dead volumes cause increased compressible flow pulsations. Double-sided machines that require flow through the pistons (see, e.g., Figure 1.1) possess increased dead volume ratios.

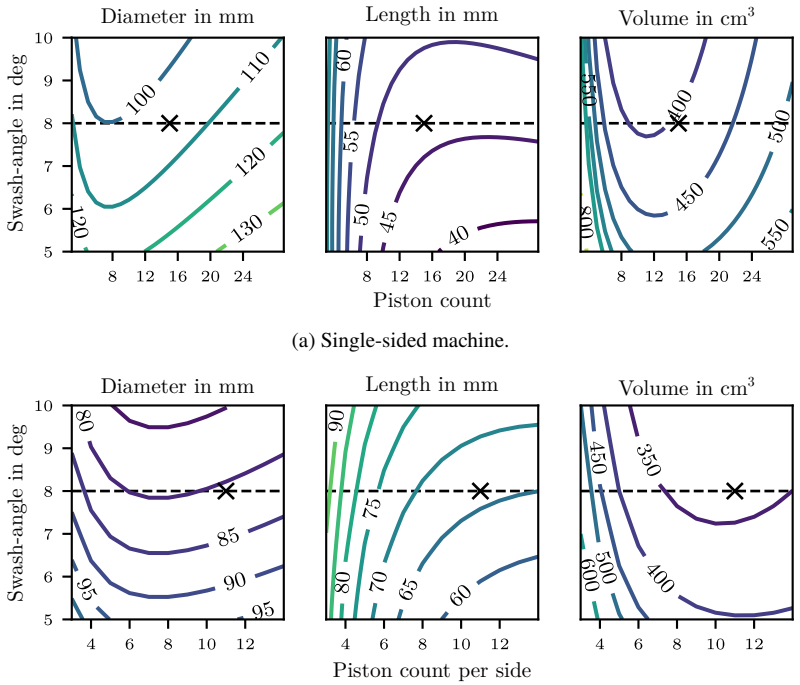
5. TORQUE RIPPLE

Mehta [8] considered the torque ripple to be the main source of noise in hydraulic machines. He presented a slipper type machine with a central manifold and mirrored rotating groups on each side of the manifold. Mehta used this design to optimise the angular offset between the rotating groups to minimise the torque ripple. For even piston counts on each side, the ideal offset is half a period, whereas for odd piston counts, the ideal offset is a quarter of a period. When neglecting commutation and compressibility effects, the best offset angle reduces the peak-to-peak torque pulsations by 75% in comparison to the worst offset angle.

6. ASPECT RATIOS

Heeger et al. [21] expanded Achten's [19] method for the scaling of rotating groups of axial piston machines for floating piston machines. Figure 6.1 shows the rotating group's diameter, axial length, and volume for single-sided and double-sided floating piston machines of the same displacement. Obviously, the double-sided machine has smaller outer diameters and larger axial lengths. Also, its volume of the rotating parts is slightly lower and the total piston count is larger for the most compact machine.

In the context of the integration with electric machines, Heeger et al. [22] stated that single-sided machines are more advantageous for a compact integration via axial stacking, whereas double-sided machines are more advantageous for a compact radial integration within the core of an electric machine.

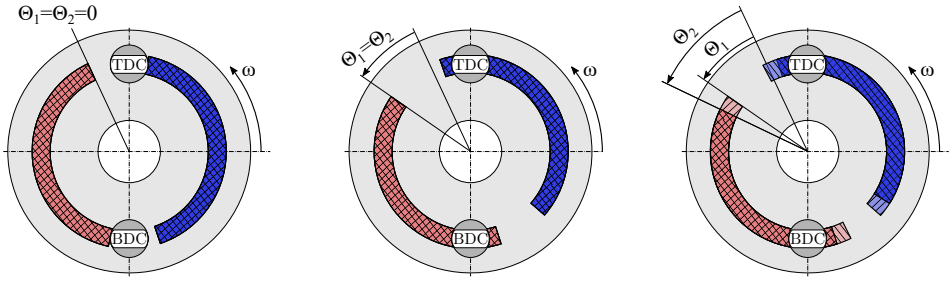


7. VARIABLE DISPLACEMENT

Variable single-sided machines vary their displacement by varying their swash-angle. Using double-sided machines opens opportunities for unconventional methods to vary displacement.

Valve plate rotation has been considered to alter the effective pre-compression for small rotation angles [23], and to provide variable displacement for large valve plate rotation angles [24]. Variable displacement via valve plate rotation however requires commutation to take place away from the dead centres and at significant axial piston speeds. This results in challenges such as cavitation, high-pressure peaks, and pulsations, and has therefore hindered a widespread application of valve plate rotation [25]. Note however that the Innas Hydraulic Transformer relies on valve plate rotation to alter the flow through each of its three ports [25].

In double-sided machines with connected sides as shown in Figure 1.1b each valve plate affects the effective pre- and de-compression angles. Therefore, the displacement and commutation behaviour can be altered at the same time. However, the high piston velocities at low setting ratios provide a significant throttling effect, and Heeger et al. [11] concluded that this method is mainly applicable to vary displacement at relatively large setting ratios but unsolved challenges remain for low setting ratios.



Alternatively, double-sided machines with separated sides can provide discretely variable displacement by circulating the flow of one machine side, e.g., using the setup sketched in Figure 7.2. This functionality is in principle available on the market where dual-flow machines can be equipped with shut-off valves (e.g., [27, 28]). This method can also be applied on double-sided machines with separated sides. However, when circulating oil at tank pressure level, the axial force is no longer balanced between the machine sides. To provide a better

(a) Both valve plate rotation angles (Θ_1, Θ_2) are zero, and the valve plates are in the same position at maximum displacement.

(b) Joint valve plate rotation: both valve plates have been rotated by the same angle.

(c) Joint and relative valve plate rotation: valve plate 2 has been rotated by an additional angle.

Figure 7.1: Concept of joined and relative valve plate rotation [26].

balancing of the axial forces, an elevated low-pressure level can be achieved by a setup as sketched in Figure 7.2 [10].

8. Channel Design

The channel design depends on the machine type and on whether one or two cylinder barrels are used. When using just one cylinder barrel and axial ports, double-sided designs require flow through the pistons. This is a significant restriction, increasing the risk for cavitation and reducing self-suction speeds [21]. Mehta [8] avoided this for a slipper-type machine by using a

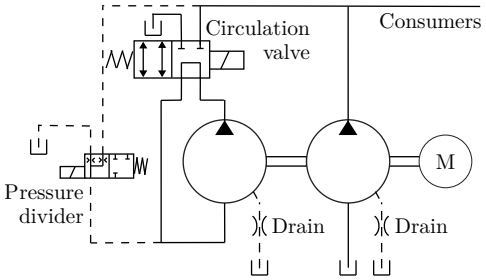

Figure 7.2: A possible setup for circulating flow from one pump half at an elevated pressure level [10].

central manifold and two cylinder barrels. A central manifold is however inconvenient for a radial integration of the hydraulic machine inside an electric machine.

The floating cup machines also uses two cylinder barrels and the flow goes through the cups, which can provide larger flow channels than pistons. The floating cup machine does not have a central manifold, instead it has two inlets and outlets, which can be combined through channels in the housing.

9. EXEMPLARY ROTATING GROUP SIMULATION STUDY

9.1. *Setup*

An exemplary simulation study aims to compare machines that are similar to traditional machines setups and to alternative machine setups. The study uses a lumped parameter model as sketched in Figure 9.1 using the software Hopsan [29]. Each machine has a displacement of 35 cc/rev. Table 9.1 shows the model inputs. The models inputs represent typical values for single-sided machines of bent-axis (A), inline (B), and floating piston (C) type, as well as for double-sided machines of floating cup (D) and floating piston (E) type. The inlet pressure is set to 3 bar. As commutation feature, pressure relief grooves as sketched in Figure 9.2 are applied. The pressure relief groove shape is set to triangular. The pressure relief grooves are manually tuned to reduce flow pulsations for operating with up to 3000 rpm and 350 bar. Only one quadrant is considered.

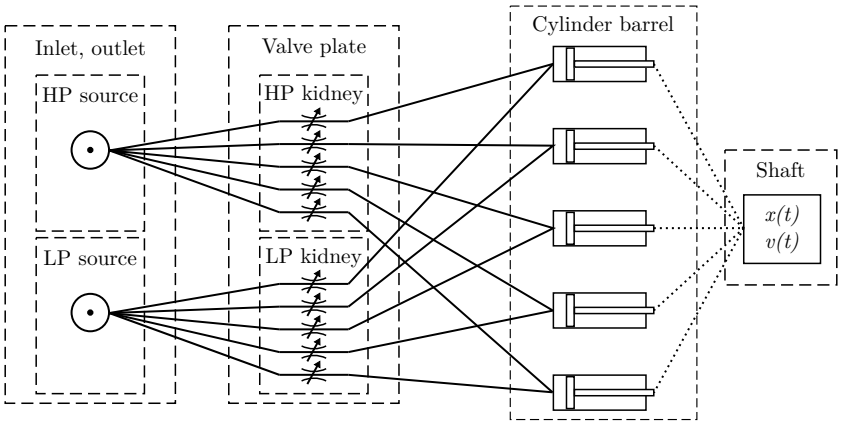

Figure 9.1: Simulation model for axial piston machines, modified from [11]. t - time, v - axial piston velocity, x - axial piston position.

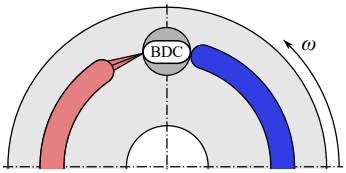
Table 9.1: Simulated setups.

Setup	Machine type	Piston count	Swash angle in degrees	Dead volume ratio	Piston pitch parameter
A	Single-sided	7	40	0.2	0.13
B	Single-sided	9	20	0.8	0.33
C	Single-sided	15	8	0.2	0.13
D	Double-sided (separated)	2x12	8	0.2	0.27
E	Double-sided (connected)	2x11	8	0.7	0.13



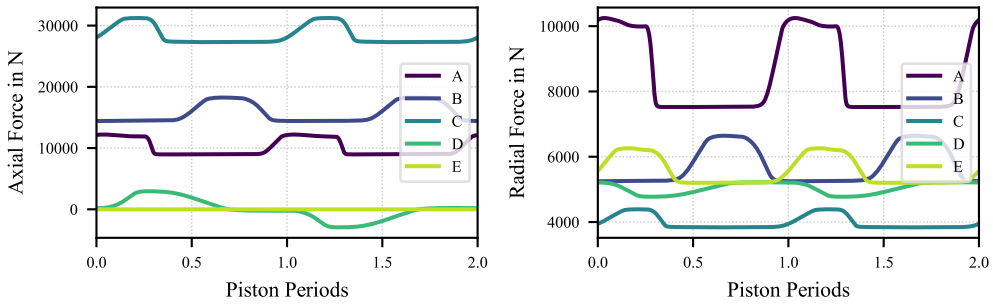


Figure 9.2: Pressure relief groove [18].

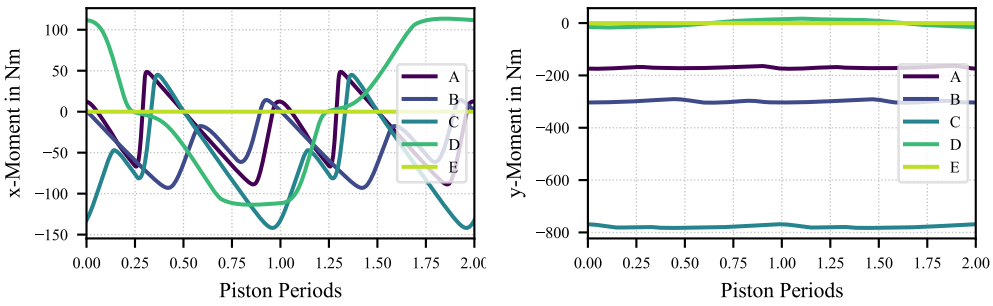
9.2. *Results*

Figures 9.3 to 9.6 show simulation results for the setups given in Table 9.1.

Figure 9.3 shows the axial and radial forces for the different setups. As expected, single-sided machines possess larger axial forces. The low displacement angle of the single-sided machine setup C causes high axial forces, and the bent-axis type machine setup A possesses large radial forces. The double-sided setups D and E provide low axial forces, but do not reduce the radial forces.

(a) Axial forces on bearings.



(b) Radial forces on bearings.

Figure 9.3: Comparison of bearing forces. Machine types see Table 9.1.

Figure 9.4 shows the bending moments for the different setups. For single-sided designs, increased displacement angles reduce the bending moment magnitudes. The double-sided setup E fully cancels the bending moments. The double-sided setup D which includes a phase shift between the sides has low moments around the y-axis but high moments around the x-axis.

Figure 9.5 shows the drive torque ripple. A higher piston count reduces the torque ripple. The double-sided design E without phase shift has significantly higher torque ripple than the double-sided design with phase shift D.

Figure 9.6 shows the flow ripples for the different setups. Similar to the drive torque ripple, a higher piston count reduces the flow ripple and a phase shift is advantageous for double-sided designs.

10. SUMMARY AND CONCLUSION

Single-sided and double-sided machine can have the same displacement with different properties. Table 10.1 gives a simplified, qualitative summary of the properties of the different setups.

Table 10.1: Qualitative summary of properties, with "-" being the worst relative rating and "++" being the best relative rating.

Property	Single-sided	Double-sided (connected)	Double-sided (separated w phase shift)
Axial force ripple	o	++	o
Side force ripple	o	o	+
Moment ripple (x-axis)	o	++	-
Moment ripple (y-axis)	-	++	+
Drive torque ripple	o	o	+
Bearing load (average)	-	++	+
Flow ripple	o	o	+
Aspect ratio	baseline	longer and thinner	longer and thinner
Variable displacement	well-proven for slipper-type	option for valve plate rotation (not well proven)	option to circulate flow (proven)
Channel design	+	depends on machine type	depends on machine type

Double-sided machines can reduce noise contributors and bearing loads by cancelling of forces and moments between the machine sides.

Double-sided machines without a phase shift can in principle fully cancel axial forces and bending moments.

Double-sided machines with a phase shift increase the effective piston count, thereby reducing the amplitudes of most noise contributors. Axial forces and bending moments around the y-axis are largely compensated.

Abstract

Cylinder Block/Valve Plate interface ideally operates with a thin fluid film separating the running surface, preventing contact and wear. At the same time, the film seals the interface, preventing leakage of high-pressure fluid in the displacement chamber. This thin film is maintained by balancing the hydrodynamic/hydrostatic pressure distribution with the external loads applied on the cylinder block. Extending the operating speeds and pressure of the pump can disrupt this balance, preventing the interface from sealing effectively, or generating wear that causes early failure of the machine. The factors limiting the operational range are therefore coupled physical phenomena, where the performance of the piston/cylinder block interface or the shaft-cylinder block spline connection may lead to the failure of the cylinder block/valve plate interface. Current state-of-the-art simulation tools focus on individual lubricating interfaces, which is not sufficient to accurately model physical behavior for finding the operational limits of the cylinder block/valve plate interface at extended operating conditions.

This paper proposes a coupled simulation method for the cylinder block/valve plate interface that includes consideration of the physical behavior at other lubricating interfaces. The paper presents simulation results when the cylinder block/valve plate interfaces is coupled with the piston/cylinder block interface and the shaft spline interface and demonstrates the significant difference in simulation results between the proposed coupled simulation method and the standalone simulations. Furthermore, the paper includes experimental test observations that validate the findings from the coupled model simulation. The coupled simulation is then used to find optimized designs for extended operating conditions, at higher pressures and higher speeds. The paper reports experimental results with the optimized design prototypes, which demonstrate performance improvement.

Keywords. Axial Piston Pump, Tribology, Lubricating Interface, Design Optimization

1. INTRODUCTION

Axial Piston Machines (APM) are among the most widely used hydrostatic pumps and motors. They are known for their ability to provide varying displacements, as well as high efficiency even at high operating speeds and pressures. Current trends in applications of hydraulic pumps and motors show continued demand for an increase in performance capabilities as well as longer operational lifespans. Therefore, it is important to understand

the behavior of APM when pushed to the limits of the operational window, to find the physical factors restricting performance, and to develop design solutions for further improvement of the machine's operation.

The cylinder block/valve plate interface is critical to the performance of an axial piston machine. The valve plate is responsible for regulating flow through the machine, and the design allows control over several key behaviors such as the flow ripple and noise generated during operation [1]. The lubricating film at this interface also regulates the leakage from the pressure ports, as well as providing hydrodynamic balancing against the loads acting on the cylinder block. Studies like Manring [2] have shown that improving the design of this interface could therefore address several issues affecting machine behavior at extremes of the operational range and improve overall performance. However, the far-reaching impact of valve plate design also increases the complexity of the design process.

Simulation models enhance the process of designing axial piston machines, reducing the need for expensive and time-consuming experimental runs, which can now be restricted to validating the final designs. Thanks to the simulation models, various design features can be parameterized and used in conjunction with optimization algorithms to generate several iterations of highly tuned efficient designs.

The lubricating interface performance of axial piston machines depends on interactive physical phenomena such as hydrodynamics, thermodynamics, heat transfer, elastic deformation due to pressure and thermal load, the micro motion of the moving parts, and fluid and solid properties. Various simulation methods have been developed targeting different aspects of this complex system.

Given the complex nature of flow within an axial piston machine, a full-scale CFD model would be particularly useful in understanding the flow behavior. Frosina et al. [3] demonstrated the use of commercial CFD models to predict flow behavior in axial piston pumps with complex design features to reduce flow ripple. Boland and Shang [4] used an axial piston pump model implemented using the CFD tool Simerics MP+ to study cavitation behavior and its scalability. CFD models can provide very detailed fluid behavior and can be very useful for studying the fluid dynamics within the pump. However, using a full-scale CFD model is computationally expensive. Ignoring or simplifying the fluid flow behavior at the lubricating interfaces can speed up the simulation but can ignore crucial flow behavior at these interfaces which can affect the accuracy of the results. Additionally, CFD approaches are restricted to fluid flow behavior, and often do not provide any further understanding on the dynamics of the solid components themselves.

Lumped parameter modelling approach is also widely used for positive displacement machines. This approach greatly reduces the computational cost of predicting flow behavior by considering the fluid volumes inside the machine as several lumped volumes, ignoring any spatial variation of fluid properties and any flow within the volume. Roccatello et al. [5] developed such a model for simulating axial piston machines and demonstrated its use in predicting pump characteristics like flow ripple and torque. Corvaglia et al [6] compared Lumped Parameter simulations to results provided by a full–scale 3D CFD model and found a good agreement between them. Lumped models are simple to develop and can provide quick results for a large variety of pump designs, compared to the speed of CFD models. They can also be used in conjunction with dynamic models to understand the motion of solid components within the machine. But the lumped volume assumption means there is no way to model detailed fluid behavior, particularly at the lubricating film interfaces.

Hasko et al [7] showed that film interfaces are a major contributor to power loss in an axial

piston machine. Therefore, a representative numerical model should be able to include the effects of lubricating films. A fluid structure interaction model for the cylinder block -valve plate interface was introduced by Zecchi and Ivantysynova [8], and for the piston-cylinder block interface by Pelosi and Ivantysynova [9]. These models involved coupling the lumped parameter model with a fluid simulation for the lubricating interfaces and demonstrated the improvement in modelling pump behavior without excessive computational cost. A tribological cylinder block/valve plate interface model was developed at IFAS and used to optimize the design geometry of the interface [10] to reduce wear due to fluid and solid friction. The benefits of detailed film modelling in developing new designs were demonstrated by Geffroy et al. [11] and the model was further validated experimentally in [12] A numerical lubricating film model was also used by Li et al. [13] to study wear characteristics at the cylinder block/valve plate interface under different operating conditions. More recently, Han et al. [14] used a cylinder block/valve plate lubricating film model to study the effects of hydrostatic pockets in reducing solid body contact in a floating piston pump.

It is clear that simulating the cylinder block/valve plate lubricating film interface would be useful in understanding how the interface performs in extreme operating conditions. However, isolated simulation models do not accurately capture the behavior of APMs. For example, the behavior at the cylinder block/valve plate interface would be affected by the forces created by the lubricating film along the piston interface. While analytical assumptions can be made for specific test cases, a general use simulation model should be able to model this coupled interaction accurately. Ransegnola developed a coupled model for an axial piston machine and used it to study the piston and slipper spin [15]. This model was able to extend methods previously used for singular lubricating interfaces, and couple them with a lumped parameter model for fluid volumes and a solid dynamics solver that resulted in a highly accurate simulation model of the entire axial piston machine assembly. Mukherjee et al. demonstrated the benefits of a coupled modelling approach by showing an improvement in estimation of power losses at lubricating interfaces with the new approach [16]. Gärtner et al. [17] developed and compared coupled models for the piston/cylinder interface, to better include the effects of the slipper/swashplate film and the slipper-piston ball joint dynamics. Coupling of multiple interfaces creates a more accurate model for the complex interactions in the APM and ensures better accuracy in studying the behavior of the cylinder block/valve plate interface.

The goal of this work is to extend the operational limits of axial piston machines through improved design of the cylinder block – distributor plate interface. The paper describes the physical behavior of the interface in extreme conditions such as high speeds and high pressures. A novel numerical modelling approach is proposed to simulate this behavior, addressing the limitations of previous numerical modelling methods for axial piston machines. Experimental validation of the improved model is done with two test cases, where the model is used to better understand the limiting factors of the interface design, and to test design changes addressing the limitations.

2. THE CYLINDER BLOCK/VALVE PLATE INTERFACE

The interface between the cylinder block and the valve plate serves three primary functions: to reduce friction between the stationary control plate and the rotating section of the APM, to for an effective seal preventing fluid from the high-pressure ports leaking out, and to provide hydrodynamic balancing for the forces and moments acting on the cylinder block

[1]. Since the film thickness distribution is primarily affected by the pressure load. the running surfaces of the cylinder block and the valve plate need to be carefully designed to ensure the lubricant film layer can sufficiently balance the load on the cylinder block. An ill-designed surface can disrupt the functioning of the film and affect its other functions.

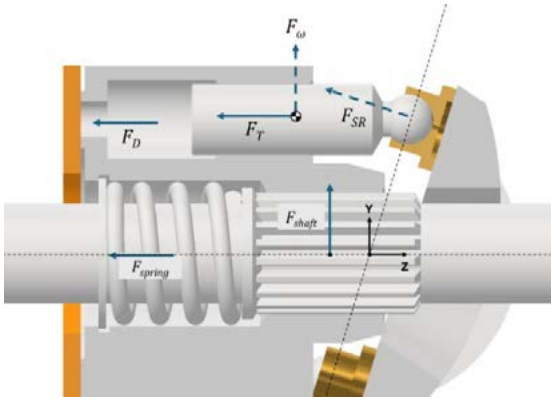

Figure 2.1. Overview of Cylinder Block Forces

Simulation models for use in understanding the behavior of the valve plate interface need to accurately include the effects of the forces and moments acting on the cylinder block. There are two main types of forces acting on the cylinder block [8,18]: forces that are directly applied on the cylinder block and reaction forces from other components transmitted through lubricating films. Figure 2.1 shows the locations where these forces are applied on the cylinder block. The direct forces are shown with dark arrows and the forces applied through film are shown in dashed arrows

Studies like Geffroy et al. [10] have shown that a numerical model of the forces on the cylinder block can be used to calculate the gap height distribution at the valve plate interface. While state of the art models can accurately include most forces, there are some factors which represent a challenge. The friction force acting on the cylinder block is a result of the lubricating interface between the block bore and moving piston surface. The friction includes both viscous losses generated by the fluid, and solid-solid friction when the surfaces are in contact with each other. Since these forces are primarily a result of lubricating film behavior, the best way to accurately calculate these forces is by simulating the films at each of the interfaces between the pistons and the cylinder block. Additionally, to properly simulate complex interactions, these film models would need to be coupled with the numerical model of the valve plate interface. This adds a high level of complexity for the model.

Another important factor governing the overall moment acting on the cylinder block is the shaft reaction force. The forces acting on the cylinder block perpendicular to the shaft axis are balanced by a reaction force provided by the shaft itself. This reaction force acts on the cylinder block on the region where it is in contact with the shaft, known as the crowning region. The location of the crowning region is important, as it determines the moment generated by the shaft reaction force on the cylinder block. The crowning region is defined by a characteristic curve added to the spline of the shaft, the peak of this curve considered as the center where the shaft would be in contact with the cylinder block, and the point where the transmission of forces and torque occurs.

The surfaces of the cylinder block and shaft in contact here can deform, as a result of the large forces acting on the cylinder block. This deformation increases if the axial piston machine is functioning at the limits of its operational range. The deformation can affect the nature of contact between the two surfaces. Figure 2.2 illustrates the effect that such deformation can have on the location of the crowning point.

Figure 2.2. Shaft Contact Behavior due to deformation

To understand better the exact behavior of contact between the shaft and the cylinder block considering deformation, a finite-element method simulation was conducted. A representative model of the Axial Piston Machine was constructed, and the simulation was conducted using Ansys Mechanical. Studying the contact region under the loads applied on the cylinder block, it is observed that contact is indeed not restricted to a single point but is instead a long region along the edge of the area of contact on the shaft spline, as shown in Figure 2.3.

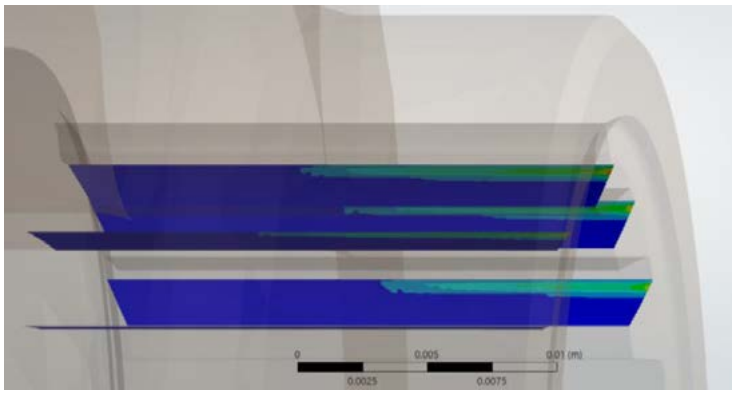

Figure 2.3. Shaft contact region from FEM Simulation

To calculate the contribution of shaft reaction moment on the block, and to accurately model the tilting of the cylinder block, it's important to define a single contact point. This point can be the center of the entire contact region, the ideal point at which the net contact force can be considered to be acting. To calculate this point, the net moment generated by the contact region on the cylinder block $\vec{M}$ is extracted from the Ansys model. Additionally, the contact pressure can be integrated with the contact area to calculate the net contact force $\vec{F_c}$. This contact force has two components, one contributing to the moment on the block, and the other countering the forces in the axial direction. To find the components of contact force normal to the moment $\vec{F}$, a simple vector calculation is performed, as described in equation 1.

$$\vec{F} = \vec{F_c} - \frac{\vec{F_c}.\vec{M}}{|\vec{M}|^2}\vec{M} \quad (1)$$

Using equations 2 and 3, the length of the normal moment arm $\vec{r}$ required by the contact force to generate the moment is calculated, which gives the location of the point at which the net contact force is acting. This is the ideal center of the contact region.

$$\vec{r} \times \vec{F} = \vec{M} \quad (2)$$

$$\vec{r}\,.\hat{F} = 0 \quad (3)$$

The inclusion of the effects of shaft deformation on the cylinder block moment, as well as the coupled modelling of piston films, represents the novelty of the modelling approach used in this study. As shown in the case studies in Section 4, the consideration of shaft deformation proves critical in the APM behavior at operational limits and ensure that design solutions proposed are indeed effective in improving performance.

3. SIMULATION MODEL

The primary goal of the simulation model for this study is to accurately capture the behavior of the cylinder block/valve plate interface. As described in section 2, the major factor affecting the behavior of this interface is the dynamics of the cylinder block, and the best way to accurately model this is using a coupled simulation model involving both the cylinder block/valve plate interface, and the piston/cylinder block interface. For this study, the lubricating interfaces are modeled using a modified version of the Reynolds equation [13], to include the effects of mixed lubrication and surface deformation, as shown in equation 4.

$$\nabla.\left(\phi_P \frac{Kh^3}{12\mu}\nabla\rho\right) = \nabla.\left(\rho v_m\left(\phi_R R_q + \phi_C h\right)\right) + \nabla.\left(\rho\frac{\phi_S}{2}R_q(v_t - v_b)\right) + \frac{\partial\rho\left(\phi_R R_q + \phi_C h\right)}{\partial t} \quad (4)$$

These modifications are necessary to account for the forces developed in the film due to varying flow regimes, and the effects of deformation on the gap height and the resulting balancing force produced by the film. To model the fluid chambers and hydraulic components like orifices, a lumped parameter fluid model is implemented to reduce computational cost. The kinematics of the various solid components in the APM are determined using a body dynamics solver.

To simulate the interaction between physical domains, the models are coupled with each other. This coupling is implemented through continuous information transfer between the models, simulating physical behavior in an APM. The lumped parameter and the solid body dynamics need to be solved with a much smaller timestep compared to the interface models, and forcing the interface model to be solved on this small timestep increases computational cost. So, the simulation is divided into independent timelines: one for each of the lubricating interfaces and one main timeline for the lumped parameter and body dynamics model. Information about the interface is interpolated between timesteps to be used by the lumped parameter and the body dynamics solver, ensuring continuous transfer of data between the models and improving the solution time.

The coupled model used in this study was built using Multics, a Multiphysics simulation tool developed by the Maha Fluid Power Research Center. Multics was first introduced by Ransegnola et al. [19] and used to perform a fully coupled simulation for external gear

machines. It included multiple models for various physical features such as tooth space volumes, floating bodies and lubricating interfaces. It also introduced the asymmetric timeline method used to improve simulation times with coupled models. The tool was further used to develop a coupled Swashplate APM model to study piston – slipper spin [15]. The flexible structure of Multics also allows for the addition of new models, which allows new physics to be introduced for various positive displacement machines. Mukherjee et al. further developed the Swashplate APM model to include the effects of thermal behavior across various physical domains in [20].

The simulation model proposed in this paper uses Multics to develop a fully coupled model consisting of the Cylinder Block/Valve plate and Piston/Cylinder Block interfaces, with mixed lubrication and deformation considerations at the interfaces, along with floating body models for moving components and lumped parameter modelling for the chambers. Additional considerations are also made to include the effects of shaft deformation in the dynamics of the cylinder block. Figure 3.1 shows an overview of the proposed model.

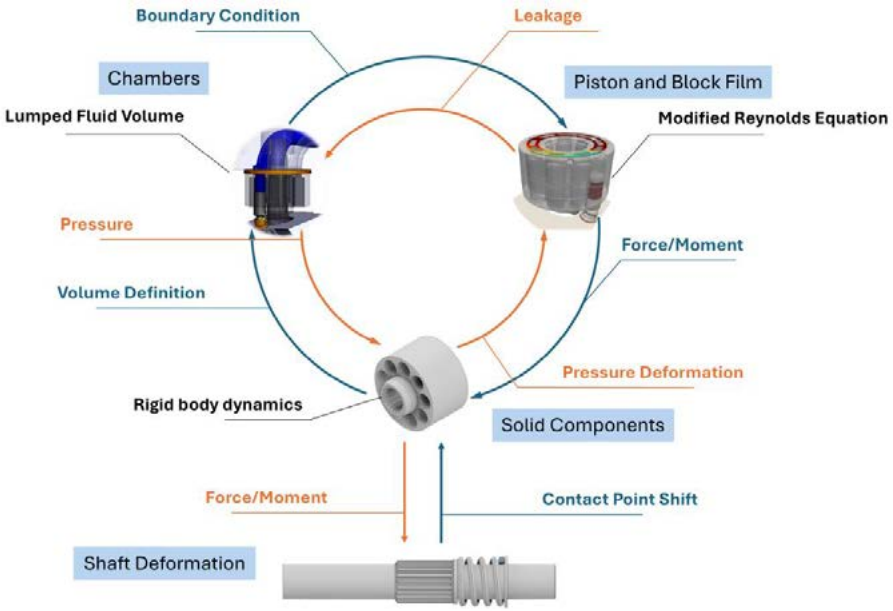

Figure 3.1. Overview of Swashplate APM Model

4. VALIDATION AND CASE STUDIES

The proposed coupled model is used in simulating the behavior of the cylinder block/valve plate interface of an axial piston machine near operational limits. Two test cases considering two different kinds of limiting behavior at the extremes of the operational range were considered:

- The first case studies the factors that define the maximum pressure capability of the pump, beyond which wear begins to appear on the valve plate running surface
- The second case studies the maximum power of an axial piston motor, beyond which the cylinder block begins to separate from the valve plate

For the two cases, simulation results for the baseline designs are validated with observations from experimental tests. Further, the simulation results are analyzed to determine the underlying factors, and to test design changes aimed at improving performance at higher pressure and operating speeds. Finally, the design solutions are validated experimentally. Additionally, the benefits of the novel considerations in the simulation model are highlighted for each of the test cases.

4.1. Study of Valve plate Wear at High Pressure

The cylinder block/valve plate interface is designed to hydrostatically balance the loads acting on the cylinder block. The lubricating film at this interface has a gap height in the order of microns, making it sensitive to the deformation of the running surfaces. When the machine is operated at high pressures, the surfaces can be deformed from the nominal plane, where 'bump' (local reduction of the film thickness) increases the change for contact and wear, and 'dent' (local increase of the film thickness) increases the leakage. This study will focus on the wear, which is a critical factor that determines the maximum operation pressure of an axial piston machine. Contact pressure is used as a parameter to measure and compare the degree of wear between the baseline design and test cases.

4.1.1. Baseline Design Simulations

The coupled numerical model is used to analyze the baseline design. The model simulates both the piston/cylinder interface and the cylinder block/valve plate interface simultaneously, to ensure the frictional forces and moments generated by the relative motion between the piston and the cylinder block are included when calculating the moments acting on the cylinder block. As shown in Figure 4.1, the simulation results from the proposed model indicate two regions of contact on the outer edge of the interface with a maximum magnitude of 1700 bar. The two contact regions, combined with the high sliding velocity between the running surfaces of the interface results in wear on the valve plate. To validate the simulation results, the location of the contact is compared to the observed location of wear in the experimental tests. As seen in Figure 4.2[A], the valve plate has deep wear marks along the outer edge of inlet and outlet ports, which are the boundaries of the interface with the rotating cylinder block.

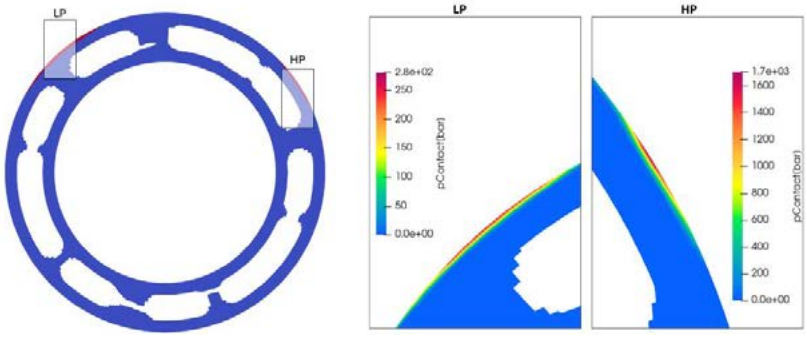

Figure 4.1. Contact Regions on Cylinder Block–Valve plate Interface.
HP and LP indicate areas of film connected to High-Pressure and Low-Pressure ports

Figure 4.2. Wear observed on valve plate after experimental tests. [A]: Baseline design, [B]: Improved Port Block, [C]: Increased Interface Area

Further investigation of the simulation results indicates that the contact pressure is a result of the combination of high tilting moments on the cylinder block under maximum pressure, the friction between the piston and bore, and the deformation of the solid bodies. Although the effect of the surface deformation of this interface was discussed in Chacon and Ivantysynova [21], the coupled simulation results indicated that the consideration of deformation alone is not sufficient to predict the contact pressure as well as the resulting wear. Figure 4.3 shows the results for the same design without considering the coupled effect from the piston–cylinder block interface. Therefore, the inclusion of the coupled model, despite the added complexity, ensures better representation of the pump's behavior at such extreme operation conditions. With the validation complete, further design solutions aimed at addressing the causes of wear are tested.

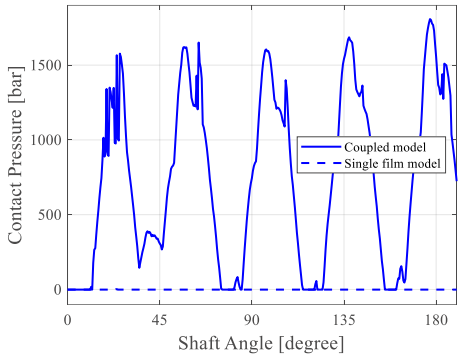

Figure 4.3. Comparison of Simulated Contact Pressure with Single Film Model

4.1.2. Design Improvements

The coupled simulation results indicated the causes of wear on the valve plate. Two design solutions were developed to reduce contact between the running surfaces.

A. Improved Port Block: The first design change was aimed at reducing the deformation of the valve plate surface by redesigning the port block. As shown in Figure 4.4, material added to the chamber walls increases support, which would reduce the deformation

caused by the high-pressure fluid in the chamber. This results in lower deformation of the valve plate, reducing contact with the moving cylinder block.

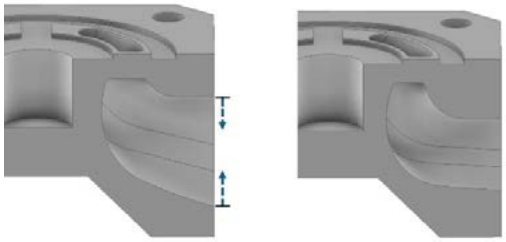

Figure 4.4. Illustration of Port Block design changes to reduce deformation

B. Increased Valve plate Interface Area: The second design change tested is increasing the sealing land area. The baseline design of the cylinder block/valve plate interface is insufficient to balance the large moments acting on the cylinder block at high operating pressures. Therefore, the interface area is increased by increasing the outer diameter and decreasing the inner diameter, as shown in Figure 4.5. This increased surface area can provide more moment balancing the cylinder block, therefore reducing the tilting and the resulting contact with the valve plate.

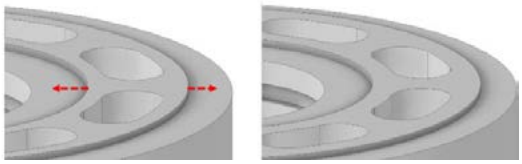

Figure 4.5. Illustration of valve plate interface area changes on Cylinder Block

4.1.3. Results

For the new port block design, simulation results indicate a reduction in maximum contact pressure, as seen in Figure 4.6.[A]. This result is validated by experimental tests for this design. As seen in Figure 4.2[B], the wear markings on the valve plate are still present, but the depth of wear is lower, showing a marginal improvement provided by the new port block.

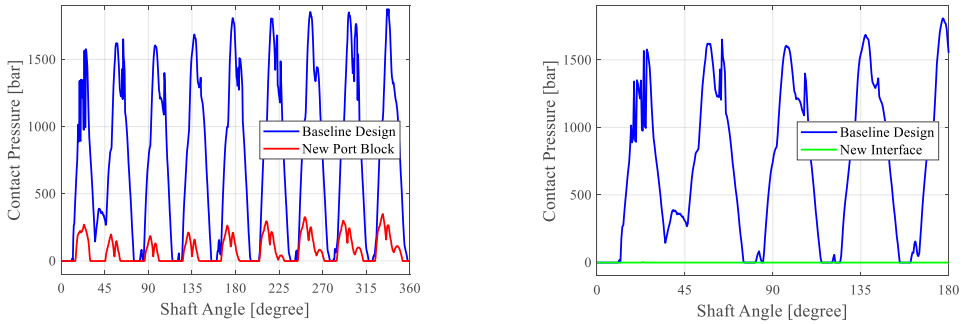

Figure 4.6. Comparison of Contact Pressure with new designs

Figure 4.6[B] shows the simulation results for the new valve plate interface design, with more film area. There is no contact observed, which shows that the cylinder block is sufficiently balanced by the new larger interface. Observing the results of the experimental tests with the new interface design in Figure 4.2[C], a significant reduction in wear is observed, matching the results of the coupled simulation model.

4.2. Study of Cylinder Block Separation at High Speeds

The hydrodynamic force in the lubricating film, the inertia force from the piston and the slipper, and the friction from the piston intensify with the increased piston machine speed. The combination of these effects tends to tilt the block, ultimately resulting in its separation from the valve plate. This failure mode can be observed as the sudden increase of drain flow rate, therefore the sudden increase of case pressure, as well as the sudden loss of high pressure when operating beyond the rated speed.

4.2.1. Baseline Design Simulations

Shaft with crowned spline is often used in piston machines to allow the block to tilt around a designed pivot point. As explained in Section 2, this pivot point may deviate from the shaft crowning point due to deformation. The proposed model considered the shift of the pivot location based on the FEM analysis. Coupled with the friction from the piston cylinder interface, this proposed model faithfully replicates the observation of the behavior of the cylinder block/valve plate interface in this case study. Those are:

- In motoring mode, the block separates from the valve plate when operating beyond the rated speed
- In pumping mode, no separation is observed, and the interface operates normally

The simulated film thickness in the cylinder block/valve plate interface is shown in Figure 4.7, where the block separation can be observed as the diverged film thickness. This figure also demonstrates that this behavior can only be replicated with the consideration of shaft deformation.

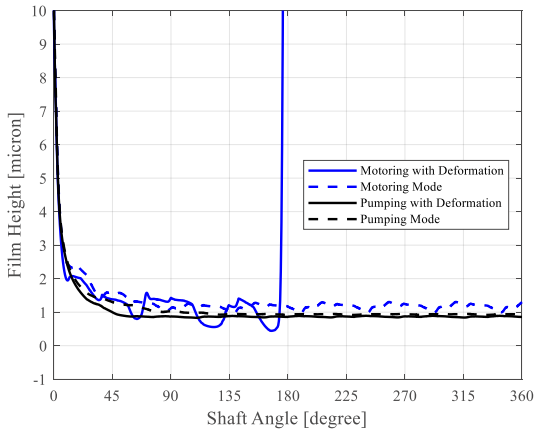

Figure 4.7. Effects of shaft spline deformation on block separation

4.2.2. Design Improvements

The coupled simulation results indicated the causes of wear on the valve plate. Two design solutions were developed to reduce contact between the running surfaces.

A. Hydrodynamic Balance Ring: Hydrodynamic balance ring is introduced to provide additional capability to counter the block tilting moments. Figure 4.8 illustrates the change of the geometry of the running surface of the cylinder block.

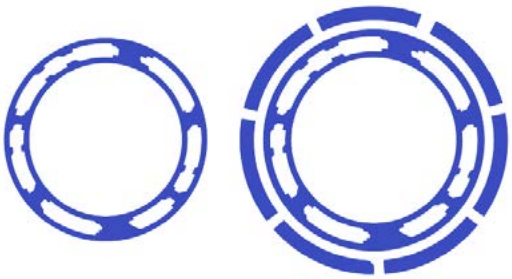

Figure 4.8. Modification of the running surface geometry of the cylinder block

B. Extended piston guide length: The length of the piston guide is defined by the distance between the beginning and end of the cylinder bore running surface. This typically is determined by the geometry of the bore undercut. It is widely understood that the increased length of the piston guide improves the sealing function of the piston cylinder interface and increases the friction due to larger area. However, the length contributes to another significant effect that determines the piston/cylinder performance – hydrodynamics. When operating in motoring mode, the piston moves outwards during the high-pressure stroke, where most of the friction happens. The high pressure tilts the piston in the bore, forming a region of wedge gap around the ends of the piston film.

In case of short bore, the film ends at the edge of the bore. The piston moves relative to the wedge gap, where the fluid is dragged out of the contact region, forcing the load to be carried by boundary lubrication. This is illustrated in Figure 4.9[A].

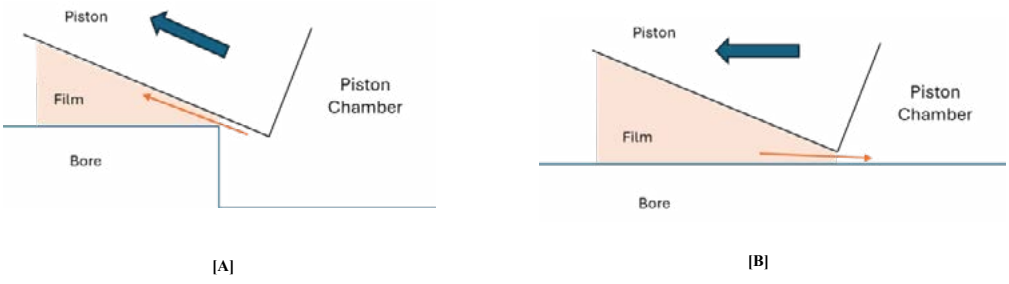

Figure 4.9. Illustration of lubrication behavior with different bore designs

In case of long bore, the film ends at the edge of the piston. The bore moves relative to the wedge gap, where the fluid is dragged into the contact, which helps carry the load hydrodynamically. This is illustrated in Figure 4.9[B]. Therefore, to improve cylinder

block/valve plate interface performance through reduction of friction from the piston in motoring more, an extended piston guide is designed as illustrated in Figure 4.10

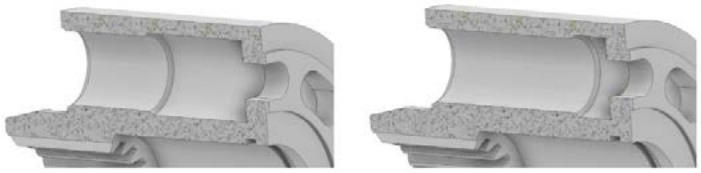

Figure 4.10. Illustration of bore design change

4.2.3. Results

Simulation results for the new interface with the hydrodynamic balance ring design are shown in Figure 4.11.[A]. The film gap heights now stay stable for the entire rotation of the cylinder block, as opposed to the baseline which is shown to separate. This indicates that the added hydrodynamic area reduces the tilting moment on the block and prevents separation.

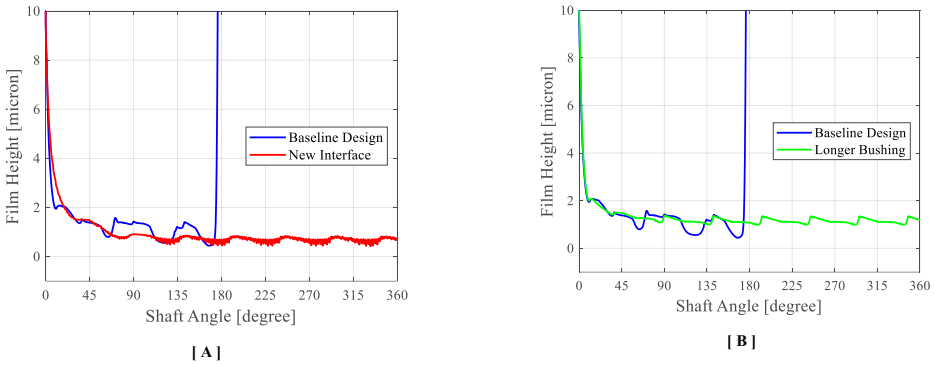

Figure 4.11. Comparison of Gap Height with new designs

Figure 4.11.[B] shows results for the new bore design with longer bushing length. The film gap height at the cylinder block/valveplate interface remains stable for the full rotation, showing that the tilting of the block has been reduced, and separation is prevented. This shows that improvement in performance of the cylinder block/valveplate interface can be achieved by changing the bore design at the piston/cylinder block interface. The coupled model used for this study enables the influence of design changes at other interfaces to be included when simulating the valve plate interface behavior, accurately showing the resulting improvements. Experimental tests show no separation with the new design, which validates the results of the coupled model.

5. CONCLUSIONS

The cylinder block/valve plate interface plays a major role in determining the operational limits of axial piston machines. The behavior of the lubricating film at this interface is dependent on the dynamics of the cylinder block, as well as the behavior of other lubricating

interfaces. Accurate numerical models need to include the effects from several interacting physical domains, in order to accurately simulate the behavior. While simplified models permit faster study of a specific parameter, several characteristics can only be understood with a full-scale model. A coupled model approach is proposed as a method to simulate such complex behavior. The proposed coupled model for the axial piston machine uses a fluid-structure interaction model to simulate the piston and valve plate lubricating interfaces, and the model is fully coupled with a body dynamics solver and lumped parameter models to simulate the solid components and the chamber volumes respectively. The effects of deformation of the cylinder block surface at the crowning region are included, to ensure that the effect of the shaft reaction moment is included.

The improvement of the simulation model is demonstrated in representing physical behavior of the axial piston machine at conditions outside the operational window. Two test cases are considered: valve plate wear at high pressures, and separation of the cylinder block at high speeds. For the two cases, the baseline designs were tested with the simulation model. The predicted behavior matched observations from experimental tests conducted for the same machine designs. Additionally, the results from the simulation model were analyzed to better understand the factors affecting performance, and design solutions were proposed addressing the causes. The improvements were first tested with the simulation model, then validated with experimental results. Table 5.1 summarizes the design changes and the resulting effects. It also highlights the improvement in simulation output with the proposed model's considerations, as opposed to the state of art models.

Designs	Proposed Model	State of Art Models	Experimental Observations
1. Valve plate Wear Study	**Operational Limit: Contact at High Pressure**		
Baseline	Contact	No Contact	Contact
New Port Block	Reduced Contact	-	Reduced Contact
Redesigned Interface	No Contact	-	No Contact
2. Cylinder Block Separation Study	**Operational Limit: Separation at High Speed**		
Baseline	Separation	No Separation	Separation
Redesigned Interface	No Separation	-	No Separation
Longer Piston Bore	No Separation	-	No Separation

Table 5.1. Summary of Test Cases and Design changes

The novel considerations of the simulation model, the coupled films and the shaft deformation, were found to be important in accurately capturing the behavior of the machine at such operating points, and ensuring the improved designs were functioning accurately. The consideration of the coupled film models, as opposed to an individual simulation of the cylinder block/valve plate interface, was found to be necessary for modelling the dynamics

of the cylinder block. Additionally, the shift in the crowning point due to deformation at the shaft ensures the simulation model captures the separation of the cylinder block from the valve plate at high speeds.

The simulation results show several cases where the cylinder block/valve plate interface is important in ensuring axial piston machines are operational at extreme operating conditions. Design changes at this interface solve issues like wear and leakage, while changes at other regions of the machine also help in improving the functioning of this interface. Therefore, the study effectively demonstrates that the operational limits of the cylinder block can be extended by optimizing the functioning of the cylinder block interface.

Biographies

Ishan Suvarna received his Bachelor's degree in Mechanical Engineering from Birla Institute of Technology and Science, Pilani – Goa Campus in 2024, and is currently pursuing his Master's degree in Mechanical Engineering at Purdue University, while working as a graduate researcher at the Maha Fluid Power Research Center. His research interests include the development and application of numerical models to analyze performance of axial piston machines, particularly under extreme operating conditions.

Dr. Lizhi Shang is Assistant Professor of Mechanical Engineering and Agricultural & Biological Engineering at Purdue University. His research interests focus on designing and modeling hydrostatic pumps and motors, hydrodynamic pumps and turbines, fluid power systems, and advanced computational and experimental tribological analysis. His research aims to improve energy efficiency, reliability, and controllability of fluid power systems by conducting interdisciplinary research on both component and system level, and to explore and expand fluid power's use and fluid power technology in new applications. Dr. Shang joined Maha fluid power research center in 2020 as an assistant professor. He graduated as a Ph.D. student in 2018. His Ph.D. advisor is the late professor Dr. Monika Ivantysynova.

Raul Rodriguez received the bachelor's degree in Mechanical Engineering from Instituto Tecnológico de Estudios Superiores de Occidente in 2012. He is currently working as a Simulation and System Engineer at Bosch Rexroth, Fountain Inn, SC, USA. His work primarily involves the simulation and analysis of mechanical components and assemblies, with an emphasis on evaluating structural integrity and mechanical strength. His professional interests include mechanical system modeling, fatigue analysis, and the development of robust simulation methodologies for complex mechanical systems.

Jeemon Kurian brings over 20 years of industry experience as a simulation engineer, with a specialized focus on hydraulics and fluid system applications. Throughout his career, he has played a pivotal role in developing and validating innovative solutions for automotive and mobile machinery systems.
He holds a Bachelor’s degree from Visvesvaraya Technological University and a Master’s degree from Coventry University. Since joining Bosch Engineering in 2005, Jeemon has contributed significantly to technological advancements within the company. Previously, Jeemon Kurian was engineering manager responsible for powertrain development at Bosch Limited India until 2019. He currently leads the Simulation team in Engineering department at Bosch Rexroth in the United States. In this leadership role, he leverages his deep technical expertise to drive innovation and establish new benchmarks in simulation excellence. His work continues to strengthen Bosch Rexroth’s position as a global leader in industrial and mobile applications.

Dr. Enrique Busquets is currently responsible for the Bosch-Rexroth Mobile Solutions business in North America encompassing sales, engineering, product management and manufacturing. In addition to this current role, Enrique has been responsible for engineering with regional product and business development responsibility on hydraulic pumps, valves, electronics, software, telematics, and electrification in North America since April 2021 and the service and aftermarket business since 2024. Additionally, since 2018, Enrique has been responsible for the testing, validation, and vehicle integration infrastructure in North America. Previously, Enrique Busquets was the engineering manager responsible for systems and software development at Bosch Rexroth North America from 2018 to 2021. The technology focus was mobile applications with electronified hydraulics and electrified systems.
Enrique holds a bachelor's degree from the University of Texas at El Paso and a master's, and doctorate degree in mechanical engineering from Purdue University with emphasis on hydraulics and electronics controls. In addition to his professional activities, Dr. Enrique Busquets is the Bosch Rexroth industry sponsor and part of the industry advisory board at the Maha research center.

New Prototype of High-Speed External Gear Pump Filling Oil from Tooth Root

Abstract.

To overcome the speed limitation of conventional external gear pumps (CEGPs) due to insufficient oil suction efficiency, a novel external gear pump (NEGP) based on tooth root-tooth tip distribution principle is proposed. A comprehensive flow-pressure mathematical model and flow field simulations are developed to analyze the tooth cavity suction process, revealing the key mechanisms responsible for inadequate oil filling in CEGPs. Additionally, the concepts of effective oil suction angle and efficient oil suction angle are introduced to facilitate a comprehensive quantitative analysis. Guided by these findings, an enhanced NEGP configuration integrating a "π"-shaped axial flow groove and a centrifugal flow baffle plate is designed to improve suction capability. This design significantly increases the effective suction area, suppresses centrifugal oil shedding, and enables dual-path oil intake via both tooth root and tooth tip, thereby extending the efficient suction angle. Both simulation and experimental results confirm the superior performance of the proposed NEGP, demonstrating a volumetric efficiency that is 12.1 percentage points higher than that of the CEGP at 3000 rpm.

Keywords. External gear pump, tooth root-tooth tip distribution principle, volumetric efficiency, effective oil suction angle, efficient oil suction angle

1. INTRODUCTION

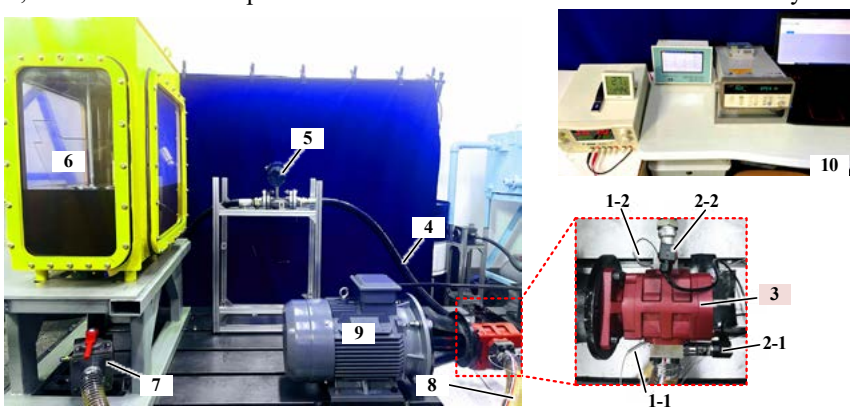
External gear pumps are widely employed in construction machinery, automotive systems, aerospace, and other industrial applications due to their simple structure, low cost, and strong resistance to contamination. To align with the efficient operating range of electric motors, gear pumps are increasingly designed for higher speeds and miniaturization. However, the maximum rotational speed of conventional high-power external gear pumps (displacement

All Open Access articles are peer-reviewed, distributed under the Creative Commons Attribution-Non Commercial 4.0 International

≥ 60 ml) is typically limited to 2500 rpm. Exceeding this threshold leads to a significant decline in volumetric efficiency, resulting in reduced energy utilization and difficulty in achieving high-speed design objectives.

The volumetric efficiency of hydraulic pumps is primarily influenced by two factors. The first is internal leakage, particularly that occurring at the gear end-face clearance, which accounts for approximately 70% of total leakage [1]. The second factor is suction efficiency, which becomes especially critical under high-speed operating conditions. Suction efficiency is governed by multiple parameters, including tooth number [2], tooth profile [3], size and orientation of the suction port [4,5], pipeline diameter and filter screen porosity [6,7], as well as pump speed [8], suction pressure [9], and the physical and chemical properties of the hydraulic fluid [10].

Various approaches to improving oil suction efficiency have been proposed in the existing literature. El-Hadj [11] suggested increasing the diameter of the suction port to reduce suction resistance. However, Corvaglia's subsequent research revealed that when the inlet diameter exceeds a certain threshold, internal recirculation occurs at the inlet, impeding oil entry into the tooth cavity and reducing its filling capacity [12]. Milani [13] experimentally compared the effects of single versus double suction ports on volumetric efficiency and found that the dual-port configuration significantly enhances pump performance. Bügener [14] applied biomimetic principles to optimize the suction channel structure, thereby improving flow streamline continuity and reducing local flow losses caused by vortices. These studies collectively provide valuable insights for addressing insufficient oil suction in gear pumps under high-speed operating conditions.



This study investigates the phenomenon of inadequate oil suction in CEGP during high-speed operation. A mathematical model of the flow-pressure dynamics during oil suction in the tooth cavity, along with a flow field simulation model, is established to systematically elucidate the underlying mechanisms contributing to reduced suction efficiency. Based on these findings, a novel external gear pump NEGP incorporating a tooth root-tooth tip distribution principle is proposed. Experimental results demonstrate that the NEGP effectively overcomes the speed limitation imposed by poor oil suction efficiency, thereby breaking through a key technical bottleneck. The findings of this research offer a theoretical foundation for the innovative design of high-speed external gear pumps.

2. ANALYSIS OF OIL SUCTION CHARACTERISTICS TO CEGP

2.1. CEGP Oil Absorption Efficiency Test

The experimental study focuses on a CEGP with a displacement of V_d=63cm^3/r. The tests were conducted under controlled conditions, with an oil temperature of 44.3°C and an ambient temperature of 27.3°C. The pump operated in an unloaded state to minimize the influence of internal leakage on volumetric efficiency, ensuring that the measured efficiency closely approximates the pump's suction efficiency. The test setup is illustrated in Figure 2.1, where HM46 anti-wear hydraulic oil is used in the reservoir. During testing, the motor drives the CEGP to draw oil from the reservoir through the suction pipe and discharge it back via the discharge pipe, forming a closed-loop circulation system. High-precision pressure sensors (accuracy: ±0.25%) and temperature sensors (accuracy: ±0.1°C) were installed at the pump inlet and outlet, respectively, to monitor oil pressure and temperature.

A turbine flowmeter with an accuracy of ±0.5% was mounted on the discharge line to measure the volumetric flow rate. After the pump reached steady-state operation, data were acquired using a data acquisition system at a sampling frequency of 10 Hz over a 20-second interval, and each test was repeated three times to ensure measurement reliability.

Figure 2.1. Experiment System for External Gear Pump

The time-averaged value was computed for each of the three data sets, and the arithmetic mean of these averages was calculated and denoted as Q_C. Subsequently, the volumetric efficiency η_C of the gear pump at various rotational speeds n was determined using Equation (2.1), with results presented in Figure 2.2. As shown by the experimental curve, η_C initially increases and then decreases with rising speed. Specifically, η_C gradually rises from 87.97% at 500 rpm, reaching a maximum of 94.2% at 2700 rpm. Beyond this point, η_C declines rapidly, dropping to 81.87% at 3000 rpm, representing a reduction of 12.33 percentage points from the peak efficiency. This trend clearly indicates a significant deterioration in oil suction performance at high operating speeds for the CEGP.

$$\eta_c = \frac{Q_c}{n \cdot V_d} \qquad (2.1)$$

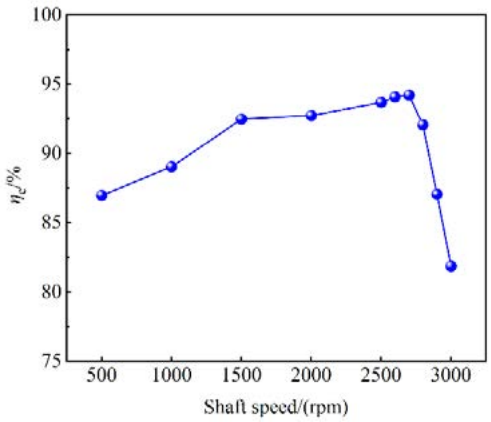

Figure 2.2. Volume efficiency of CEGP at different speeds

2.2. *CEGP Cavity Flow - Pressure Characteristics*

The CEGP employs a radial oil suction method from the tooth tip. The flow rate entering the tooth cavity is determined by the minimum flow area A formed during gear disengagement. To facilitate analysis, it is assumed that when the gears rotate to a specific angular position, the oil suction process can be approximated as quasi-static. Under this assumption, the minimum pressure difference Δp required for an instantaneous flow rate q to pass through the minimum flow area A is calculated. To clearly differentiate between the two suction configurations, the minimum suction area associated with radial suction from the tooth tip is denoted as A_r, and the corresponding minimum pressure difference is defined as Δp_r. For axial suction from the tooth root, the minimum suction area is denoted as A_a, and the minimum tooth cavity volume is represented as V. The oil flow paths for the two suction methods and the gear structural parameters are illustrated in Figure 2.3.

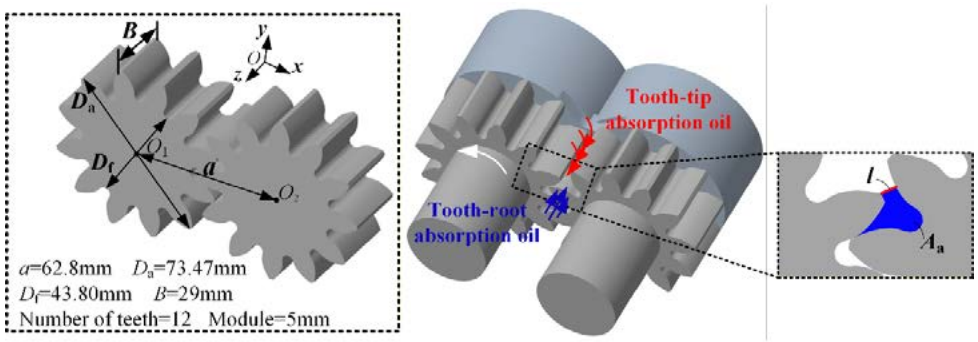

Figure 2.3. Diagram of different oil absorption directions and the gear structural parameters

By integrating 3D model analysis with data fitting, the variations of the shortest inter-tooth distance l, the radial oil suction area A_r, and the axial oil suction area A_a as functions of the rotation angle θ were systematically characterized in a quantitative manner. Consequently, the analytical expressions for A_r, A_a, and the minimum tooth cavity volume V were rigorously derived as follows:

$$l = \begin{cases} 0.063 \ (0° \le \lambda < 14°) \\ 45.83\theta^2 - 14.85\theta + 0.96 \ (14° \le \lambda \le 35°) \end{cases} \quad (2.2)$$

$$A_r = l \cdot B \quad (2.3)$$

$$A_a = 226.84\theta^2 - 1.9\theta + 10.74 \ (0° \le \lambda \le 35°) \quad (2.4)$$

$$V = A_a \cdot B \quad (2.5)$$

$$\begin{cases} \theta = \omega t \\ \lambda = \theta \cdot \dfrac{180}{\pi} \end{cases} \quad (2.6)$$

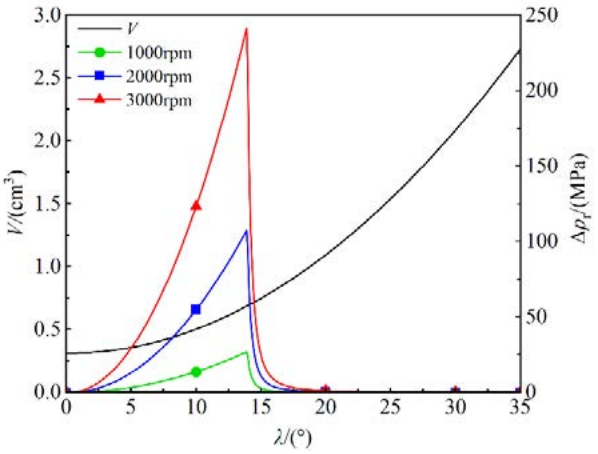
$$\omega = \frac{2\pi n}{60} \quad (2.7)$$

where ω represents the angular velocity of the gear.

As derived from reference [15], the relationship between flow rate and pressure can be expressed as:

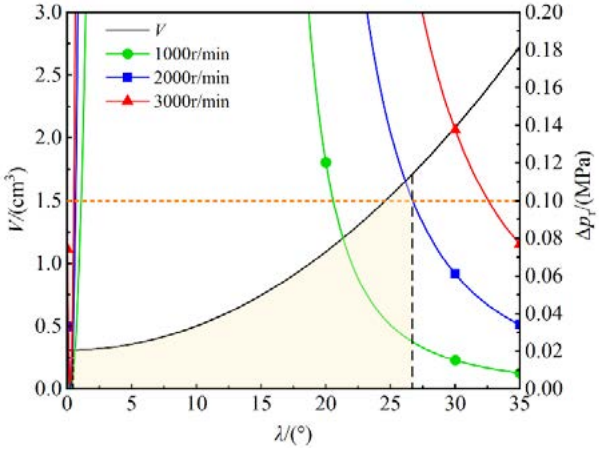
$$q = C_{\mathrm{d}} A \sqrt{\frac{2\Delta p}{\rho}} \quad (2.8)$$

Equation (2.8) can be transformed into



$$\Delta p = \frac{\rho}{2C_{\mathrm{d}}^2}\left(B\frac{\mathrm{d}A_{\mathrm{a}}}{\mathrm{d}t}\right)^2 \frac{1}{A^2} = \delta \cdot \frac{1}{A^2} \quad (2.9)$$

$$\delta = \frac{\rho}{2C_{\mathrm{d}}^2}\left(B\frac{\mathrm{d}A_{\mathrm{a}}}{\mathrm{d}t}\right)^2 = \frac{\rho}{2C_{\mathrm{d}}^2}\left[B\left(453.68\omega^2 t - 1.9\omega\right)\times 10^{-9}\right]^2 \quad (2.10)$$



By substituting equation (2.3) into equation (2.8), the minimum pressure difference Δp_{r} required for radial oil suction can be determined. The resulting expression for Δp_{r} as a function of angular velocity ω is given by:

$$\Delta p_{\mathrm{r}} = \begin{cases} \delta \cdot \dfrac{1}{\left(0.063B\times 10^{-6}\right)^2} & (0° \le \lambda < 14°) \\ \delta \cdot \dfrac{1}{\left[B\left(45.83\omega^2 t^2 - 14.85\omega t + 10.74\right)\times 10^{-6}\right]^2} & (14° \le \lambda \le 35°) \end{cases} \quad (2.11)$$

Using the discharge coefficient $C_{\mathrm{d}} = 0.72$ [1] and fluid density $\rho = 860$ kg/m³, the variation curves of the tooth cavity volume V and the minimum pressure difference Δp_{r} with respect to the rotation angle θ are presented in Figure 2.4(a). The detailed profile of Δp_{r} within the range of 0 to 0.2 MPa is shown in Figure 2.4(b), where the yellow-shaded region indicates the minimum tooth cavity volume at a rotational speed of 2000 rpm under the condition that $\Delta p_{\mathrm{r}} \ge 0.1$ MPa.

(a)Δp_{r} global diagram

(b) Local graph of Δp_r from 0 to 0.2 MPa

Figure 2.4. V and Δp_r change curves with λ

As illustrated in Figure 2.4, under the tooth tip radial oil suction configuration, at rotational speeds of 1000, 2000, and 3000 rpm, the minimum proportions of the tooth cavity volume satisfying the condition $\Delta p_r \geq 0.1$ MPa account for 29.77%, 52.55%, and 83.07% of the total tooth cavity volume, respectively. This increasing trend demonstrates that higher rotational speeds require a larger angular range over which the gear pump must maintain sufficient oil suction pressure to ensure effective filling. However, the oil suction pressure is solely supplied by atmospheric pressure (approximately 0.1 MPa), which significantly reduces the available time for liquid filling. The underlying cause of this limitation is the inherently small radial oil suction area at the tooth tip, which severely constrains the flow runner capacity and thus impedes efficient oil delivery.

2.3. CEGP Internal Flow Field Characteristics

The theoretical analysis presented in Section 1.2 is confined to the flow–pressure difference relationship during the initial formation stage of the tooth cavity and does not yield an analytical solution for the internal flow dynamics after the cavity is fully developed. To address this limitation, the present study employs Pumplinx software to conduct numerical simulations. The RNG k-ε turbulence model is adopted to accurately capture turbulent flow characteristics. Boundary conditions are defined as follows: the inlet is assigned an absolute pressure of 0.1 MPa, and the outlet is set to 0.3 MPa. The oil properties are specified with a dynamic viscosity of 0.037 Pa·s and a density of 860 kg/m³, while the gear rotational speed is fixed at 2500 rpm. To ensure mesh independence, the outlet flow rate is monitored across different grid resolutions. The resulting simulation data are illustrated in Figure 2.5.

As illustrated in Figure 2.5, the time-averaged volumetric flow rate gradually converges with increasing cell density. When the cell count rises from 8.0×10^5 to 11.3×10^5, the flow rate variation is only 0.28%, which satisfies the criterion for mesh independence. Therefore, considering the balance between computational efficiency and numerical accuracy, a cell size of 8.0×10^5 is selected for all subsequent simulations.

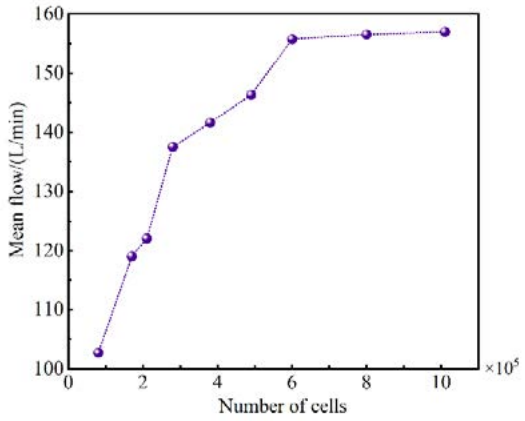


Figure 2.5. The output flow of the CEGP simulation model under different cell numbers

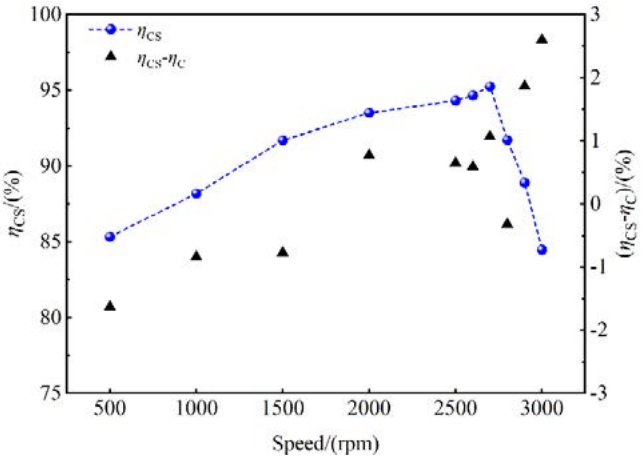
Furthermore, by monitoring the outlet flow rate in the CEGP simulation, the relationship between the volumetric efficiency η_{CS} and rotational speed is established, along with the difference between the simulated value η_{CS} and the experimental value η_C, as depicted in Figure 2.6. As illustrated in Figure 6, the trend of η_{CS} with respect to rotational speed is in good agreement with the experimental results. The maximum and average absolute differences $|\eta_{CS}-\eta_C|$ are 2.6% and 1.11%, respectively. The small discrepancy between simulation and test values indicates that the numerical model exhibits high reliability.



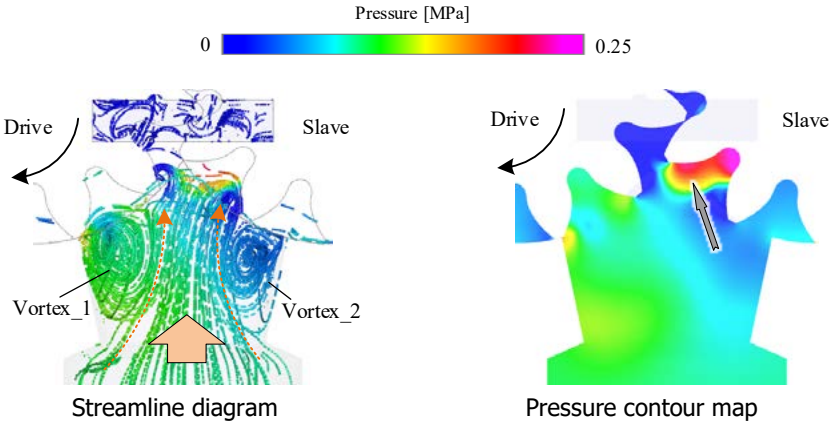


Figure 2.6. η_{CS} and(η_{CS}-η_C) of EGP at different rotational speeds

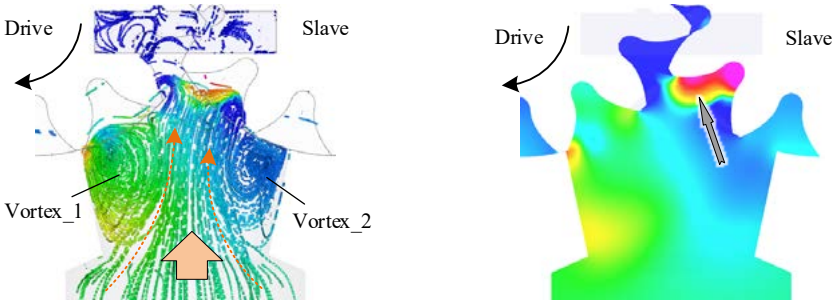

As shown in Figure 2.7, the streamline distribution within the CEGP at rotational speeds ranging from 2700 to 3000 rpm is presented. With increasing rotational speed, the number of streamlines entering the vortex region gradually increases, and the spatial extent of the vortex expands significantly. Concurrently, the effective flow area into the tooth cavity diminishes, and the density of streamlines decreases accordingly. This vortex structure impedes the normal inflow of oil into the tooth cavity. The underlying mechanism is attributed to the high centrifugal pressure generated within the fully formed tooth cavity due to the rotating gear's centrifugal force, which intensifies with rotational speed. Under this

pressure gradient, part of the oil is expelled radially outward and collides with incoming oil flowing in the opposite direction, thereby inducing localized vortex formation.

Figure 2.7. Inlet flow diagram of CEGP at different speeds

Based on the above analysis, the high-speed oil suction deterioration process in CEGP can be characterized by three progressive stages. First, as the gear teeth begin to disengage and form a complete tooth cavity, the radial oil suction at the tooth tip is insufficient to meet the required flow rate, resulting in a low cavity filling efficiency. Second, under the influence of high rotational speed and centrifugal force, part of the oil within the fully formed cavity is expelled radially outward, further reducing the filling level. Finally, the expelled oil collides with the incoming radial flow, generating two prominent local vortices at the pump inlet that significantly impede the subsequent oil suction process.

2.4. Effective Oil Suction Angle and Efficient Oil Suction Angle

To further analyze the influence of flow characteristics at each stage on the tooth cavity's oil suction efficiency, two key angular parameters are defined: the effective oil suction angle and the efficient oil suction angle. The effective oil suction angle refers to the angular range over which the tooth cavity can freely absorption and discharge fluid, with its filling performance influenced by the radial oil suction area and the inlet vortex. The efficient oil suction angle denotes the portion within the effective oil suction angle where the cavity filling rate is not constrained by these two factors and can achieve an ideal, loss-free filling state.

The geometric definitions of these angles are illustrated in Figure 2.8 and described as follows:

Effective oil suction angle α: This denotes the angular displacement between the line c_1, which connects the edge position of the pump body's oil suction port to the gear center, and the $+x$ reference axis.

Radial oil suction area influence angle β: As introduced in Section 1.3, this represents the angular displacement during which $\Delta p_r \geq 0.1$ MPa, reflecting the extent to which the radial oil suction area limits oil inflow.

Inlet vortex influence angle γ: This is the angle between line c_1 and line c_3, where c_3 is drawn from the gear center tangent to the boundary of the inlet vortex influence zone. It quantifies the angular extent of obstruction caused by the inlet vortex.

Finally, the efficient oil suction angle φ is determined by the equation $\varphi=\alpha-\beta-\gamma$, representing the optimal angular range for oil suction that remains unaffected by hydraulic losses.

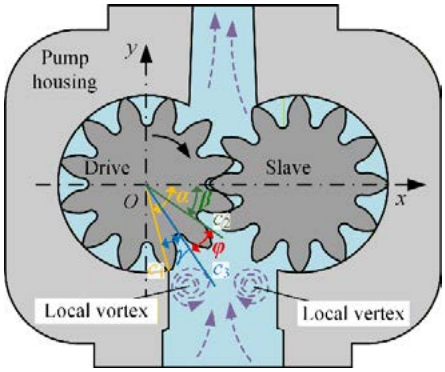

Figure 2.8. Diagram of α, β, γ, φ

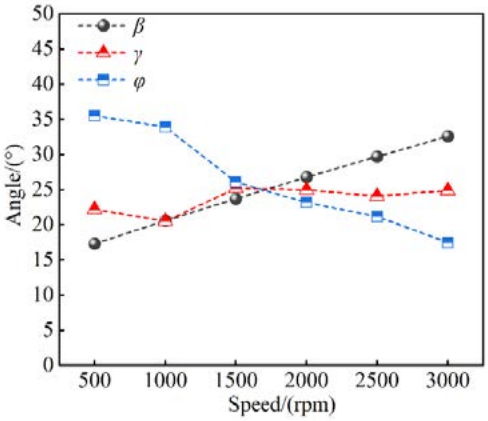

Figure 2.9. The change curve of the β, γ and φ with speed

The variation of each angular parameter with rotational speed is presented in Figure 2.9. As shown in the figure, the radial oil suction area influence angle β increases significantly with rising rotational speed, whereas the inlet vortex influence angle γ exhibits a moderate upward trend with a relatively limited increment. Under these conditions, the efficient oil suction angle φ, primarily governed by the rapid expansion of β, decreases sharply as rotational speed increases, leading to a substantial reduction in the effective liquid filling time of the tooth cavity.

3. Design Principles and Verification for NEGP

Based on the aforementioned analysis, the efficient oil suction angle is primarily constrained by two factors: the radial oil suction area and the inlet-localized vortex. Therefore, the NEGP structural optimization proposed in this study is conducted with respect to these two aspects.

3.1. Design of the New Distribution Structure for NEGP

(1) Centrifugal Flow Baffle Plate and Radial Flow Distribution Groove

According to the analysis in Section 2.3, the local vortex at the inlet is primarily caused by the centrifugal force generated during high-speed gear rotation, which drives the oil out of the tooth cavity. To mitigate this phenomenon, a centrifugal flow baffle plate is incorporated into the pump housing to prevent oil from being expelled under centrifugal force. Additionally, to maintain an adequate low-pressure oil suction passage in the tooth tip region, a radial distribution groove is machined at the center of the flow baffle plate, thereby balancing the dual requirements of flow containment and sufficient oil supply.

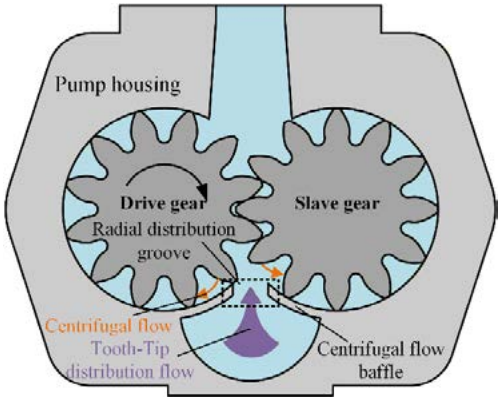

Figure 3.1. Diagram of Tooth-Top distribution flow

(2) "π" -shaped axial flow distribution groove

As described in Section 2.2, single radial oil suction at the tooth tip requires a relatively high suction pressure differential due to its limited flow area, making it prone to becoming a flow bottleneck under high-speed operating conditions. According to Equation (3.1), the centrifugal force acting on a fluid element is directly proportional to the radius of gyration and the square of the rotational speed. Consequently, the centrifugal pressure in the tooth root region is lower than that in the tooth tip region.

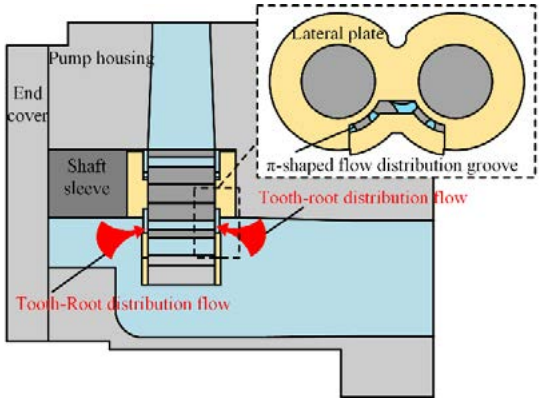

Figure 3.2. Diagram of Tooth-Root distribution flow

To address this imbalance, a π-shaped axial flow distribution groove is machined into the floating lateral plate adjacent to the gear tooth root and connected to the axial suction runner. This feature establishes an auxiliary suction path characterized by lower centrifugal

pressure, thereby compensating for insufficient oil supply at the tooth tip by enhancing suction capacity at the tooth root. As this design primarily leverages and enhances the inherent suction potential in the tooth root region, it is termed tooth-root flow distribution. The detailed configuration is illustrated in Figure 3.2.

$$p = \rho\omega^2 \frac{r^2}{2} + p_0 \qquad (3.1)$$

where r is the radial radius.

The radial distribution groove and the π-shaped axial distribution groove collectively constitute the root-to-tip flow distribution system. When flow allocation is based on suction area, the radial suction flow rate $q_{r,c}$ can be calculated using Equation (3.2). Likewise, the volume delivered to the tip tooth cavity $V_{r,c}$ is derived from Equation (3.3).

$$q_{r,c} = q \cdot \frac{A_r}{A_r + 2A_a} \qquad (3.2)$$

$$V_{r,c} = V \cdot \frac{A_r}{A_r + 2A_a} \qquad (3.3)$$

Substituting equation (3.2) into equation (2.9) yields

$$\Delta p_{r,c} = \frac{\rho}{2C_d^2} \cdot q_{r,c}^{\ 2} \frac{1}{A_r^2} \qquad (3.4)$$

The results calculated from Equations (3.3) and (3.4) are presented in Figure 3.3.

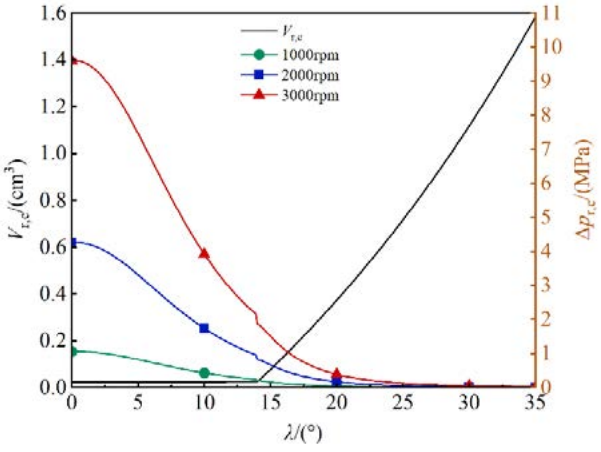

Figure 3.3. $V_{r,c}$ and $\Delta p_{r,c}$ change curves with λ

It can be observed that the pressure difference $\Delta p_{r,c}$ required for parallel oil suction is significantly lower than that of Δp_r under single radial oil suction. At rotational speeds of 1000, 2000, and 3000 rpm, the proportions of the total tooth cavity volume experiencing a pressure difference exceeding 0.1 MPa under the parallel oil suction mode are 4.26%, 22.5%, and 40.45%, respectively, reflecting reductions of 25.51, 30.05, and 42.62 percentage points relative to the single radial oil suction mode. These findings provide theoretical validation that the parallel oil suction configuration at both the tooth root and

tooth tip effectively improves oil suction conditions at high rotational speeds and exhibits superior oil suction performance.

3.2. Internal Flow Field Characteristics of NEGP

Under the same simulation conditions as those applied to CEGP, the fluid domain model of NEGP was analyzed. The volumetric efficiency of NEGP at various rotational speeds is presented in Figure 3.4. The results show that the volumetric efficiency increases rapidly with rising rotational speed within the range of 500 to 2500 rpm, while the rate of increase diminishes in the high-speed range from 2600 to 3000 rpm. Compared with the simulation data for CEGP, NEGP exhibits a volumetric efficiency improvement of 2.18%, 5.0%, and 9.61% at 2800, 2900, and 3000 rpm, respectively—demonstrating that the new distribution structure offers significant performance advantages under high-speed operating conditions.

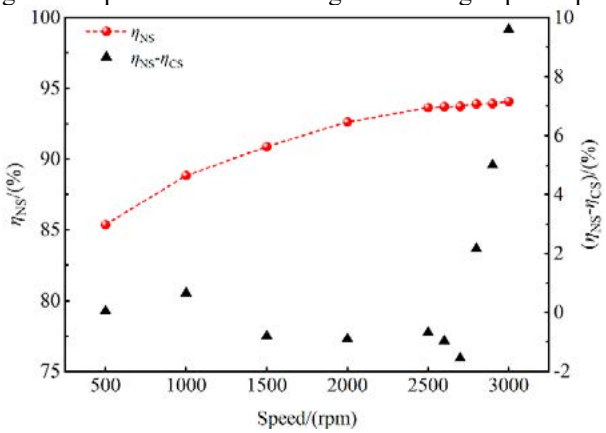

Figure 3.4. Volumetric efficiency of NEGP' simulation model

Figure 3.5 shows the internal streamline distribution of the NEGP at a specific angle under a rotational speed of 3000 rpm. As can be seen from the figure, no local vortices occur in the inlet area, and the oil is clearly divided into three independent and smooth streamlines entering the tooth cavity.

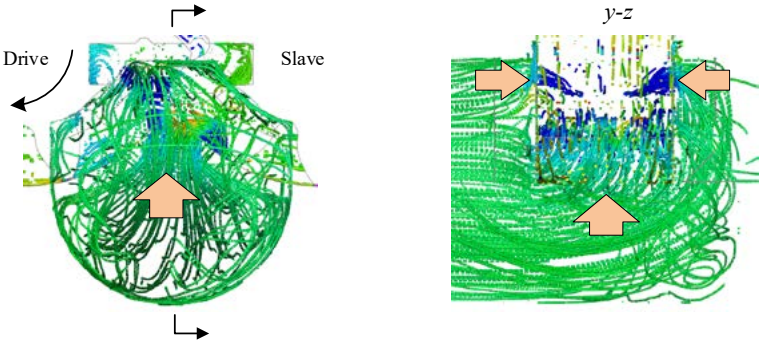

Figure 3.5. Inlet streamline figures of NEGP under 3000rpm

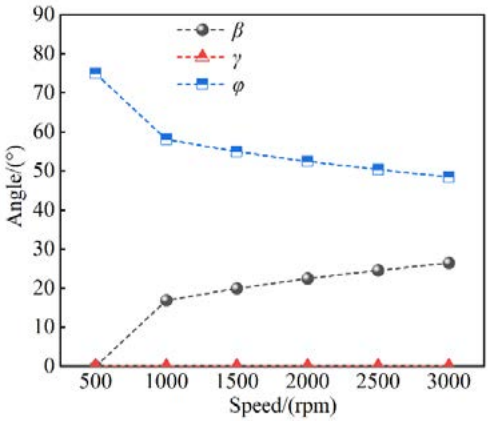
Figure 3.6 further illustrates the variation in angular parameters of NEGP. For NEGP, the vortex influence angle γ remains consistently zero, attributable to the optimized inlet flow field that effectively eliminates local vortices. Although the oil suction area influence angle

β increases rapidly with rotational speed, leading to a reduction in the effective oil suction angle φ, the value of φ at 3000 rpm is increased by 227.54% compared to CEGP. This significant expansion provides substantially improved oil suction duration for the gear pump under high-speed operating conditions, thereby providing a fundamental explanation for its enhanced performance.



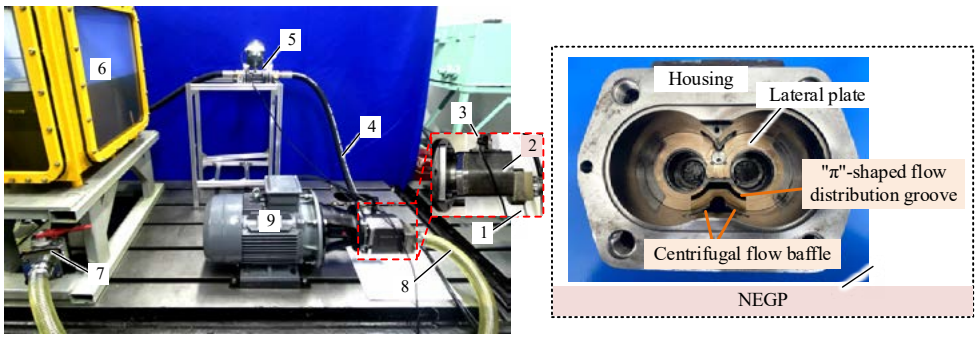


Figure 3.6. The change curve of the β, γ and φ with speed of NEGP

3.3. Experimental Verification to NEGP

To further validate the rationality of the root-to-tip parallel flow distribution principle employed in NEGP, a test bench as shown in Figure 3.7 was constructed, with operating conditions maintained consistently with those of the CEGP test.

1-Temperature sensor 2- NEGP 3- Pressure sensor 4-Discharge pipe 5-Turbine flowmeter 6-Oil tank 7-Switch valve 8-Suction pipe 9-Motor

Figure 3.7. Experimental bench of NEGP

The volumetric efficiency η_N of the NEGP varies with rotational speed, as shown in Figure 3.8. As can be observed from the figure, the volumetric efficiency of NEGP increases rapidly with rising speed within the range of 500 to 2500 rpm, while the rate of increase slows in the range of 2600 to 3000 rpm, reaching a peak value of 93.97% at 3000 rpm. When the rotational speed exceeds 3000 rpm, η_N begins to decrease, dropping to 79.51% at 4000 rpm. Compared with the efficiency η_C of CEGP, η_N exhibits only a small difference within the 500-2700 rpm range. However, at 2800, 2900, and 3000 rpm, η_N improves by 1.71, 6.92,

and 12.1 percentage points, respectively. Based on these results, 2700 rpm can be identified as the critical speed for significant improvement in NEGP's volumetric efficiency. The experimental results clearly demonstrate that NEGP effectively extends the speed range for efficient oil suction and offers distinct performance advantages under high-speed operating conditions.

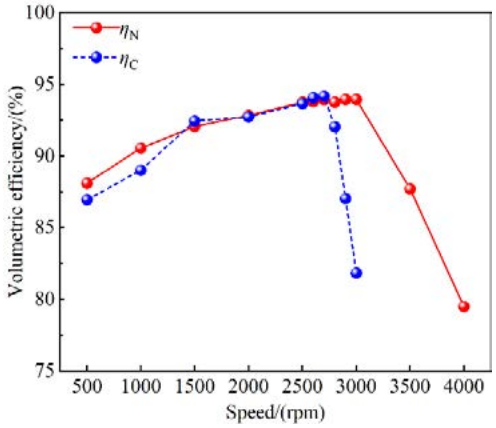

Figure 3.8. Volumetric efficiency of NEGP under different speeds

4. CONCLUSION

The intrinsic mechanism underlying the decline in oil suction efficiency of CEGP under high-speed operation was el1ucidated. This process can be divided into three stages: First, during the initial cavity formation stage, the narrow radial oil suction area at the tooth tip results in insufficient initial filling rate. Second, the centrifugal effect induced by high-speed rotation expels oil from the cavity, further reducing the filling rate. Third, the expelled oil collides with radially incoming oil at the pump inlet, generating two large local vortices that impede radial oil suction at the tooth tip. Collectively, these factors lead to a significant reduction in the effective oil suction angle of CEGP, inadequate effective filling duration, and ultimately result in poor high-speed oil suction performance and low volumetric efficiency.

A novel external gear pump based on the tooth root-tooth tip parallel distribution principle was proposed. Its innovative design incorporates a π-shaped axial distribution groove on the floating side plate to enhance oil suction capacity in the tooth root region. Additionally, a centrifugal flow baffle plate featuring radial distribution grooves is integrated into the pump housing to suppress centrifugal oil ejection while preserving volumetric oil suction at the tooth tip. The axial and radial distribution grooves serve as the primary pathways for centrifugal oil suction at the tooth root and volumetric oil suction at the tooth tip, respectively, forming a dual-channel oil supply system in NEGP.

Simulation and experimental results validate the superior performance of NEGP. Flow field analysis reveals the absence of local vortices at the NEGP inlet, with the effective oil suction angle being significantly larger than that of CEGP. Experimental data show that the volumetric efficiency of NEGP reaches a peak of 93.97% at 3000 rpm, and its efficient operating range is extended. Comparative performance analysis indicates that, with 2700

rpm identified as the critical speed, the volumetric efficiency of NEGP at 2800, 2900, and 3000 rpm exceeds that of CEGP by 1.71, 6.92, and 12.1 percentage points, respectively.

Abstract.

Underground load-haul-dump (LHD) vehicles, with the excellent maneuverability and efficiency, are widely used to the materials removal in underground mines and constructions. Owing to the harsh operation environment, the autonomous functions of LHDs have been urgently needed for the consideration of safety, efficiency, and cost. Dumping is one of the core functions for underground load-haul-dump (LHD) vehicles. Typical underground environment including narrow space and varying dumping locations restricted the unconstrained autonomous dumping. This paper probes into the autonomous dumping control of LHDs under narrow and constrained environment based on the reinforcement learning (RL) frame. Firstly, the kinematic and dynamic models of a LHD are established considering the data-dependency of the RL method. The duty-based RL control method, is proposed to realize the coordinative control of the driving system and the working system in dumping duty, in which the safety in avoiding collision and working efficiency were considered. A test platform was established with the LHD to validate the methods. For the RL-based method, the performance of different algorithms was evaluated. A typical dump duty was performed to validate the method. The results shown that the method could finish the dumping operation autonomously under constrained environment. The duty-based RL control method shown great coordinative characteristics and environmental adaptability with the RL frame under constrained environment.

1. INTRODUCTION

Underground load-haul-dump (LHD) vehicles are essential equipment in underground mining and construction due to the excellent maneuverability and operational efficiency[1-2]. However, the harsh and confined working conditions pose significant challenges to automation, driving an urgent need for autonomous LHDs functionalities to enhance safety, productivity, and cost-effectiveness. The autonomous operations of LHDs evolve through five stages: driver-only, assisted, semi-autonomous, highly-autonomous, and fully autonomous, with current operations transitioning from assisted to semi-autonomous[3].

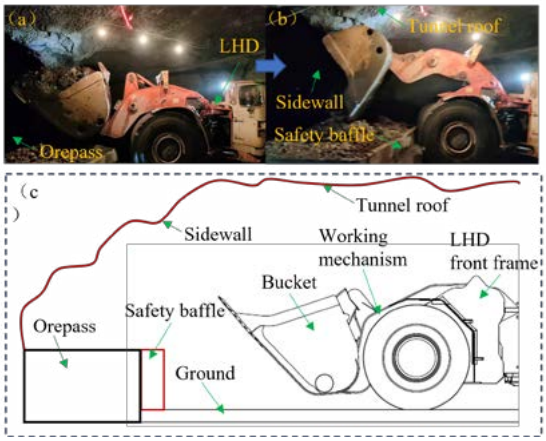

Figure 1: Typical dumping environment of underground LHD

The working environment of LHDs is narrow and constrained, as shown in Fig. 1, which functions include loading, hauling, and dumping materials. The autonomous loading function has been focused for many years considering the decisive effect on working efficiency. However, the interaction between materials and bucket is complex and the characteristics of materials varies significantly[4], which blocked the practical application and made the autonomous loading challenging and long term developing-needed. The autonomous hauling can be realized with the trajectory tracking of articulated vehicles, which has been applied in the practical working process. The dumping operation, one of the core function of LHDs, involved the control of the driving system and the working mechanism. Although the operation could be performed with the pre-set automation program, the driving system and working mechanism were not controlled coordinately as manual control. Current autonomous dumping would be inefficiency and unsafe in constrained environment. In addition, the variation of dump point and environment constraints could not be covered. Therefore, the improvement of autonomous dumping function would be practical and effective for the autonomous development transition[5-6].

The dumping function of LHDs could be realized with the pose (including trajectory and attitude angle) control of bucket. For the pose control, the traditional proportional-integral-derivative (PID) method would be the first choice considering the simple structure and stable performance. There are two problems to be addressed before the application of PID. First, the target/reference values of the controlled lift, dump cylinders, and the driving system should be provided via the inverse kinematics of the vehicle and the working mechanism.

The kinematics of the six link mechanism provided a feasible solution obtained from cumbersome calculation. Second, the parameters of PID must be tuned individually. Different algorithms had been used to tune the parameters, such as fuzzy logic, neural network (NN), and genetic algorithm (GA). Some modern control methods were also used to the trajectory tracking of bucket, including mode predictive control (MPC), optimal control, and RL-based methods[7-9]. However, most of these researches studied the trajectory control of bucket in open area and unconstrained environment, or only the working mechanism of LHDs[10] was mainly focused.

Inspired by the aforementioned researches, this paper explores the duty-based RL autonomous dumping control method. First, the models of the LHD and the corresponding test platform are established considering the data-dependency of the RL methods. Then, the duty-based RL control method (DRLC) is proposed with the RL frame, in which the completion rate, working efficiency, and environment constrains are covered. The performance of different algorithms and preview horizon in the methods, including deep deterministic policy gradient (DDPG), twin Delayed Deep Deterministic policy gradient algorithm(TD3), SAC, and distributional SAC (DSAC)[11], are evaluated under typical dumping operation. The main contributions of this paper include: (1) An environment-adapted control method for autonomous dumping of LHDs is established based on the RL frame; (2) The performance of different algorithms and preview horizon are uncovered under typical dumping operations; (3) The performance of RL-based methods is evaluated in terms of safety and efficiency.

2. KINEMATIC AND DYNAMIC MODEL

The working mechanism of the LHD is a typical reverse Z-shape six link mechanism, as shown in Fig. 2, the actuators of the whole system are the lift and dump cylinders. During the lifting process, if only the lift cylinder is controlled, the angle of bucket would vary, which would lead the scattering of the ore materials. Therefore, the whole autonomous dumping operation in constrained environment can only be realized with the coordinate control of the driving system and the working mechanism.

2.1. Model of LHD

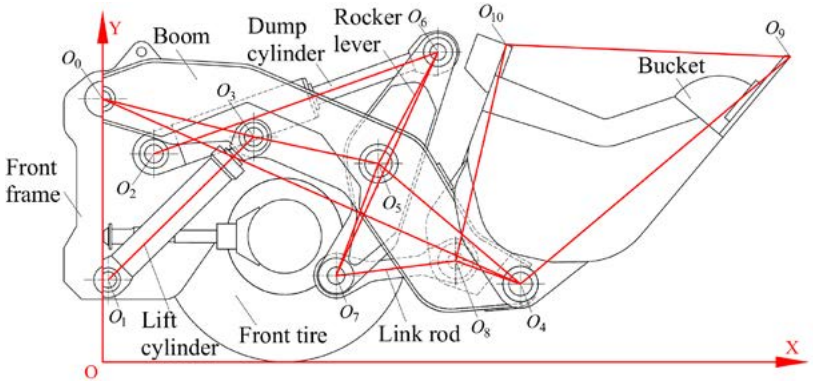

Figure 2: Working mechanism of LHD

The kinematic model of LHD and the working mechanism are involved during the dumping operation control. For working mechanism, as shown in Fig. 2, the boom is connected with the front frame (at O_0), rocker lever (at O_5), bucket (at O_4), and the lift cylinder (at O_3). The two connecting points of cylinders are O_1 and O_2, respectively. The motion of the working mechanism can be described in the coordinate frame (XOY), in which the vertical direction across the O_0 is defined as Y axis, and the horizontal tangent direction of front tire is defined as X axis.

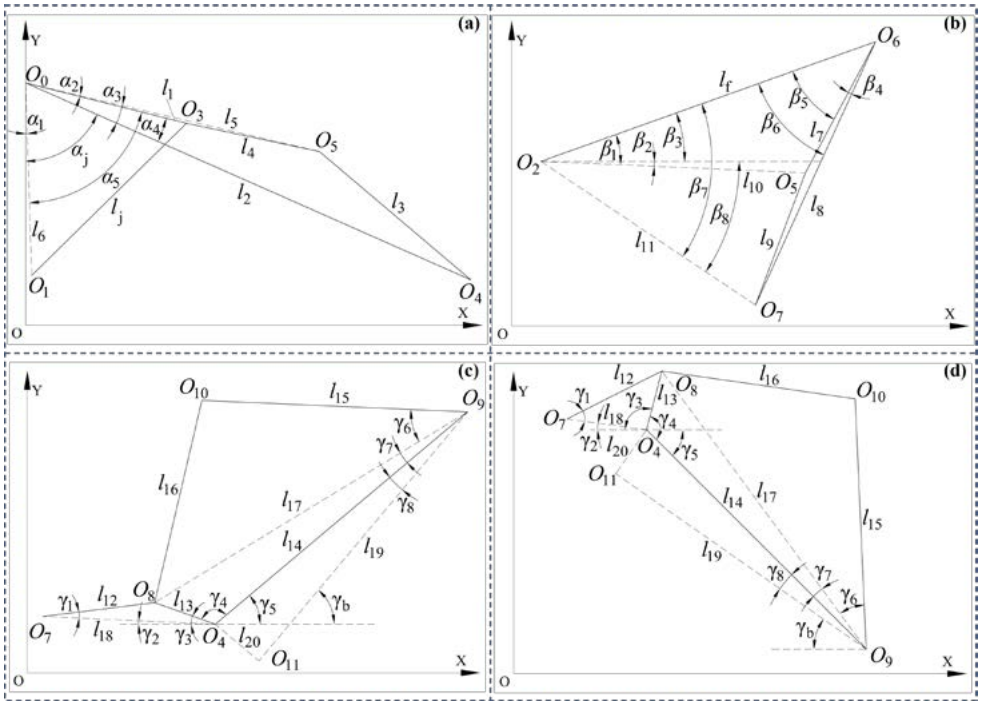

Figure 3: Geometric relationship of different states of working mechanism

The geometric relationship of bucket in dumping state is shown in Fig. 3 (d), and the coordinate of bucket tip O_9 can be expressed as:

$$\begin{cases} X_9 = X_4 + l_{14}\cos\gamma_5 \\ Y_9 = Y_4 + l_{14}\sin\gamma_5 \\ X_{10} = X_9 - l_{15}\cos(\gamma_6 + \gamma_7 - \gamma_5) \\ Y_{10} = Y_9 + l_{15}\sin(\gamma_6 + \gamma_7 - \gamma_5) \end{cases} \tag{1}$$

in which γ_b is the angle between bucket bottom and horizontal direction., the forward kinematics of the working mechanism can be obtained with the related geometry relationship in Figure 3.

Considering that the dumping operation is finished with driving system and working mechanism (no steering maneuver is involved), the longitudinal dynamic model of the LHD should be established. The longitudinal dynamic model of LHD in the X axis of global coordinate frame can be described as:

$$m\ddot{x} = F_{tx} - F_r \tag{2}$$

in which, m is the mass of LHD, F_{tx}, F_r are the longitudinal driving force, and total resistance force, respectively, x is the longitudinal distance of LHD in global coordinate frame.

The longitudinal force of tires can be given by Magic Formula:

$$F_{tx} = S_y + Dsin\left\{Carctan\left[\begin{matrix} B(X_m - S_x)(1-E) \\ +EarctanB(X_m - S_x) \end{matrix}\right]\right\} \tag{3}$$

where X_m denotes the slip ratio of the tire, which are defined as η; F_{tx} denotes the longitudinal force of tire; the parameters S_x, S_y, B, C, D, and E are constant, where in this study $S_x = 0$, $S_y = 0$, and other parameters are calculated by equations with vertical load. The slip ratio of different tire can be given by:

$$\eta = \begin{cases} (r_d\omega_t - v_x)/r_d\omega_t \times 100\% & Drive \\ (r_d\omega_t - v_x)/v_x \times 100\% & Brake \end{cases} \tag{4}$$

where r_d denotes the rolling radius of different tires, ω_t denotes the angular velocity of tires, and v_x denotes the longitudinal velocity of LHD. The final drive torque in the wheel overcomes the rolling resistance force and braking force to produce the longitudinal driving force, and the detailed model can be expressed as:

$$I_w\dot{\omega}_t = T_d - f_r - F_{tz}r_d - F_{tx}r_d \tag{5}$$

where I_w is the rotational inertia of the wheel, and T_d is the driving torque, F_{tz} is the vertical load of tires. f_r is the rolling resistance force, which can be expressed as:

$$\begin{cases} f_r = 0.00792 + 0.00025v_x & v_x \neq 0 \\ f_r = 0 & v_x = 0 \end{cases} \tag{6}$$

The longitudinal dynamic model of LHD can be obtained by combing equation (2) - (6). Therefore, the bucket pose in global frame could be given by combing the kinematic and dynamic models:

$$\begin{cases} X_{11} = x + X_4 + l_{14}\cos\gamma_5 \\ Y_{11} = y + Y_4 + l_{14}\cos\gamma_5 \end{cases} \tag{7}$$

where X_{11}, Y_{11} are the coordinates of bucket tip O_9 in global frame. y is the vertical distance of local and global frames.

2.2. Model validation

To validate the involved models, an LHD test system is established, as shown in Fig. 4. The control system is a two-layer structure system, in which an industrial computer is used in the upper layer for the functions of perception, navigation, and control decision. A 16 line LiDAR and inertial measurement unit (IMU) are used to obtain the vehicle state and the operation environment in the test site. The control target of the driving system and the working mechanism, including the velocity of LHD, angle of boom and displacement of dump cylinders, are given to the lower controller, including five EPEC controllers. The EPEC controllers are used to control the longitudinal velocity and the hydraulic related actuators, including steering, lift, and dump cylinders. Only the control of the driving system and the working mechanism during dumping operation are considered in this paper considering that the steering system is not involved during the late stage of dump operation. A displacement sensor is used to obtain the displacement of dump cylinder. For pressure sensors are used to record the pressure data of the two

cylinders during operations. Two angle sensors are used to measure the angle of boom and the spatial angle state of bucket. In addition, a revolution sensor is used to obtain the rotation speed of front tire, i.e., the longitudinal velocity of LHD. The controllers can communicate with each other via CAN bus. The details of the involved devices are shown in Tab. I.

Table 1: Detail parameters of the devices

Device	Parameters
Industrial computer	Nvidia jetson agx Xavier
IMU	XW-GI5610
LiDAR	LSLIDAR C16
Displacement sensor	BTL6, 0~10V, 0~1000mm
Angle sensor	SVCK15, ±180°
Revolution sensor	HC3806-1024, 12V
Pressure sensor	SUP-P300, 0-30MPa
EPEC controller	EPEC 3724

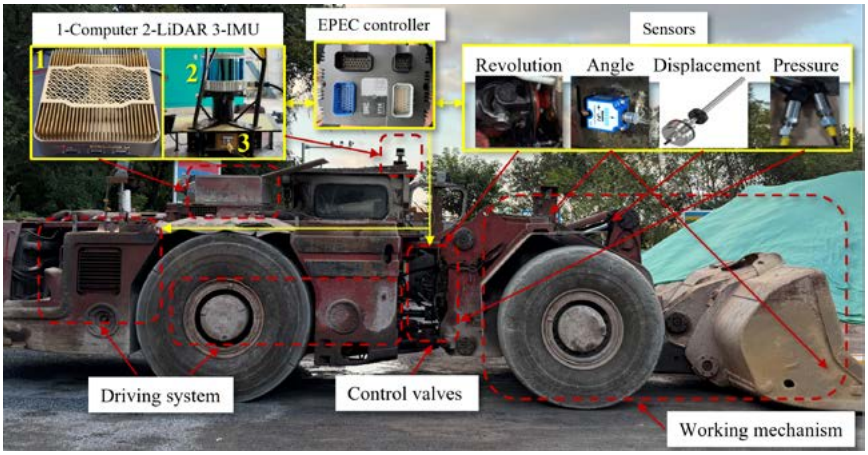

Figure 4: Schematic of test system

The dynamic model of LHD and kinematic model of the working mechanism were validated, separately. For the validation of longitudinal dynamic model, same control signal of driving system was used in the model simulation and field test, and the responses of longitudinal velocity and position were compared in Fig. 5. The longitudinal velocity of test and simulation results coincided well during the test interval, and only minor differences appeared during the free-running period, i.e., 39~41.8 s and 9.2~10.1 s. This error was brought on by the rolling resistance force model. The used resistance force model was established based on the paved road condition, while the test road was an unpaved road. The maximum velocity of the test was about 7.1 km/h, and the corresponding result was about 6.9 km/h. Fig. 5 (b) shown the position result of test and simulation. As it can be seen, the longitudinal position was about 26.4 m, and the next stop position was about 52.6 m. The simulation results given the 25.3 m and 52.1 m. It meant that the maximum position error was less than 4.2 %. These results indicated that the established dynamic model could reveal the dynamic characteristics of LHD in longitudinal direction.

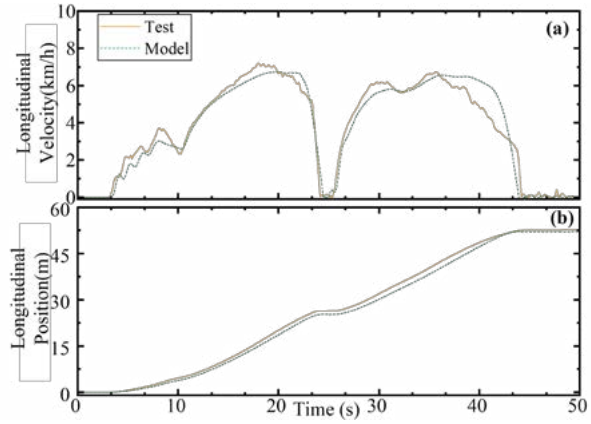

Figure 5: Comparing results of longitudinal dynamic model validation

For the validation of working mechanism, the displacement of cylinder and angle of boom and bucket were recorded. And the coordinate of bucket tip point O_9 was manually measured. Then the displacement results and angle results were input into the forward kinematic model, and the results of bucket angle and coordinate of bucket tip point were obtained continuously as the simulation results. According to the results in Fig. 6 (a)(b), the displacement of dump cylinder varied between 1256.8 – 1852.8 mm and the angle of boom varied between 65.3° - 109.4°. The comparing results of bucket tip position was shown in Fig. 6 (c), in which nine scatter coordinates are the actual measured values. The detailed values of bucket tip position were compared in Tab. II. The average error in Y-axis was larger than the error in X-axis, and the average error rate was about 0.2% and 0.5% in X and Y directions, respectively. The angle of bucket varied between -59.8° - 46.2° according to Fig. 6 (d). The maximum angle error was about 1.4°, at about 36 s. The error rate of angle was about 1.1%. These results indicated that the kinematic model was accurate enough for the research of dumping control.

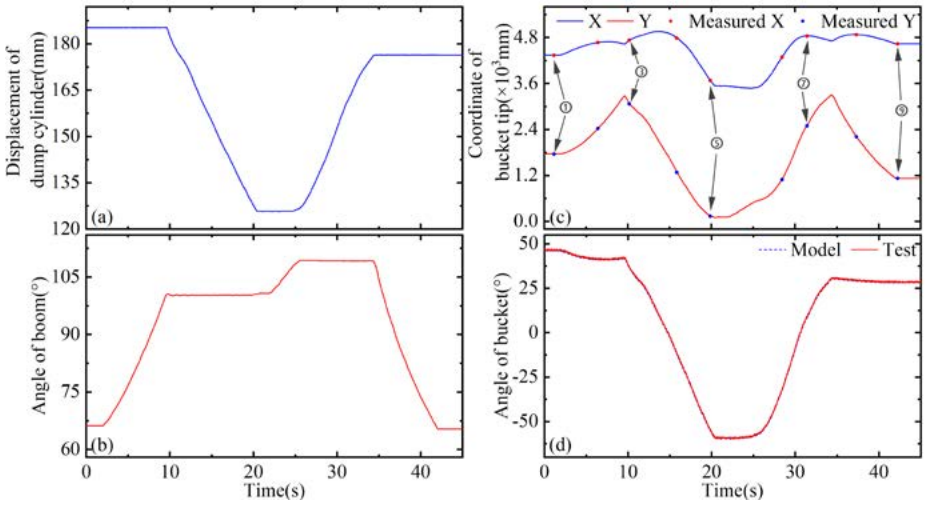

Figure 6: Comparing results of kinematic model validation

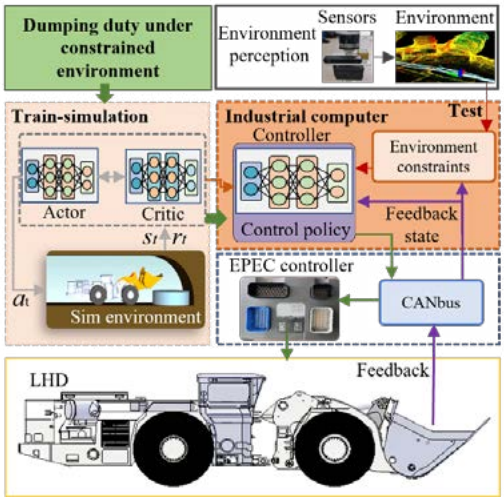
Table 2: Detail values of bucket tip position

	Model(mm)	Measured(mm)	Error(mm)
1	x=4343.6, y=1757.0	x=4336.9, y=1761.7	ex=6.7, ey=4.7
2	x=4669.3, y=2418.5	x=4664.7, y=2413.3	ex=4.6, ey=5.2
3	x=4732.0, y=3077.8	x=4728.2, y=3088.9	ex=3.8, ey=11.1
4	x=4788.9, y=1291.9	x=4782.7, y=1300.3	ex=6.2, ey=8.4
5	x=3686.0, y=150.4	x=3679.2, y=157.6	ex=6.8, ey=7.2
6	x=4291.3, y=1105.0	x=4283.7, y=1114.7	ex=7.6, ey=9.7
7	x=4841.0, y=2504.9	x=4832.2, y=2521.1	ex=8.8, ey=16.2
8	x=4876.7, y=2210.8	x=4870.4, y=2221.3	ex=6.3, ey=10.5
9	x=4632.9, y=1117.3	x=4628.7, y=1113.2	ex=4.2, ey=4.1

Based on the above analysis results, it can be concluded that the established dynamic and kinematic models could reveal the characteristic of driving system and working mechanism during dumping operation. And the models were accurate enough for the RL-related method.

3. AUTONOMOUS DUMPING CONTROL METHODS

The RL frame was used to realize the coordinate control of the driving and the working system in this section. During the manual operation, the operator can freely perform the control according to current states and target duty until the required duty is completed. Therefore, we designed the duty-based RL control method (DRLC), the duty-driven characteristics of manual operation is considered.



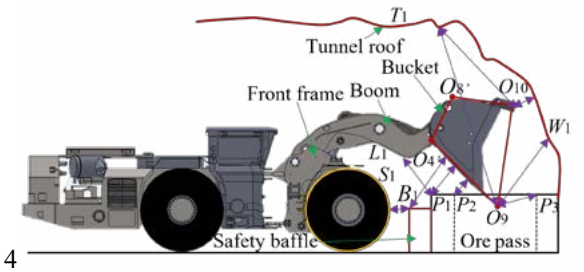


Figure 7: Schematic of RL-based dump control method

As stated before, the LHD is operated in narrow underground mine. The excellent efficiency of manual LHD originates from the preview characteristic of operators. It means that the operator could see the target ore pile, path, and ore pass in advance. Reasonable operation for driving system and working mechanism could be implemented according to the current states of LHD and the information of duty and

environment. Inspired by this characteristic, the DRLC is designed in this section. We designed an autonomous dump system for LHD based on the RL frame in this section to improve the efficiency and safety, as shown in Fig. 7.

For the whole system, the environment information, including the position of ore pass, tunnel, safety baffle, and LHD, were obtained with related sensors, as stated in test system. The environment constraints, including the tunnel roof, side wall, and safety baffle, are extracted. The trained control policy with RL frame in the controller gives the target trajectory of bucket point considering the collision risk, states and actuator constraints of LHD and further specifies the actuator targets of EPEC controllers, as shown in Fig. 7. The target trajectory contains the attitude angle of bucket, and X and Y location in global frame. Special attention is spent on the design of policy training based on RL.

The RL-based controller is a trained policy in essence based the RL train frame. The policy can give the control signals according to the feedback states, defined in s_t. The collision constraints during dumping operation is shown in Fig. 8. As it can be seen, the whole situation is simplified as the plane view. It means that the longitudinal symmetry line of LHD coincides with the symmetry line of the circular ore pass. The tunnel roof, sidewall, and front tire are denoted as T_1, W_1, and S_1, respectively. The outline of bucket is marked as O_4'$O_9O_{10}O_8$'. The outline of safety baffle is marked as B_1. For the ore pass, the out point is marked as P_1, and the inner points are marked as P_2 and P_3, respectively. The lower point of boom is marked as L_1.

4

Figure 8: Collision constraints during dumping operation.

For the safety baffle, the collision, with front tire S_1, lower point of boom L_1, and bucket O_4'$O_9O_{10}O_8$', might occur. For ore pass, the collision might occur between ore pass, low point of boom, and bucket. As it can be seen from Fig. 8, although the outline of bucket and ore pass is intersecting, no collision occur. It means that the middle channel of ore pass is free for bucket. For the main moving parts, the collision might occur between bucket and tunnel roof, bucket and sidewall of tunnel. All of the safety constraints is expressed as:

$$C = S(g(f_1,\ f_2)) \tag{8}$$

in which C is the collision results, it has two values, i.e., 1 and 0. The value 1 denotes the collision occurs, and the value 0 denotes the motion of LHD is free to collision. $g(\cdot)$ is the closest distance calculation function. f_1 contains O_4'$O_9O_{10}O_8$', S_1, and L_1, f_2 contains T_1, W_1, B_1, and P_1 - P_3. $S(\cdot)$ is specified as:

$$S(x) = \begin{cases} 1 & x \le x_{lim} \\ 0 & x > x_{lim} \end{cases} \tag{9}$$

in which x_{lim} is the threshold for collision detection. Then the collision reward could be given by:

$$r_c = -c_6 C \tag{10}$$

4. RESULTS AND DISCUSSION

4.1. Simulation validation of ADC

A dumping operation is performed firstly in simulation environment to validate DRLC. The control policy was obtained with DSAC algorithm. The dump operation scene is concretized, as shown in Fig. 9. As it can be seen, the ore pass is concretized as a hollow cylinder with a height of 0.8 m, an inner diameter of 2.8 m, and an outer diameter of 1 m. The safety baffle is a rectangular prism with a section height of 0.6 m and a width of 0.4 m. The distance between the center of the front wheel and the center of the ore pass is 22.0 m. The distance between the center of the front wheel and the left side of safety baffle is 20.0 m. The motion of bucket is constrained with 3.8 m in the top direction, which is the distance between the tunnel roof and front wheel center. The side wall around ore pass is simplified as a circular arc with 3.0 m radius.

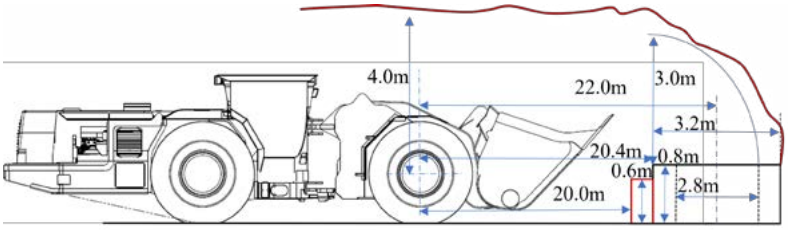

Figure 9: A typical dumping scene in constraint environment

The results of DRLC are shown in Fig. 10 - Fig. 11. The state results of bucket tip were shown in Fig. 10, in which the subfigures (a), (b), and (c) are the results of displacement in X direction, in Y direction, and attitude angle, respectively.

As it can be seen from Fig. 10 (a), the LHD was planned to run longitudinally from start point 0 m to final point 21.9 m. The control result coincided well reaching the target location. The front point of bucket was within the range of ore pass, which is very important for the dumping operation. As it can be seen from Fig. 10 (b), the vertical direction distance, i.e. the Y axis was planned to lift from 1.74 m to 3.19 m, and then fallen from 3.19 m to 0.72 m. The motion of simulation coincided well avoiding obstacles and reaching the target location. For the attitude angle of bucket, i.e., γ, shown in Fig. 10 (c). The angle varied slightly during the lifting stage. The variation was about 5.4°, during 40.8° and 46.2°, which made sure there was no scattering dumping the lifting stage. Then bucket was operated to tilt during 21 s - 29 s. The final tilt angle was about -54.2°.

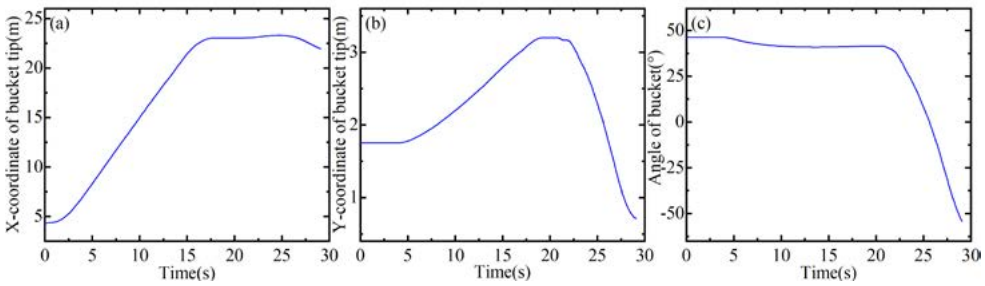

Figure 10: Simulation results of displacement and angle in dump operation.

In order to analyze the dumping operation, the trajectories of bucket tip and front tire were recorded in Fig. 11. The location of ore pass and safety baffle was also indicated in the figure. As it can be seen, the DRLC can control the trajectory of bucket front tip to finish dumping operation. The final operation was finished within the range of ore pass. In addition, the LHD stop in front of safety baffle with an appropriate distance according the results of tire trajectory. Based on the above analysis, it can be concluded that the DRLC can control LHD to finish dump operation autonomously and precisely.

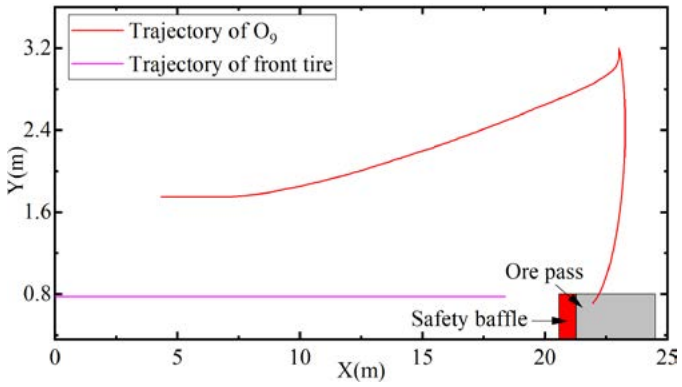

Figure 11: Bucket tip trajectory results of RLPC

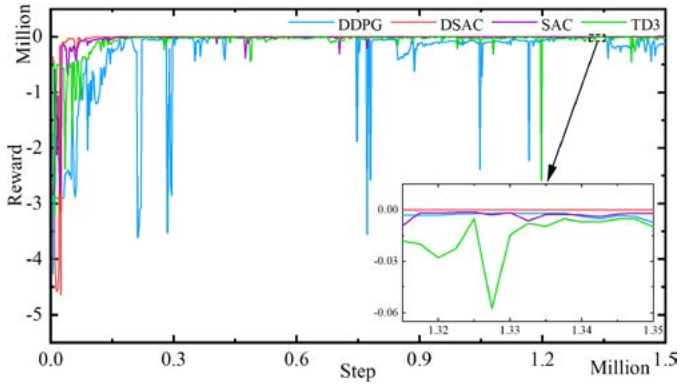

Figure 12: Reward results of different algorithm.

In order to explore the performances of different RL algorithms, trains of different algorithms, including DDPG, TD3, SAC, and DSAC, were performed based on the same dump operation and RLPC. For the train process, the same environment was used, and same values were used for the same parameters.

The reward of different algorithms was shown in Fig. 12. The maximum train step is 1.5 million. As it can be seen, DSAC and SAC show a faster increase trend at the start stage, and the TD3 is also fast than DDPG. The DSAC and SAC also show a more stable increase trend during the middle stage. In addition, the detailed figure also indicated that the DSAC shown higher reward during the whole process, which indicated that it given better comprehensive performance during the dumping operations.

4.2. Test results and discussion

In order to validate the proposed methods further, the test of dumping operation was performed with the aforementioned test platform. The system was implemented with the control policy trained with DSAC. The velocity and longitudinal location results were shown in Fig. 13 (a) and (b), in which the output of RL controller was marked as "Sim", and the actual results of LHD was marked as "Test".

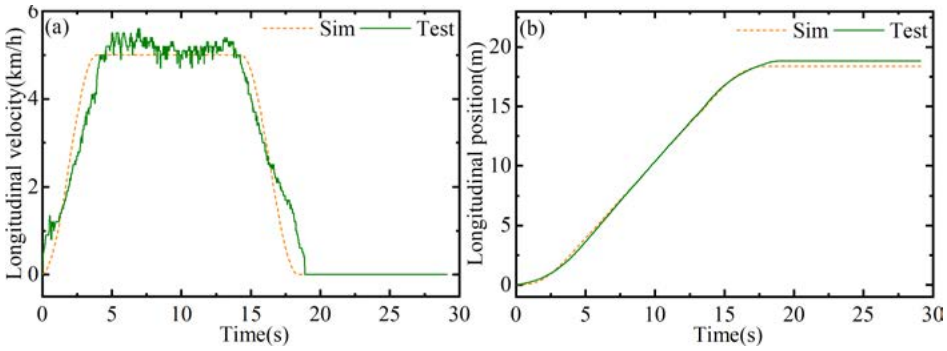

Figure 13: Velocity and longitudinal distance test results of RL-based method.

As it can be seen, the proposed method could control LHD run to target ore pass location. The max deviation during running process was about 0.2 m. The last stop point in the test was about 20.0 m. The error of longitudinal control was less than 1.2%. It was less than the error threshold for engineering application, i.e., 5%. The fluctuation of the velocity aroused during the acceleration and deceleration phases, as shown in Fig. 13. The actual velocity results indicated that the proposed method could guarantee LHD run as expected, although more fluctuation occurred in the actual velocity result. The maximum velocity error was about 0.33 m/s. The longitudinal result validated the drive system control performance of the proposed method.

The results of lift and dump cylinder displacement, and the attitude angle of bucket, γ, are shown in Fig. 14. As it can be seen, the dump cylinder kept static during the driving stage, 0 - 20 s. The displacement of dump cylinder at this stage was about 184.3 cm. The attitude angle of bucket varied slightly during 44.5° and 39.8° and the variation was about 4.7°. The lift operation started at 4.0 s, the LHD was still run with the 5.0 km/h velocity. The dump operation was performed at 21.4 s after the LHD stopped and

the lift cylinder arrived at the target displacement. The results of boom angle shown that the lift and dump cylinder were controlled coordinately between 21.4s to 29.1s. The range of boom angle varies from 100.0° to 111.3°, while the displacement of dump cylinder changed between 184.3 cm to 130.7 cm. The final attitude angle was about -52.1°, which guarantee the dump of ore materials. Therefore, it can be concluded that the proposed method, DRLC, could finish the dump operation autonomously and coordinately.

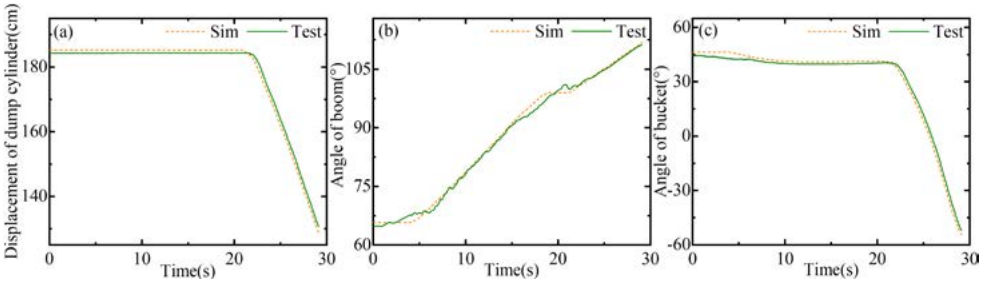

Figure 14: Cylinder displacement test results of RL-based method.

In order to further analyze the dump operation during test, the trajectory of bucket tip in the LHD frame is shown in Fig. 15. As it can be seen, the start and stop point of test and reference almost coincided with each other, although the difference occurred during the internal process. The final resulting bucket tip position was about 22.5 m in longitudinal direction, and 0.52 m in vertical direction. Therefore, it can be concluded that the proposed method could control the bucket to finish the dump operation safety. The whole dump operation was finished within 29.1 s according to the results.

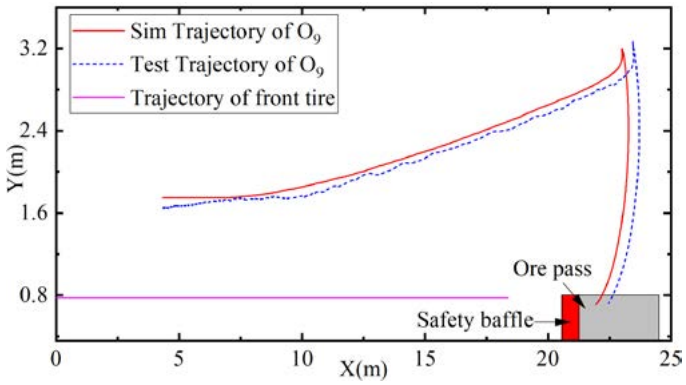

Figure 15: Trajectory of bucket tip in test.

Based on the above results, the proposed method in this paper could finish the dump operation with 29.1 s. The coordinate control in the proposed method guarantee the better state of bucket in lift process. The variation of attitude angle was about 5°, and meet the error threshold for engineering application. The less variation meant that less ore materials was scattered during lift process. The appropriate stop point result also indicates that the method could guarantee collision safety during the dump motion.

Therefore, it could be concluded that the method could finish dump operation with excellent safety, efficiency, and environmental adaptability.

5. CONCLUSION

This paper proposed an autonomous dump control method based RL frame for LHD under constrained environment. The involved dynamic and kinematic model during dump operation were established and validated with a LHD test platform. The kinematic model errors in terms of longitudinal, vertical position, and attitude angle were 0.2%, 0.5%, and 1.1%, respectively, and the longitudinal dynamic model error was about 4.2 %. The corresponding design details about the duty-based method (DRLC) was presented, in which the constraints of driving system and working mechanism actuators, and collision safety were considered, while also accounting for the completion status of the dumping operation. The effect of different RL algorithms was explored for dump occasion, in which the DSAC shown better performance. The field tests of autonomous dump operation with DRLC was performed. The results shown that the proposed method could finish the dump operation with 29.1 s under the premise of ensuring safety and efficiency. Therefore, the proposed method could finish dump operation with excellent safety, efficiency, and environmental adaptability.

From February 2021 to July 2023, he was a postdoctoral with the school of mechanical engineering from University of Science and Technology Beijing. His current research interests include motion control of hydraulic power system, reinforcement learning application, intelligent mining heavy-duty vehicles.

Zihang Zhang received the bachelor's degree in vehicle engineering, in 2022, from the University of Science and Technology Beijing, where he is currently working toward the master's degree in vehicle engineering. His research areas include control of underground Load-Haul-Dump vehicle working mechanisms, simulation of hydraulic power systems, and reinforcement learning.

Prof. **Katharina Schmitz** studied mechanical and chemical engineering at RWTH Aachen University and Carnegie Mellon University, Pittsburgh (USA) and graduated 2015 as Dr.-Ing. at RWTH Aachen University. Since 2018, she is full professor at RWTH Aachen University and director of the Institute for Fluid Power Drives and Systems (ifas). In addition, she is Vice Dean of the Faculty for Mechanical Engineering at RWTH Aachen, a position she holds since 2020. Prof. Schmitz’s awards and honors include several best paper awards and 2023 IMechE Joseph Bramah Medal award.

Energy efficiency evaluation of hybrid distributed-centralized load sensing system for electrified excavator

a State Key Laboratory of Mechanical Transmission for Advanced Equipment, Chongqing University, Chongqing 400044, China

Abstract. A hybrid distributed-centralized load sensing (HDC-LS) system is a potential solution for reducing energy consumption in electric construction machinery. It balances load differences by establishing a hybrid distributed-centralized actuator (HDCA) through the parallel connection of a distributed actuator alongside the original hydraulic cylinder. The characteristic of the excavator actuator, which is highly involved in compound motions, is exploited to equip the arm with the HDCA in this study. A parameter design approach is proposed that fully considers multiple HDCA factors, including load balance capacity, nominal power, and installation space. Compared with the conventional EHA, the integrated HDCA reduces the volume and mass by 43.9% and 27.3%, respectively, for a nominal power of 5 kW. Simulation results for a 6 T electrified excavator show that battery energy consumption is reduced by 2.2% – 15.6% for HDCA nominal powers of 3 – 7 kW, compared with the conventional load sensing (LS) system.

Keywords. Electric excavator, Load sensing, Load differences, Integrated, Installation space, Energy efficiency evaluation.

1. INTRODUCTION

With the international community increasingly focusing on policies of carbon neutrality and carbon peaking, the development of new, highly efficient construction machinery has become more urgent in recent years [1]. The load sensing (LS) system matchs pressure by controlling the pump outlet pressure to be one pressure margin higher than the load pressure. Offering advantages such as simple and reliable operation control, it is widely used in small and medium-sized excavators. However, the system exhibits substantial energy losses that originate from two dominant mechanisms.

(1) Control valve losses. These losses are termed meter-in (upstream) or meter-out (downstream) throttling losses, depending on their location relative to the actuator. The former can be partially reduced by variable pressure margin control, but this approach requires extra sensors and signal-conditioning electronics [2]. The latter can be addressed by potential energy recovery, but this requires additional energy-conversion components, the implementation of which is often constrained by space limitations. The independent metering control system is an effective solution for reducing these throttling losses [3]. However, the excessively low pressure differential across the valve orifice can easily trigger oscillations, resulting in poor system stability [4].

All Open Access articles are peer-reviewed, distributed under the Creative Commons Attribution-Non Commercial 4.0 International

(2) Load differences loss. Previous studies have tackled this problem through four mainstream approaches. 1) The hydraulic transformers. Due to their complex structure, production costs remain high, posing significant challenges to commercialization [5]. 2) The multi-pressure sources. These systems require multiple components (e.g., pumps, accumulators, switching valves), leading to complex structures, high costs, and large space requirements [6]. 3) The multi-chamber cylinder. When the actuator load changes, frequent mode switching by the control valve is required to select a new working chamber. This results in pressure shocks and poor system controllability [7]. 4) The distributed control systems. Purely distributed systems suffer from high installed power and large installation space.

To address the issue of low energy efficiency caused by load difference, a hybrid distributed-centralized load sensing (HDC-LS) system was proposed in our previous work [8]. The results obtained from an excavator's boom showed advantages of high energy efficiency and ease of implementation. In this study, the parameter design criterion for the HDCA is further discussed to systematically consider its key factors, including load balance capacity, nominal power, and installation space. A parameter design approach is proposed for the HDCA and the control valve to make tradeoffs among nominal power, installation space, and energy-saving capacity. Furthermore, an integrated HDCA with a four-chamber hydraulic cylinder is designed and validated on a 6 T electrified excavator under different nominal powers.

2. LAYOUT OF THE HDC-LS SYSTEM

As shown in Figure 2.1, the basic mechanism of the HDC-LS system is to establish an HDCA by connecting an electro-hydrostatic actuator (EHA) (distributed actuator) in parallel alongside the original hydraulic cylinder (centralized actuator). The four-quadrant operation of the EHA is exploited to balance the load difference. When the HDCA is the highest-load actuator, the EHA applies an auxiliary force to adjust the meter-in chamber pressure down to that of the second-highest actuator, thereby reducing LS pump energy consumption. Conversely, when the HDCA is not the highest-load actuator, the EHA applies a resistive force to achieve pressure matching, thereby recovering the lost energy of the pressure compensator. Furthermore, the EHA can also recover the potential energy under overrunning loads during load balancing. The principle of the EHA controller is shown in Figure 2.1 (d), with details referenced in our previous work [8]. In this study, the case of the HDCA installed on the excavator's arm is considered to discuss a design criterion. There are three reasons as follows.

(1) The nominal power of the HDCA should be high enough to achieve full load balance and energy recovery under different conditions. The arm experiences more complex four-quadrant loads than the boom. Therefore, accurate and uniform evaluation of the load difference under compound motion is necessary.

(2) The HDCA includes many components such as an electric motor, a valve block, and a hydraulic pump. The increased mass has a significant impact on the required force and, thereby, on the energy consumption.

(3) The HDCA is sensitive to size constraints when installed on the arm of the excavator or other machinery. The HDCA should be designed carefully within limited installation space to avoid structural interference.

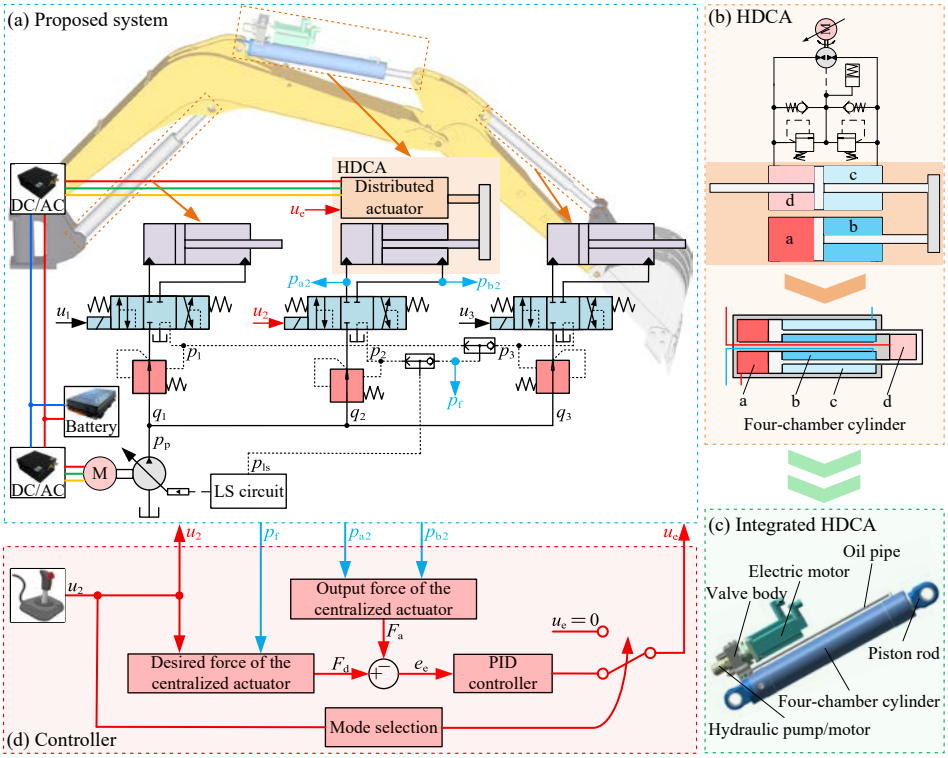

Figure 2.1. Working principle of the HDC-LS system

3. PARAMETER DESIGN APPROACH

The flow diagram of the parameter design is shown in Figure 3.1. For the distributed actuator, the key criterion for parameter design is to identify the relationship between EHA nominal power (HDCA nominal power) and energy-saving capability. The load forces of three actuators during the excavating cycle are obtained through load characteristic modelling. The EHA output force is calculated assuming fully balanced load differences, and its probability distribution is derived. A power coverage ratio is calculated by combining the probability distribution of EHA velocity, and this ratio is used as an index for evaluating energy-saving capability. For the centralized actuator, the meter-out orifice of the control valve is redesigned based on the selected HDCA nominal power to compensate for loads exceeding the nominal power.

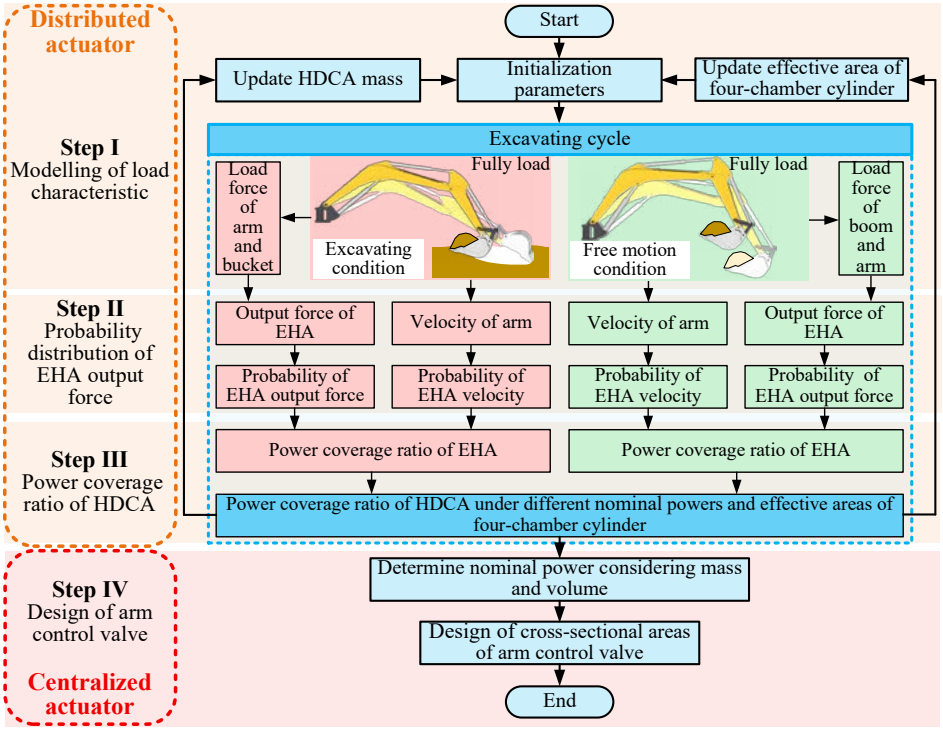

Figure 3.1. Flow diagram of the parameter design

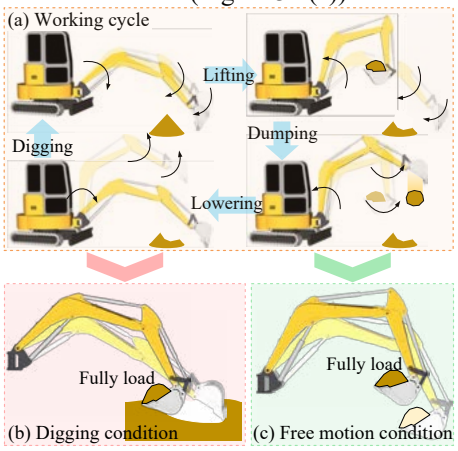
3.1. Distributed actuator

3.1.1. Modelling of load characteristic

A typical excavating cycle is shown in Figure 3.2(a), which consists of four working steps: digging, lifting, dumping, and lowering. To evaluate the energy-saving capability of the HDCA, the excavating cycle is divided into two conditions: soil interaction condition (Figure 3.2(b)) and free motion condition (Figure 3.2(c)).



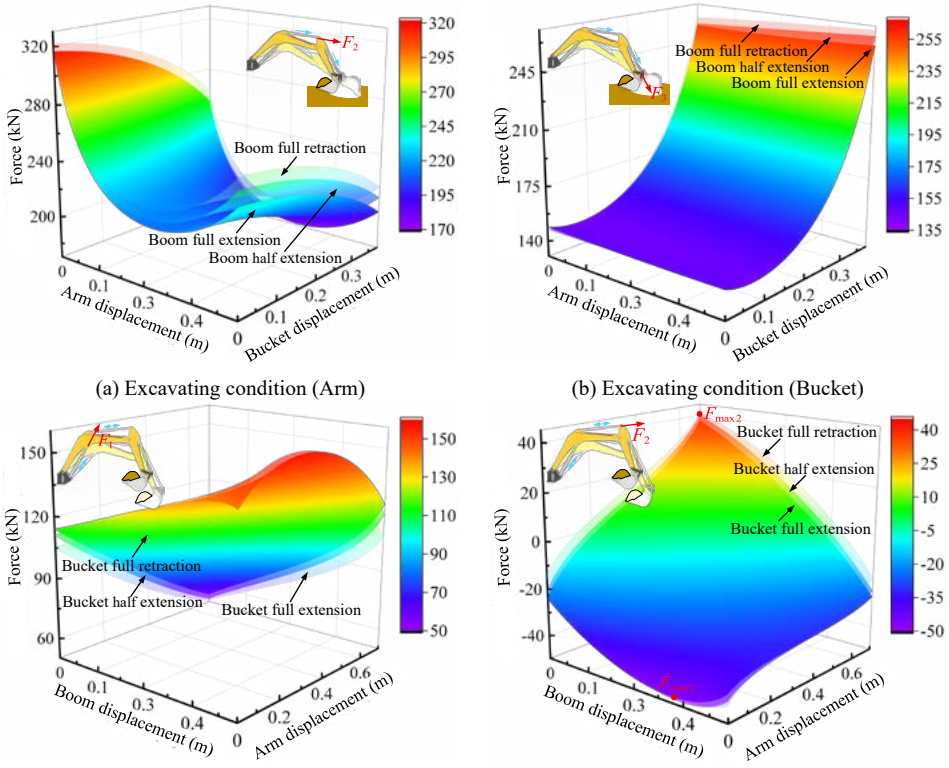


Figure 3.2. Typical excavating cycle and its two conditions

1) Full load excavating condition. The arm and bucket cylinders typically extend in a compound motion for soil excavation, while the boom has a rare or small movement. The digging force is applied to the bucket tip by the soil. Specifically, the mass of the HDCA impact on energy consumption is considered in the modelling process. Furthermore, to guarantee that the load forces represent the operating conditions of the arm and bucket cylinders across various postures, the modelling process considers different boom displacements. 2) Full load free motion condition. The boom, arm, and bucket cylinders perform a compound motion to complete the soil dumping. Similarly, the effects of different bucket displacements on the load forces are considered. During the excavating condition, static equilibrium balances the excavating force and manipulator gravity against the hydraulic cylinder output. During the free-motion condition, it balances the combined gravity of the soil and manipulator against the hydraulic cylinder output. The load force of the actuators is shown Figure 3.3.

(a) Excavating condition (Arm)

(b) Excavating condition (Bucket)

(c) Free motion condition (Boom)

(d) Free motion condition (Arm)

Figure 3.3. Load forces of the actuators

3.1.2. Probability distribution of EHA output force

The four-chamber cylinder structure is shown in Figure 3.4. To ensure the digging force of the arm, the effective area A_{a2} of chamber "a" in the four-chamber cylinder of the centralized actuator must not be less than that of the original cylinder. 1) Full load excavating condition. When the excavator is in excavating condition, both the arm and bucket actuators are typically extended. Ignoring friction, the steady state force equilibrium equation for the arm and bucket can be expressed as:

$$\begin{cases} F_2 = (p_{a2}A_{a2} - p_{b2}A_{b2}) + F_{Eha} \\ F_3 = p_{a3}A_{a3} - p_{b3}A_{b3} \end{cases} \tag{3.1}$$

where F_2 and F_3 represent the load forces on the arm and bucket, respectively (positive direction is defined as cylinder extension); F_{Eha} indicates the output force of the EHA; p_{a2} and p_{b2} denote the pressure in chambers "a" and "b"; A_{b2} is the effective area in chamber "b"; p_{a3} and p_{b3} are the head-side and rod-side pressures of the bucket cylinder; and A_{a3} and A_{b3} represent the corresponding effective areas. Here, p_{b2} with the meter-out orifice fully open for potential energy recovery. p_{b3} can be derived from the orifice equation, which is:

$$q = C_d A_d \sqrt{\frac{2\Delta p}{\rho}} \tag{3.2}$$

where q represents the flow rate; C_d indicates the flow coefficient; ρ denotes the oil density; A_d is the cross-sectional area; and Δp represents the differential pressure. Therefore, p_{b2} and p_{b3} can be expressed as:

$$\begin{cases} p_{b2} = 0, & \text{Arm extends} \\ p_{b3} = \dfrac{\rho q_{b3}^2}{2C_d^2 A_{db3}^2}, & \text{Bucket extends} \end{cases} \tag{3.3}$$

where q_{b3} and A_{db3} represent the flow rate and cross-sectional area of the bucket control valve, respectively. When the EHA adjusts the load pressure of the centralized actuator so that it is consistent with the load-pressure feedback from other actuators, the load differences are fully balanced, that is:

$$p_{a2} = p_f = p_{a3} \tag{3.4}$$

where p_f represents load pressure feedback from other actuators. From Eqs. (3.1) and (3.4), F_{Eha} can be inferred as:

$$F_{Eha} = F_2 - \frac{F_3 + p_{b3}A_{b3}}{A_{a3}} A_{a2} \tag{3.5}$$

From Eq. (3.5), F_{Eha} can be calculated for different displacements of the arm and bucket, as shown in Figure 3.5. 2) Full load free motion condition. Similarly, F_{Eha} can be obtained according to the direction of motion of the boom and arm, as shown in Figure 3.6.

(c) Boom retracts and arm extends

(d) Boom and arm retract

Figure 3.6. Output force of the EHA under free motion condition

3.1.3. Power coverage ratio of HDCA

As shown in Figure 3.5 and Figure 3.6, F_{Eha} is stochastic under different motion conditions. To better describe this complex load characteristic, its probability distribution is calculated for the typical excavating cycle by uniformly segmenting F_{Eha} several zones. The probability distribution and segmenting can be expressed as:

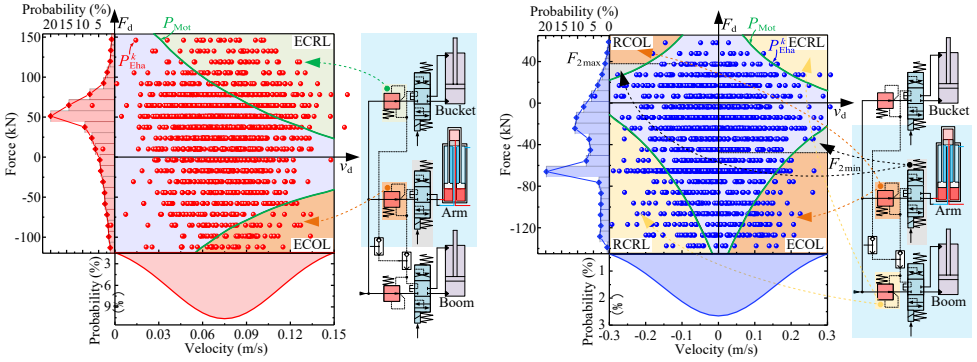
$$\begin{cases} \begin{cases} P_{\mathrm{FDig}} = \dfrac{n_i}{n_{11}} \cdot 100\%, \\ F_{\mathrm{D1}} + \dfrac{F_{\mathrm{U1}} - F_{\mathrm{D1}}}{z_1}(i-1) \le F_{\mathrm{Eha}} < F_{\mathrm{D1}} + \dfrac{F_{\mathrm{U1}} - F_{\mathrm{D1}}}{z_1} i, \end{cases} & i = 1,2,3,\ldots,z_1 \quad \text{Excavating condition} \\ \begin{cases} P_{\mathrm{FFre}} = \dfrac{n_j}{n_{21}+n_{22}+n_{23}+n_{24}} \cdot 100\%, \\ F_{\mathrm{D2}} + \dfrac{F_{\mathrm{U2}} - F_{\mathrm{D2}}}{z_2}(j-1) \le F_{\mathrm{Eha}} < F_{\mathrm{D2}} + \dfrac{F_{\mathrm{U2}} - F_{\mathrm{D2}}}{z_2} j, \end{cases} & j = 1,2,3,\ldots,z_2 \quad \text{Free motion condition} \end{cases} \tag{3.6}$$

where P_{FDig} and P_{FFre} represent the probabilities within the output force of segment i and j, respectively; F_{U1}, F_{D1}, F_{U2} and F_{D2} indicate the upper and lower limits; z_1 and z_2 denote the number of segments; n_i and n_j are the number of sample points within each segment; and n_{11} and n_{21} represent the numbers of sample points for F_{Eha} Figure 3.5 and Figure 3.6 (each actuator displacement step corresponds to a sample point). During each motion phase, the velocities of the arm actuator typically tend toward a normal distribution. Therefore, the probability β_{v} at the velocity v_{Eha} can be expressed as:

$$\beta_{\mathrm{v}}=\frac{\mathrm{e}^{-\frac{\left(v_{\mathrm{Eha}}-\mu\right)^{2}}{2\sigma^{2}}}}{\sqrt{2\pi\sigma}}\cdot 100\% \tag{3.7}$$

where μ and σ represent the mean and standard deviation, respectively. The total number of the EHA power sample points is defined as w. In each segment, m output-force samples are calculated based on the probability distribution, and m velocity samples are generated randomly according to the velocity distribution. Considering the efficiencies η_{Pum} and η_{Cyl} of the hydraulic pump and cylinder, the power P_{Eha}^{k} corresponding to each sample point for the distributed side can be expressed as:

$$P_{\mathrm{Eha}}^{k}=\begin{cases}\dfrac{F_{\mathrm{Eha}}^{k}v_{\mathrm{Eha}}^{k}}{\eta_{\mathrm{Pum}}\eta_{\mathrm{Cyl}}}, & \left(F_{\mathrm{d}}^{k}v_{\mathrm{d}}^{k}\geq 0\right)\ \text{Under resistive condition}\\ F_{\mathrm{Eha}}^{k}v_{\mathrm{Eha}}^{k}\eta_{\mathrm{Pum}}\eta_{\mathrm{Cyl}}, & \left(F_{\mathrm{d}}^{k}v_{\mathrm{d}}^{k}<0\right)\ \text{Under overrunning condition}\end{cases},\ k=1,2,\cdots,w \tag{3.8}$$



where F_{Eha}^{k} and v_{Eha}^{k} represent the output force and velocity corresponding to each sample point, respectively. To achieve better load balance, a higher nominal power of the EHA is preferable to cover all P_{Eha}^{k}, but is limited by the installation space of the arm. To evaluate the load balance capacity, the power coverage ratio of the HDCA is introduced as an evaluation index. The schematic of the power coverage ratio under different motion conditions is shown in Figure 3.7. Here, the red and blue points represent power sample points P_{Eha}^{k}, and the green curve is the nominal power P_{Mot} of the EHA electric motor. P_{Eha}^{k} are distributed according to the joint probability distribution of the velocity and the output force of the distributed side. The light blue area represents the sufficient nominal power ($P_{\mathrm{Eha}}^{k}\leq P_{\mathrm{Mot}}$), while other colored areas represent the insufficient power ($P_{\mathrm{Eha}}^{k}>P_{\mathrm{Mot}}$). The EHA operates in two-quadrant modes during the soil interaction condition: extension condition with resistive load (ECRL) and extension condition with overrunning load (ECOL). When $P_{\mathrm{Eha}}^{k}>P_{\mathrm{Mot}}$ (light green and orange regions in Figure 3.7(a)), the excess power is consumed by the pressure compensator (ECRL mode: bucket compensator; ECOL mode: arm compensator). During the free motion condition, the EHA operates in four-quadrant modes: ECRL, ECOL, retraction condition with overrunning load (RCOL), and retraction condition with resistive load (RCRL). Similarly, when $P_{\mathrm{Eha}}^{k}>P_{\mathrm{Mot}}$ (yellow, orange, and black regions in Figure 3.7(b)), the excess power is consumed by the pressure compensator or control valve. Under ECRL and RCRL modes, it is consumed by the boom compensator. Under RCOL and ECOL modes, the arm control valve takes priority and consumes the excess power, while the arm pressure compensator compensates for the insufficient power. Therefore, the power coverage ratio P_{Cov} of the EHA can be expressed as:

$$P_{\mathrm{Cov}}=\frac{w_{1}}{w}\cdot 100\% \tag{3.9}$$

where w_{1} presents the number of sample points ($P_{\mathrm{Eha}}^{k}\leq P_{\mathrm{Mot}}$). The distributions of the excavating condition and the free motion condition are determined to be 1/3 and 2/3, respectively, through statistical analysis of multiple typical excavating cycles. Therefore, the power coverage ratio P_{Cyc} of the HDCA under excavating cycle can be expressed as:

$$P_{\mathrm{Cyc}}=\frac{P_{\mathrm{CovDig}}}{3}+\frac{2P_{\mathrm{CovFre}}}{3} \tag{3.10}$$

where P_{CovDig} and P_{CovFre} represent the power coverage ratios of the EHA for the excavating condition and free motion condition, respectively.

(a) Excavating condition (b) Free motion condition

Figure 3.7. Schematic of the power coverage ratio under different motion conditions

The power coverage ratio of the HDCA needs to consider the effects of its mass and the effective area of the four-chamber cylinder:

(1) HDCA mass. The mass of the HDCA can be equivalently transferred to the boom when the arm is equipped with the HDCA, as shown in Figure 3.8. Thus, the equivalent mass m_1' of the boom can be expressed as:

$$m_1' = m_1 + k_{\mathrm{L}} m_{\mathrm{Hdca}} \tag{3.11}$$

where k_{L} represents the coefficient; m_1 indicates the mass of the boom; and m_{Hdca} denotes the additional mass of the HDCA.

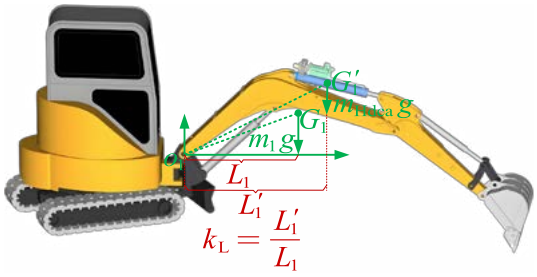


Figure 3.8. Equivalent mass of the boom

(2) Effective area of the four-chamber cylinder. To guarantee that the EHA can output maximum force within pressure limits in the EHA circuit, the effective areas A_{c2} and A_{d2} of the symmetrical chambers are selected to be half of A_{a2}.Therefore, the area coefficient k_{Are} can be described as:

$$k_{\mathrm{Are}} = \frac{2A_{\mathrm{b2}}'}{A_{\mathrm{a2}}}, \quad 0 < k_{\mathrm{Are}} < 1 \tag{3.12}$$

where A_{b2}' represents the new effective area of chamber "b" in the four-chamber cylinder.

The comparison of volume and mass between HDCA and conventional EHA (arm EHA with purely distributed drive in [9]) is shown in Figure 3.9. It can be observed that the percentage decrease in volume and mass of the HDCA gradually decreases with P_{Mot}. When P_{Mot} is 5 kW, the volume and mass are reduced by 43.9% and 27.3%, respectively. By combining Eqs. (3.1) – (3.12), P_{Cyc} for different values of P_{Mot} and k_{Are} can be calculated, as shown in Figure 3.10.

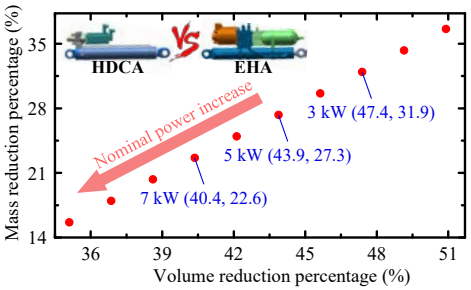

Figure 3.9. Comparison of volume and mass between HDCA and EHA

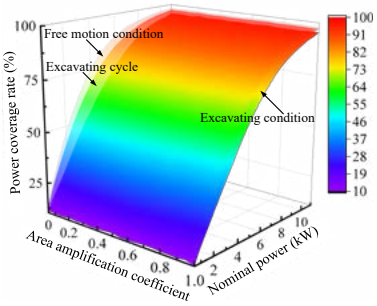

Figure 3.10. Power coverage ratio of the HDCA

3.2. Centralized actuator

When the arm is in overrunning mode, it is necessary to avoid the HDCA overspeed because of insufficient output force. Therefore, the cross-sectional area acquires to be redesigned. The energy-saving effects of the system are evaluated for $k_{\mathrm{Are}} = 0.43$ and P_{Mot} of 3 kW, 5 kW, and 7 kW. Correspondingly, P_{Cyc} is 56.8%, 76.2% and 87.3%, respectively, from Figure 3.10. Considering the limitations of the EHA components, the actual output force F_{EhaAct} can be expressed as:

$$F_{\mathrm{EhaAct}} = \min\left(\left|\frac{P_{\mathrm{Mot}}}{v_{\mathrm{Eha}}\eta_{\mathrm{Pum}}\eta_{\mathrm{Cyl}}}\right|, F_{\mathrm{Com}}\right), \quad \text{EHA under overrunning condition} \tag{3.13}$$

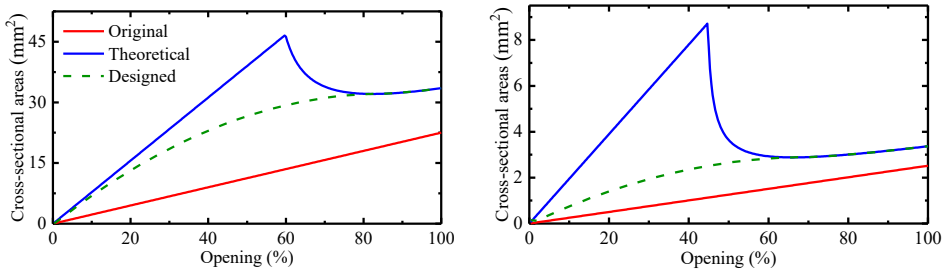
where F_{Com} represents the maximum output force limited by the EHA components. The back pressure p_{Bac1} and p_{Bac2} required at the control valve can be expressed as:

$$\begin{cases} p_{\mathrm{Bac1}} = \max\left(p_{\mathrm{s}}, \dfrac{F_{\mathrm{Min2}} - F_{\mathrm{EhaAct}}}{A_{\mathrm{b2}}}\right), & \text{Arm extends} \\ p_{\mathrm{Bac2}} = \max\left(p_{\mathrm{s}}, \dfrac{F_{\mathrm{Max2}} - F_{\mathrm{EhaAct}}}{A_{\mathrm{a2}}}\right), & \text{Arm retracts} \end{cases} \tag{3.14}$$

where F_{Min2} and F_{Max2} represent the maximum gravitational forces that the EHA needs to overcome in overrunning mode (shown in Figure 3.3(d)); and p_{s} indicates the minimum pressure to guarantee control performance. The flow rate q_{Bac1} and q_{Bac2} of the control valve can be expressed as:

$$\begin{cases} q_{\mathrm{Bac1}} = A_{\mathrm{b2}} v_2, & \text{Arm extends} \\ q_{\mathrm{Bac2}} = A_{\mathrm{a2}} v_2, & \text{Arm retracts} \end{cases} \tag{3.15}$$

Here, v_{Eha} can be expressed through the control valve opening k_{Ope} as follows:



$$v_{\mathrm{Eha}} = k_{\mathrm{Ope}} v_{\mathrm{Max2}} \tag{3.16}$$

where v_{Max2} represents the maximum velocity of the arm. From Eq. (3.2), the designed cross-sectional area A_{d1} and A_{d2} can be calculated using the flow formula as follows:

$$\begin{cases} A_{\mathrm{d1}} = \dfrac{q_{\mathrm{Bac1}}}{C_d\sqrt{\frac{2(p_{\mathrm{Bac1}} - p_{\mathrm{T}})}{\rho}}}, & \text{Arm extends} \\ A_{\mathrm{d2}} = \dfrac{q_{\mathrm{Bac2}}}{C_d\sqrt{\frac{2(p_{\mathrm{Bac2}} - p_{\mathrm{T}})}{\rho}}}, & \text{Arm retracts} \end{cases} \tag{3.17}$$

where p_{T} represents the tank pressure ($p_{\mathrm{T}} = 0$). From Eqs. (3.13) – (3.17), A_{d1} and A_{d2} (blue curve) for different k_{Ope} values are obtained when P_{Mot} is 3 kW, 5 kW, and 7 kW, respectively, as shown in Figure 3.11. To reduce the difficulty of valve machining, A_{d1} and

A_{d2} are modified to obtain a smooth and monotonically increasing design curve (green curve).

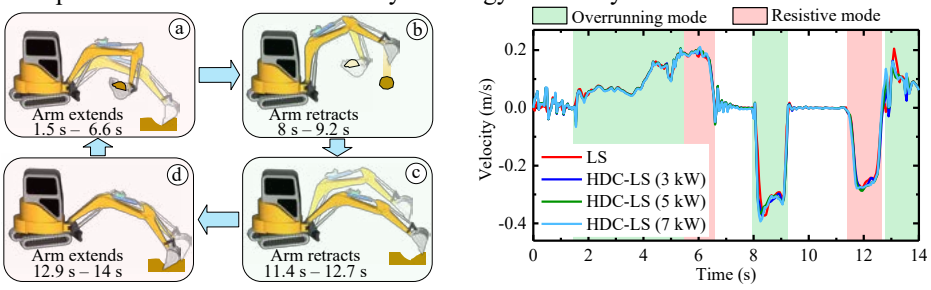
4. SIMULATION STUDY



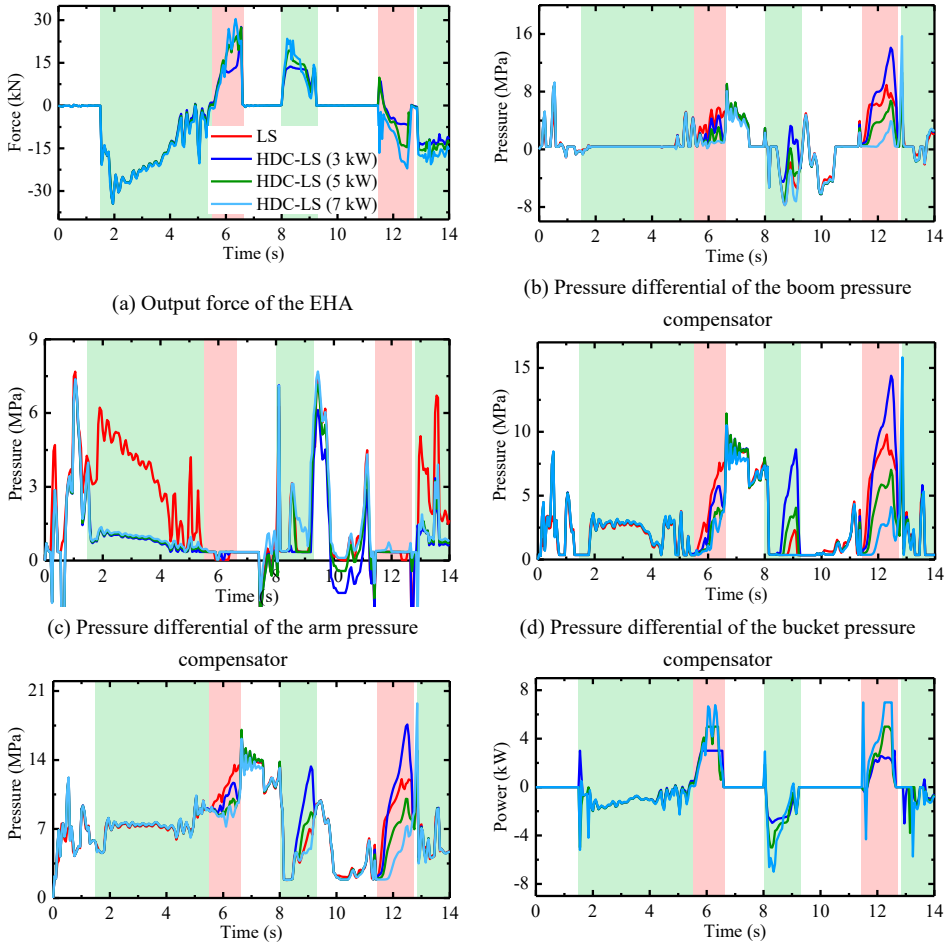
4.1. Simulation modelling

A 6 T electric excavator driven by a conventional LS system is taken as the reference prototype. A simulation model of this prototype is built in the AMESim environment. Based on the simulation model, the arm cylinder is replaced with an HDCA to establish the HDC-LS system. The models are simulated under the same excavation cycle to evaluate the energy-saving effects and the velocity performance at HDCA nominal powers of 3 kW, 5 kW, and 7 kW.

4.2. Comparative analysis

4.2.1. Motion performance

As shown in Figure 4.1(a), the HDCA enters the extend mode and the retract mode according to the arm control signal during a typical excavation cycle. As shown in Figure 4.1(b), during the entire motion process, the arm actuator maintains nearly identical velocities with smooth dynamic speed variations because the flow control method of the conventional LS system is retained. Therefore, the designed cross-sectional area of the control valve avoids overspeed dropping caused by insufficient HDCA nominal power. This guarantees the consistent motion profiles and evaluation accuracy of energy efficiency.



(a) Typical excavating cycle of the excavator (b) Arm

Figure 4.1. Excavating cycle and actuator velocities

4.2.2. *Energy consumption performance*

As shown in Figure 4.2, by controlling the EHA output force to adjust the pressures in chambers a and b of the four-chamber cylinder, the pressure differential and the energy losses across the pressure compensators are reduced. The output energy of the LS pump is reduced effectively since the EHA outputs an auxiliary force. When the EHA outputs a resistive force, it prioritizes recovering potential energy while balancing load difference.

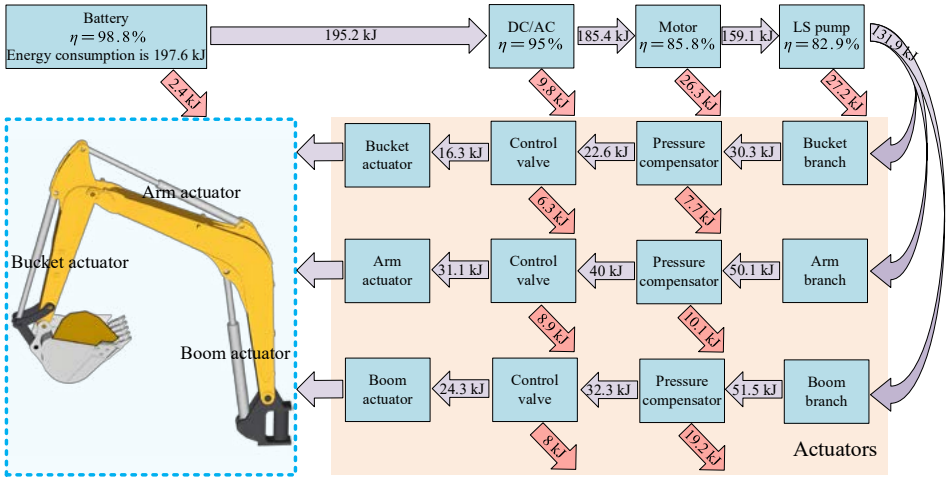
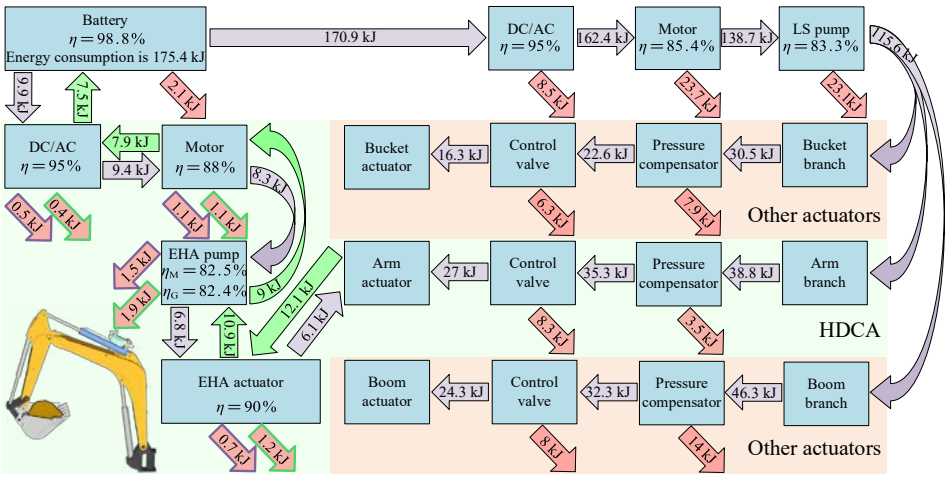
(d) Pressure differential of the bucket pressure compensator

(e) Outlet pressure of the LS pump



(f) Power of the EHA

Figure 4.2. Simulation results of the conventional LS and HDC-LS systems



The system efficiency can be calculated as:

$$\begin{cases} \eta_{\mathrm{C}} = \dfrac{E_{\mathrm{Ct}} - E_{\mathrm{Cp}}}{E_{\mathrm{ct}}} \cdot 100\% \\ \eta_{\mathrm{P}} = \dfrac{E_{\mathrm{Pt}} - E_{\mathrm{Pp}}}{E_{\mathrm{Pt}}} \cdot 100\% \\ \eta_{\mathrm{S}} = \dfrac{E_{\mathrm{T}} - E_{\mathrm{P}}}{E_{\mathrm{T}}} \cdot 100\% \end{cases} \tag{4.1}$$

where η_C and η_P represent energy-saving efficiency of the pressure compensator and LS pump, respectively; η_S indicates the energy-saving efficiency; E_{Ct}, E_{Pt} and E_T denote the energy consumption of the pressure compensator, LS pump, and battery in the conventional LS system; and E_{Cp}, E_{Pp} and E_P are the energy consumption of the pressure compensator, LS pump, and battery in the HDC-LS system. Based on Eq. (4.1) and combined Figure 4.3, the system efficiencies for different HDCA nominal powers are calculated in Table 1. It can be observed that both the energy loss in the pressure compensator due to the load difference and the output energy by the LS pump are significantly reduced. As the nominal power of the HDCA increases, the load difference effect of the EHA becomes more pronounced, leading to increasing energy savings. At nominal powers of 3 kW, 5 kW, and 7 kW, the energy consumption of the battery is reduced by 2.2 %, 11.2 %, and 15.6 %, respectively.

5. CONCLUSION

In this study, a parameter design approach suitable for the HDCA when installed on the arm of electric excavator is proposed. Furthermore, the HDCA is designed to achieve an integrated drive. Compared with the conventional EHA, the integrated HDCA reduces the volume and mass by 43.9% and 27.3%, respectively, for a nominal power of 5 kW. A 6 T electric excavator simulation model of the HDC-LS system is established. The energy-saving effects of the HDC-LS system are evaluated under HDCA nominal powers of 3 kW, 5 kW, and 7 kW. The energy losses of the pressure compensator (boom + arm + bucket) are reduced by 8.4%, 31.4%, and 41.9%, respectively, through the EHA load balancing effect. This approach reduces battery energy consumption by 2.2%, 11.2%, and 15.6%. With the increase in HDCA nominal power, the energy-saving effect of the proposed system becomes increasingly significant.

Abstract

Hydraulic fan drive systems offer advantages for thermal management in mobile machinery, particularly in construction and agricultural equipment applications. Compared to traditional mechanical or direct-drive electric systems, hydraulically actuated fans enable flexible installation, provide good control and reduced power consumption by decoupling fan speed from engine speed. In the design of hydraulic fan drive systems for mobile machinery, optimizing the design to be both compact and affordable is essential for meeting customer expectations. For the status quo, two independent valves are required to achieve both fan speed control and radiator cleaning functionality provided by fan reversal. Simplifying the hydraulic system by using one valve instead of two would enable for size and cost reduction. This paper presents a patented and innovative hydraulic fan drive solution incorporating a single integrated valve in an external gear motor to control both fan speed and reversing direction. The objective of this paper is to verify the feasibility of the one-valve solution by means of a 1D simulation model. Simulation results demonstrated that the one-valve solution, when integrated with its enhanced feed-forward control, delivers performance comparable to the current two-valve solution, particularly in dynamic response and maintaining consistent flow characteristics despite pump speed fluctuations. This provides compelling evidence that the one-valve solution offers a simplified, cost-effective, and dynamically robust alternative for future mobile hydraulic systems.

Keywords. Mobile hydraulics, Fan drive.

1. INTRODUCTION

Mobile machinery applications, such as construction and agricultural equipment, operate in competitive markets where cost efficiency and system compactness are critical factors in equipment design. These machines generate heat during operation, primarily from the engine and the hydraulic system itself. Thermal management is necessary for maintaining optimal operating temperatures and it is achieved by matching heat rejection with minimal energy consumption. The engine's heat is absorbed by coolant fluid, then carried to the radiator, where the heat is exchanged with ambient air [1]. For diesel engines of mobile

All Open Access articles are peer-reviewed, distributed under the Creative Commons Attribution-Non Commercial 4.0 International

machinery, it is estimated that the power dissipated in the heat exchanger is 45% of the power output [2] and 30% of fuel energy [3]. To improve heat rejection, a cooling fan actively forces the air across the radiator. The faster it spins, the more air it pulls through the radiator, and the more engine power it consumes. Therefore, regulating the fan speed is required for efficient thermal management.

Fan drives can be mechanical, electric, or hydraulic. Mechanical systems, using pulleys and belts, often overcool due to fixed speed ratios. Electric drives suit low to medium power demands. Hydraulic fan drives are a common solution for heavy-duty off-road vehicles due to their power delivery, ability to control fan speed independent of engine speed and assembly flexibility [1]. This ability means that the fan is not wasting energy by rotating faster than it needs to, just because the engine is running at high speed. This work focuses on hydraulic fan drives.

Optimizing the design of hydraulic systems used in fan drive application to be compact, and affordable is essential for meeting customer expectations. It needs to be compact to fit in increasingly physically optimized machines and affordable to keep up to the market competitiveness [4]. However, the design should still meet functional and reliability performance. As one of the world's leading suppliers for drive and control technologies, Bosch Rexroth offers, among other things, hydraulics, electric drive and control technology, gear technology as well as linear motion and assembly technology. In the fan drive application, the company established a strong presence with its solutions featuring external gear motors and valves manifold. To maintain competitiveness, two strategic approaches were considered for product improvement.

As presented in Figure 1.1, the architecture of the hydraulic system for fan drive is defined by three subsystems: 1) hydraulic pump, usually powered by diesel engine, 2) hydraulic motor, which drives the fan, and 3) valves, when specific functions are necessary, which can be in an external manifold or integrated in the motor. Integrated options are increasingly used in the market because they optimize space, reduce the number of pipes and hoses, and decrease number of connections, which are potential leak points.

Different combinations of hydraulic pumps and motors are possible. In this paper, the focus is a system with external gear pump with external gear motor, both with fixed displacements. For this combination, several possible functions can be implemented by valves such as:

- fan drive speed control,
- radiator cleaning functionality provided by fan reversal,
- cavitation mitigation for the period when the pump stops, and the motor continues to rotate for a certain time due to the fan rotational inertia.

The need for each of the functions depends on the specification of the machine and its application.

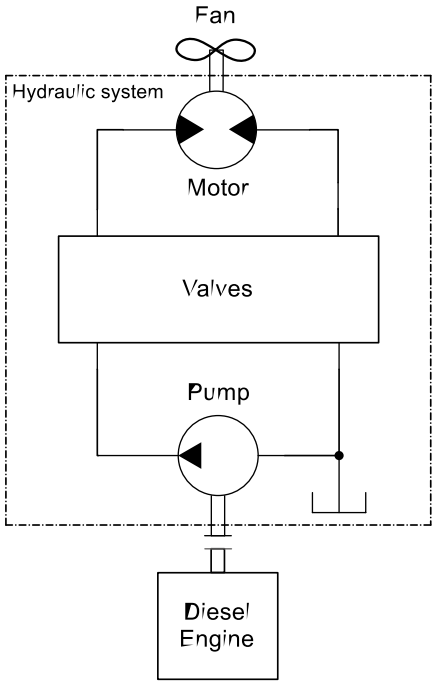

Figure 1.1 – Schematics of a generic hydraulic system for fan drive with fixed displacement pump and motor

In the status quo solution, available in the market, the speed control and the fan reversal is performed by two different hydraulic valves. This paper presents and patented and innovative solution that combines the two functions in one single valve proportional direction valve [5]. The novel concept is called then one-valve design and the status quo, two-valve design. Combining two functions in one valve allows for size and cost optimization.

The proportional directional valve is however sensible to input flow rate from the pump, which is a challenge. In mobile machinery the pumps are usually powered by diesel engines. If the diesel engine speed varies, the pump speed also changes and consequently the input flow rate. For the novel solution, this could cause then a variation in the fan speed, which is not desirable. To overcome this, a feedforward controller is proposed.

Although, the motivation behind the one-valve design is to reduce size and cost, in this paper the objective is to verify the feasibility, by means of 1D simulation, that the novel one-valve design with feedforward controller can have similar or better functional performance than two-valve design, which is the current status quo. Representative operation cycles derived from typical mobile applications will be defined and applied to the model to compare its performance to the two-valve solution.

In the following next section, it will be explained how the status quo design works. Later, a novel concept will be explored the by explaining the difference to status quo, the challenged raised by it, and how to overcome it. Then, the simulation model developed, and the

simulation results for the performance verification will be presented and discussed. Finally, the main findings and outline the next steps will be summarized.

2. STATUS-QUO SOLUTION

A hydraulic system for fan drive may be required to perform several distinct functions to meet the full range of operational demands. The specific system utilized for this investigation and presented in Figure 2.1 is designed with three primary capabilities delivered by valves: fan speed control for thermal management optimization, a reversing function for radiator cleaning, and an integrated anti-cavitation to protect the hydraulic motor.

In the status quo solution, the speed control is performed by proportional pressure relief valve (V1) and the fan reversal by on/off 4/2 directional valve (V2). The status quo solution using two independent valves (V1 and V2) inherently increases system size, and cost. Typically, an anti-cavitation valve is used for cavitation mitigation. In this paper no change is proposed for this function.

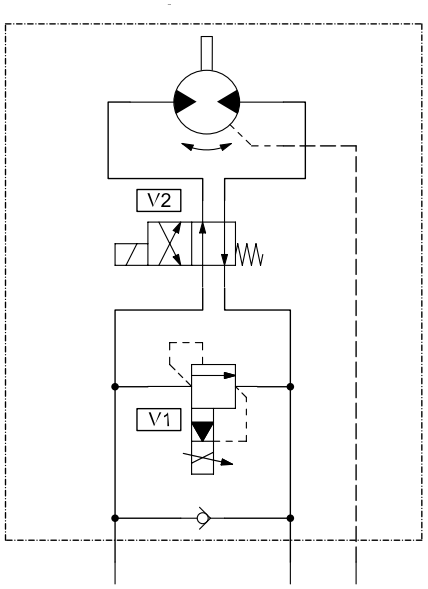

Figure 2.1. Hydraulic schematics of the status quo two-valve design (pump is omitted)

2.1. Speed control

Thermal management, which is crucial for maintaining optimal operating temperatures in mobile machinery, relies on cooling fans actively forcing air across the radiator. The rate of heat rejection is directly proportional to the volumetric airflow through the radiator, which in turn is directly proportional to the fan rotational speed. In pursuit of higher operational efficiency, the control system is designed to regulate the fan's rotational speed to the minimum level required by the current thermal conditions [1]. The logic of speed control using a proportional pressure relief valve is shown in Figure 2.2.

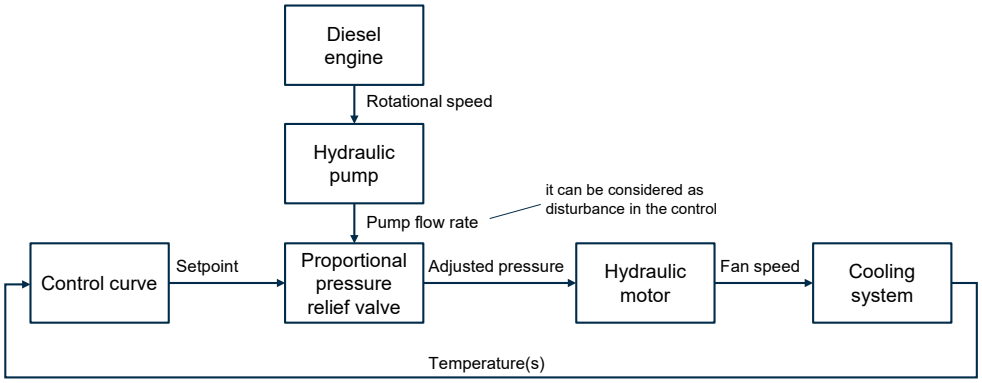

Figure 2.2. Speed control logic using proportional pressure relief valve

At lower temperatures, a reduced cooling airflow is needed, and therefore a lower fan speed is sufficient. The relationship between system temperature and required fan speed is typically defined by a control curve (often referred to as a "cooling curve") defined to meet machine's specific cooling requirements. Figure 2.3 illustrates an example of cooling curve. Fan can be set to standstill if the temperature is below a defined threshold [6].

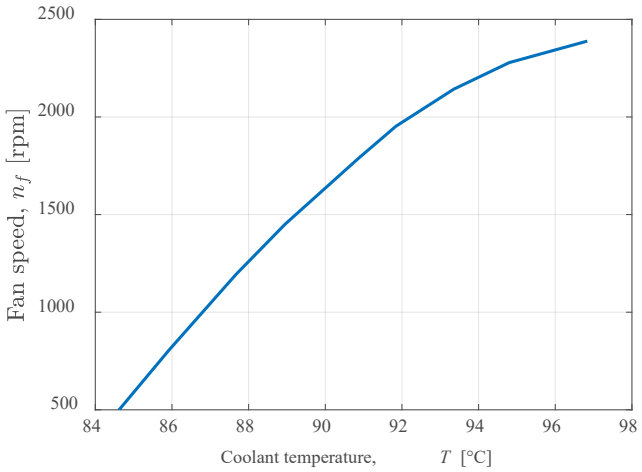

Figure 2.3. Typical fan speed control curve as a function of engine coolant temperature, adapted from [3]

The proportional pressure relief valve (V1 of Figure 2.1), which modulates system pressure in response to an electrical setpoint. Because the motor's torque is a direct function of the pressure differential across it, controlling the pressure effectively controls the torque. Since primary load on the motor is the fan's aerodynamic drag, it requires greater torque to achieve higher speeds. Consequently, a direct relationship is established where system pressure, as regulated by the valve, dictates the fan's rotational speed.

To ensure the engine does not overheat during an electrical failure, the system is designed to be fail-safe. If the control signal is lost, the fan automatically runs at maximum speed. This is achieved using negative control logic: as the electrical signal increases, the fan speed

decreases. Therefore, a zero signal commands maximum fan performance. As presented in Figure 2.4, the Bosch Rexroth KBVS.3B valve is a common example of a component that uses this principle in fan drive systems.

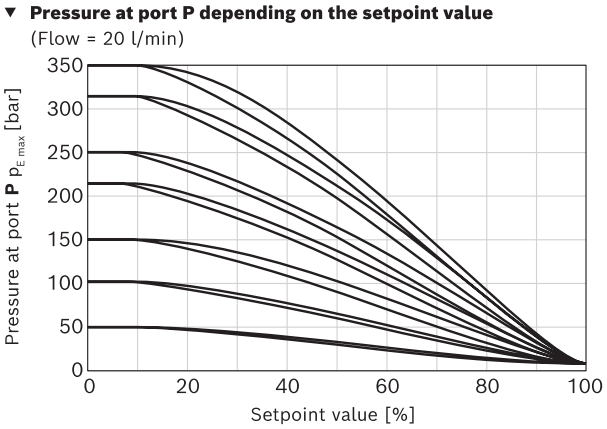

Figure 2.4. Pressure to setpoint relationship of KBVS.3B [7]

While a constant electrical setpoint to the proportional pressure relief valve should ideally maintain a constant system pressure and, therefore, a stable fan speed, the valve's inherent pressure-flow (P-Q) characteristic (Figure 2.5) causes a deviation from this ideal behaviour. As the pump's output flow increases – typically due to an acceleration of the diesel engine – a greater portion of this flow must be diverted through the valve. According to the P-Q curve, this results in in a change in system pressure even though the electrical setpoint remains fixed. This effect makes the fan speed to change under variations in pump speed. This inherent sensitivity of the status quo design will serve as the performance benchmark against the novel solution.

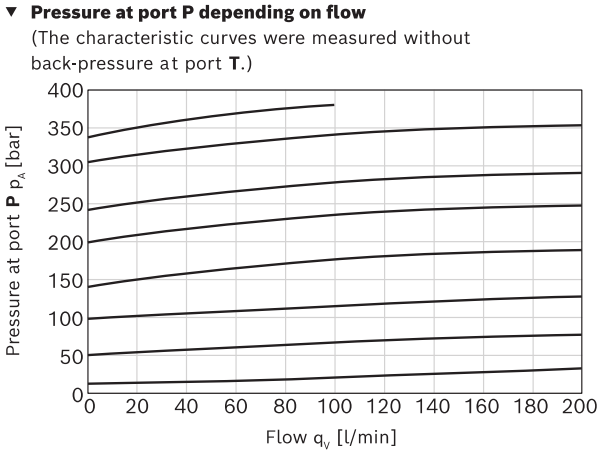

Figure 2.5. Pressure to flow relationship of KBVS.3B [7]

2.2. Reversal of speed

In many off-highway and agricultural applications, machinery operates in environments with high concentrations of airborne particulates, such as dust, chaff, and other debris. This debris can accumulate on the surface of the radiator, clogging the cooling and severely impeding airflow. A clogged radiator leads to a reduction in heat exchange efficiency, which can cause the engine and other hydraulic systems to overheat, reducing overall productivity and potentially causing damage to critical components [1].

To mitigate this issue, different radiator cleaning solutions have been developed, mainly by forcing air in the opposite direction to dislodge accumulated debris and carry the dirt away. Two usual methods are 1) changing the pitch of the fan blades [8] and 2) reversing the fan's direction of rotation [1]. This paper will focus on the latter approach, where the fan's rotational direction is reversed to generate a burst of air in the opposite direction of normal operation.

In the hydraulic system under investigation, this reversing function is accomplished by changing the fluid path to the hydraulic fan motor. As presented in Figure 2.6, this is typically achieved using a 4/2 on/off directional control valve that switches the pressure and return lines. During normal cooling operation, the pump's pressure port P is connected to working port A of the motor, while the port B is connected to the reservoir T. To initiate the cleaning cycle, the solenoid “a” is actuated, valve shifts, connecting the pressure port P to the working port B and working port A to reservoir T. This change in flow direction causes the motor and, consequently, the fan to rotate in the opposite direction.

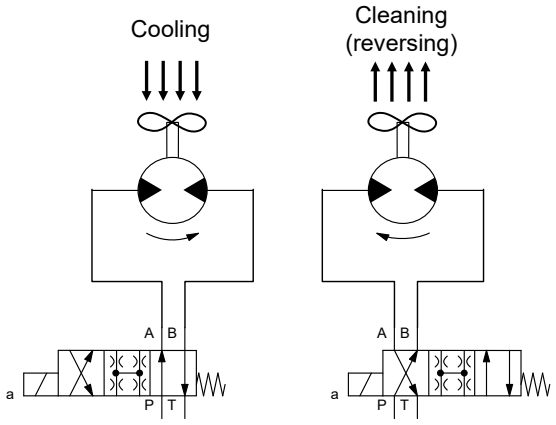

Figure 2.6. Directional positions for cooling and cleaning (reversing) modes

The activation of the reversing cycle is managed by the machine's controller. This can be initiated manually by the operator via a button in the cab or programmed to occur automatically at periodic intervals. The frequency of these automatic cleaning cycles can be tailored to the specific application and expected level of debris.

3. NOVEL SOLUTION

The idea behind the novel solution is to use a simplified hydraulic system combined with a feedforward control system to achieve the functionalities required for the fan drive

application with similar performance as status quo solution. As shown in the hydraulic schematics of Figure 3.1, in the novel concept, the speed control and fan reversal functions are combined in one single proportional directional valve (V3). Therefore, the novel concept is called one-valve design. The spool design is explained in section 3.1 and the feedforward controller in section 3.2.

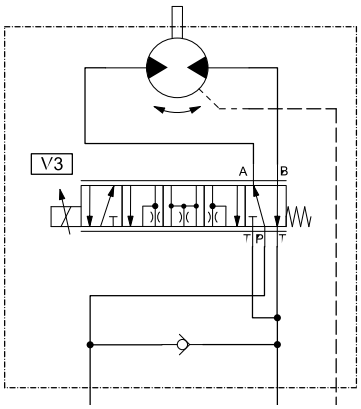

Figure 3.1. Hydraulic schematics of the novel concept one-valve design (pump is omitted)

3.1. Spool valve design

This novel solution employs a single proportional directional valve whose spool geometry is designed to achieve both fan speed control and direction change. This valve features a spool specifically designed for fan drive applications through control edges to achieve the performance required. The spool position can be continuously set from 0 to 100% by an electrical signal, which is referred as setpoint. Figure 3.2 illustrates a simplified representation of the spool valve geometry and its 5 functional stages.

Stage	Setpoint	T A P B T	Mode	Fan speed
1	0%		Cooling	Maximum
2	25%		Cooling	Intermediate
3	50%		Standstill	Stop
4	75%		Cleaning	Intermediate
5	100%		Cleaning	Maximum

Figure 3.2: Simplified representation of the spool in its five stages

Please find below an explanation of the five stages:

1. To meet the fail-safe requirement, at "zero" setpoint the maximum fan speed in the cooling mode is achieved by connecting P to A and B to T. The meter-in (P to A) edge is designed to achieve pressure drop of ~3 bar at 40 L/min to meets the market requirements, which is similar to other parts in body solutions of Bosch Rexroth such as SM12 open control block [10]
2. By increasing the setpoint, the P-A and B-T connections are maintained, but the A-T connection partially starts to open, causing some of the flow that would go to the motor to now divert to the reservoir. This causes the motor to decrease its speed, but still kept in the same direction and therefore cooling mode.
3. When the setpoint reachs 50%, then all four ports PABT are connected by specific designed metered edges. This allows for a smooth transition when reversing. Also, if the controller keeps the 50% setpoint, then the motor is set to standstill mode, i.e., it stops.
4. By this stage, the reversing starts connecting P to B and A to T, but not at full speed since there is a connection between B to T, as a mirror of stage 2. Therefore, this stage is in the cleaning mode with partial speed.
5. When the connection between B to T closes, then the fan operates at cleaning mode at full speed, as a mirror of stage 1.

To control the speed of the fan, the flow rate going to the motor (Q_m) is reduced by diverting part of the pump flow rate (Q_p) to reservoir, which is known as bleed-off flow rate (Q_b) as shown in Equation 3.1.

$$Q_m = Q_p - Q_b \qquad (3.1)$$

This technique allows for flow control without throttling, i.e., restricting, the path from pump to the load [11]. The challenge of the proposed flow control is the hight sensitivity of the controlled motor flow rate to the pump flow rate. To explain, if the speed of the diesel engine increases, the pump flow rate also increases, and if the bleed-off flow rate remains the same, the motor flow rate and consequently the fan speed will increase, which is not desired. As will explained in the next section, to overcome this sensitivity, a feedforward controller is developed where it takes account the diesel engine speed as input to keep a stable fan drive speed.

3.2. Control with feedforward

The objective of the control with feedforward is to keep the fan speed stable, even with fluctuations in pump speed. As shown in the Figure 3.3, it calculates the spool position setpoint (x') based on the fan speed setpoint (n_f'), determined from control curve according to the measured temperature (T), and adjusted to the measured pump speed (n_p), which is commonly available in the electronics of modern machines. It allows to the controller to automatically adjust the bleed-off flow rate to compensate for a possible fluctuation in pump flow rate (Q_m), which keeps a constant controlled flow rate to the motor (Q_m), therefore a stable fan speed (n_f).

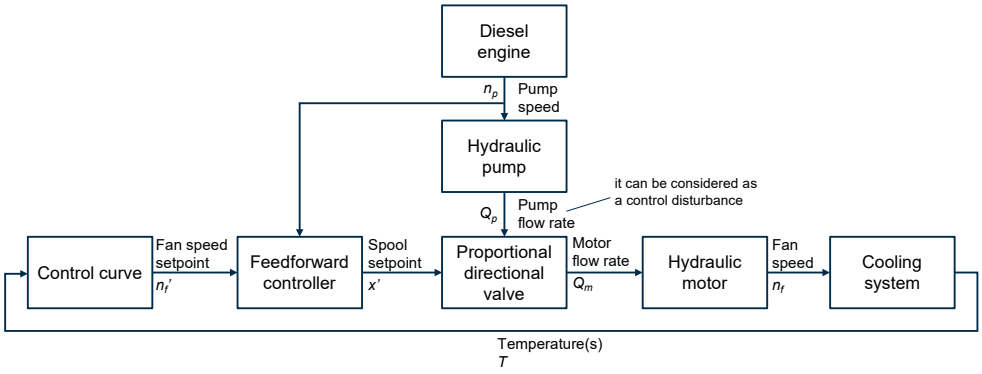

Figure 3.3. Speed control logic with proportional directional valve

To understand behind how the control calculates the spool setpoint based on the fan speed setpoint and the pump speed, the Equation 3.1 is reorganized to isolate the bleed-off flow rate (Q_b):

$$Q_b = Q_p - Q_m \tag{3.2}$$

Knowing the measured pump speed (n_p), the pump displacement (V_p), and the volumetric efficiency of the pump ($\eta_{p,v}$), it is possible to calculate the flow rate as follows:

$$Q_p = n_p V_p \eta_{p,v} \tag{3.3}$$

Similar way, it is possible to calculate the motor flow rate (Q_m) knowing the desired motor speed, which is the same as the fan speed setpoint (n_f'), the motor displacement (V_m), and the volumetric efficiency of the pump ($\eta_{m,v}$):

$$Q_m = n_f' V_m \eta_{m,v} \tag{3.4}$$

Consolidating Equations 3.3 and 3.4 in 3.2:

$$Q_b = n_p V_p \eta_{p,v} - n_f' V_m \eta_{m,v} \tag{3.5}$$

The bleed-off flow rate is controlled by the spool opening, which can be described as a turbulent orifice [12]:

$$Q_b = C_d A \sqrt{\frac{2}{\rho} \Delta p} \tag{3.6}$$

Where C_d is discharge coefficient, normally considered 0,7, A the orifice area of the bleed-off control edge, which varies according to spool position, and (Δp) the pressure differential across the bleed-off control edge.

The pressure differential across the motor can be considered the same as the differential across the bleed-off control edge, since its orifice area is significantly more restrictive than the meter-in and meter-out. As explain in the section 2.1 for the status quo design, the relationship between pressure differential across the motor (Δp) and fan speed setpoint (n_f') is known:

$$\Delta p = f(n_f') \tag{3.7}$$

The orifice area of the bleed-off control edge (A) depends on the spool setpoint (x') and its relationship is defined in the spool design:

$$x' = g(A) \qquad (3.8)$$

Combining Equations 3.5, 3.6, 3.7 and 3.8, then:

$$x' = g\left(\frac{n_p V_p \eta_{p,v} - n'_f V_m \eta_{m,v}}{C_d \sqrt{\frac{2}{\rho} f(n'_f)}}\right) \qquad (3.9)$$

Equation 3.9 therefore governs the behaviour of the feedforward controller by continuously calculating the spool setpoint (x') according to fan speed setpoint (n'_f), and the measured pump speed (n_p).

4. SIMULATION MODEL

Having clarified how the status quo solution works, which is the performance benchmark, and the challenges involved in the novel solution, a simulation model was created to support the product development. The use of a simulation model significantly accelerates the design cycle and reduces costs by enabling early performance validation and optimization of spool geometry reducing the design iterations. The objective of the model in this phase is to confirm the feasibility of the novel solution by performing a preliminary assessment of system performance in comparison to status quo.

The model was created using AMESim, a mechatronic systems simulation platform [13]. For this comparative analysis, models for both the existing and novel solution were created. The schematic diagrams for both are presented in Figure 4.1 side-by-side, with key components labelled for clarity. Parameters used in the model such as the size of the pump, motor and fan are not from any specific machine, but those fall within the range commonly found in fan drive application. If necessary, in the future it is possible to parameterize the model to validate a specific configuration.

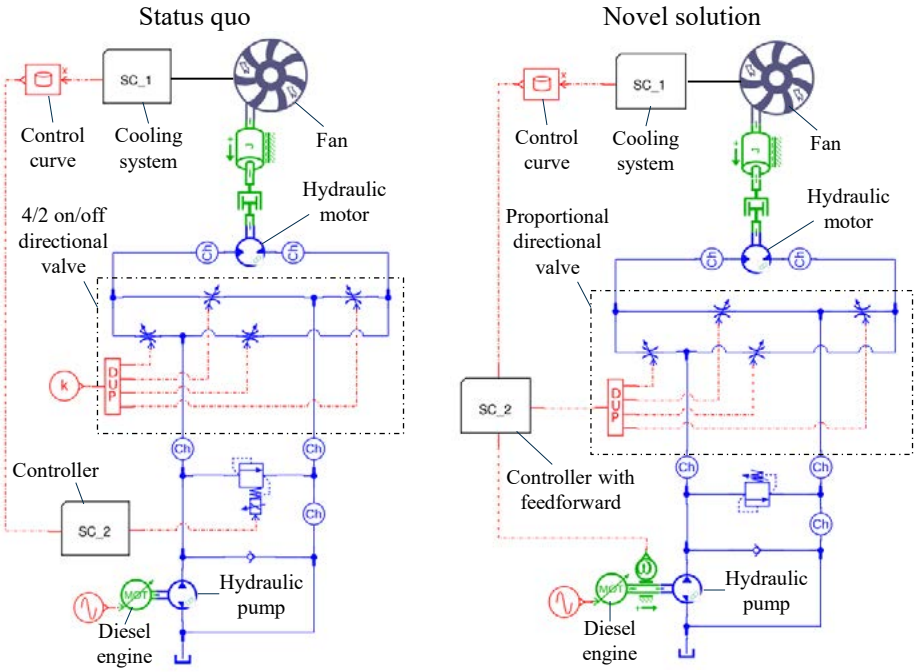

Figure 4.1. Schematics of simulation models

For the 4/2 on/off directional valve (status quo model) four orifices with turbulent conditions were used, one for each connection P-A, P-B, A-T and B-T. The orifice area (A) of each connection varies according to the spool setpoint (x'), where the relationship is defined by the spool geometry including the notches. The time response of the valve is defined by a first order response, where a 99% of the setpoint is achieve within 100 ms. Same approach is used for the proportional directional valve (novel solution model). It was considered a fan with a torque of 50 Nm at 2500 rpm. For the pump and motor, it was chosen Rexroth external gear units of 28 ccm and 19 ccm respectively, where volumetric efficiencies were taken from datasheet curves [14] [15]. The oil properties followed the ISO VG 46 classification. The influence of temperature variation on the parameters of the hydraulic components was not considered. Other models are standard from AMESim library. The main parameters of the model are available in Table 4.1.

Table 4.1. Main parameters of simulation model

Component	Description	Value	Unit
Motor	Displacement	19	ccm
	Volumetric efficiency	0.92	-
Pump	Displacement	28	ccm
	Volumetric efficiency	0.95	-
Fan Drive	Static friction	5	Nm
	Running friction	4	Nm
	Viscous friction coefficient	0.0184	Nm/rpm
	Moment of Inertia	0.07	kg.m²
Valves	First order time constant	0.0217	s
Proportional Pressure Relief Valve	Flow Rate Pressure Gradient	6.15	L/min/bar
Fluid	Fluid density	865	kg/m³

5. RESULTS

The performance of the novel solution (one-valve design) was evaluated under a significant disturbance by varying the pump speed and compared to the status quo (two-valve design), as illustrated in the Figure 5.1. To show that feedforward controller is indeed necessary, the novel solution behaviour was presented both with and without this controller. As presented in Graph b, a periodic disturbance was introduced by varying the pump speed sinusoidally between approximately 1,000 rpm and 2,400 rpm over a 20-second cycle. The fan speed of status quo, novel solution without feedforward, novel solution with feedforward is presented in Graph a. The objective was to maintain a constant fan speed of 1,400 rpm.

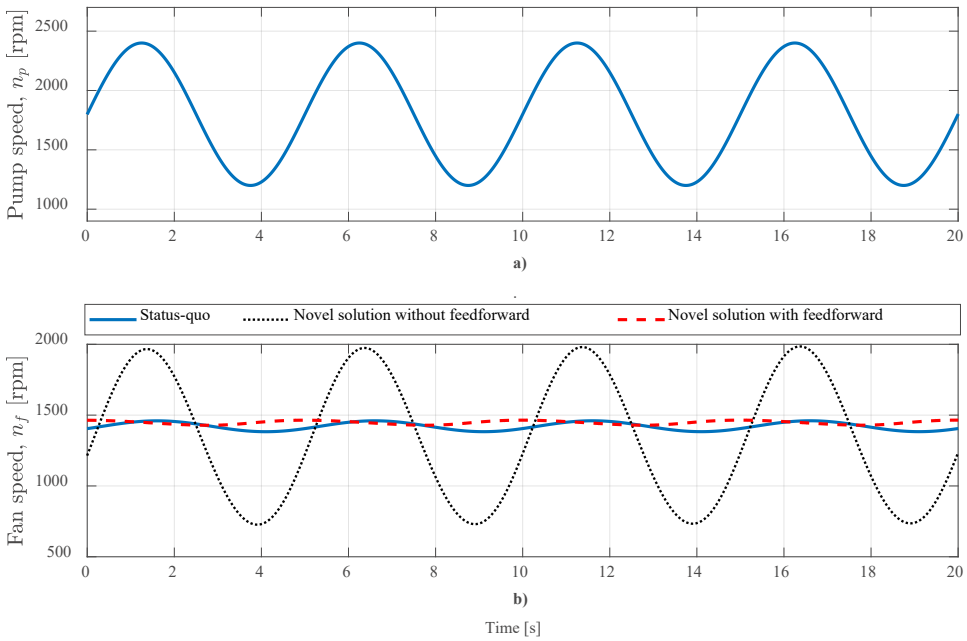

Figure 5.1. Fluctuation in fan drive speed due to variation in pump speed (simulation)

- **Status quo (benchmark):** The existing control system (solid blue line) serves as the reference for performance. It demonstrates partial disturbance rejection, with oscillations of approximately ±38 rpm amplitude.
- **Novel solution without feedforward:** When compared to the benchmark, this control strategy (dotted black line) was unable to compensate for the disturbance. The fan speed exhibited large, unstable oscillations with amplitude of approximately ±623 rpm, demonstrating a clear failure to regulate the system and a significant degradation in performance.
- **Novel solution with feedforward:** The proposed controller incorporating a feed-forward mechanism (dashed red line) demonstrated better performance than Status quo. It effectively attenuated the disturbance from the pump with oscillations of approximately ±18 rpm amplitude.

These results indicate that the inclusion of a feedforward control loop provides a substantial improvement in disturbance rejection and system stability over both the status-quo and non-feed-forward solutions. Other investigations were also carried out using the simulation model, such as the assessment of peak pressure and velocity during reversal, where the requirements were met However, these were not presented in detail since the focus of this paper is on the stability in speed control.

6. CONCLUSION

This paper successfully demonstrated by simulation, that the novel one-valve solution, when integrated with its enhanced feed-forward control, can overcome the challenge of fan speed instability caused by engine speed fluctuations when using proportional directional valves. The feedforward control strategy shows to be capable of providing robust disturbance rejection to pump speed variation, using the status quo solution, which is a pressure-controlled fan drive, as a performance benchmark.

Simulation results revealed that the status quo exhibited fan speed oscillations of approximately ±38 rpm under variable pump speeds. The proposed novel solution with feedforward controller effectively compensated for these disturbances by achieving ±18 rpm oscillation, while without controller it presented low performance with ±623 rpm oscillations.

The findings show that the use of a feedforward controller can enable the use of a cheaper and more compact hydraulic system, while maintaining low sensitivity to variations in engine speed. Furthermore, the development process underscored the value of simulation as a powerful tool for rapidly designing and validating control concepts prior to hardware implementation.

Future work should prioritize the experimental validation of these simulation results on a physical test bench to confirm the real-world performance of the hydraulic system and controller. Further investigations could also explore the system's robustness against other operational variables, such as changes in valve’s time response and geometry tolerances.

His research areas include hydraulics, mobile application, fatigue assessment, finite element method (FEM), and reliability.

Pedro Condessa received his bachelor’s degree in Mechanical Engineering from the Federal University of Santa Catarina (UFSC) in 2025. He worked as an intern in Advanced Engineering External Gear Units Department at Bosch Rexroth, where he focused on thermal-hydraulic system simulation and analysis. His research interests include hydraulic systems, system modeling and simulation, and data-driven analysis.

Stefan Kock received his Mechanical Engineering degree from the Technical University of Dresden, Germany, and his Ph.D. from RWTH Aachen University, where his research focused on wind turbine drive trains and torque measurements. He is currently Team Leader for Advanced Engineering for External Gear Units at Bosch Rexroth. His research areas include drive train technology, mechatronic systems, fatigue assessment, finite element method (FEM), and fluid power drives.

Martin Laube received his Diploma degree as Dipl.-Ing. (univ.) in Mechanical Engineering from the Technical University of Munich (TUM) in 1996. He specialized during his studies in the field of Design and Development with a focus on machine elements, vehicle technology and fluid technology. He started his industrial career in 1996 as a development engineer for railway systems at Mannesmann Rexroth, Lohr a. Main. After holding various positions in sales and engineering for industrial applications at Mannesmann Rexroth and Bosch Rexroth (since 2001), he assumed the position of Engineering Director for Hydraulic Power Units, Manifolds and Systems at Bosch Rexroth AG in 2013. Since July 2024, he has been Vice President and Head of Product Area External Gear Units in the Business Unit Mobile Components at Bosch Rexroth AG.

An Electro Hydraulic Hybrid System to Downsize Motor Power of Electric Wheel Loader Working Function

Abstract.

The electro-hydrostatic variable speed drive system (VSD) is one of the effective ways to improve energy efficiency of electric wheel loader working function. However, the VSD system still has the limitations including large installed motor power, low-efficiency operating points of the electric motor-pump, and high dynamic response requirement of components. Therefore, an electro-hydraulic hybrid variable speed drive system (EH-VSD) is proposed to reduce the installed power with maintaining the energy efficiency. Unlike VSD system that relies on motor speed control, the proposed solution incorporates a high-pressure hydraulic accumulator in parallel configuration. The electric motor-pump supplies the average power demand, while the accumulator responds to peak load requirements. An energy management strategy based on the dynamic programming is developed to manage the power distribution of two energy sources. Simulation results show that the installed motor power of EH-VSD system reduces by 54.5% compared to VSD system (from 110 kW to 50 kW). The EH-VSD system achieves a significant reduction in installed power while maintaining a high energy efficiency comparable to that of the VSD system, effectively avoiding substantial throttling losses.

Keywords. Electro-hydraulic hybrid system, variable speed drive, dynamic programming, installed power, electric wheel loader.

1. INTRODUCTION

With the growing global demand for energy conservation and emission reduction in construction machinery, traditional machines powered by internal combustion engines are increasingly unsuitable due to their high energy consumption, substantial carbon emissions, and severe environmental impact [1]. Electrification technology, which replaces conventional engines with electric motors powered by batteries or cables, enables zero emissions at the point of use and significantly improves system energy efficiency. Consequently, it has become a prominent research focus in the field of construction machinery [2].

To reduce energy consumption in the working system of electric wheel loader, an electro-hydrostatic variable speed drive (VSD) system has been proposed for application in wheel loaders [3], as illustrated in Fig. 1.1. This system controls the velocity of the hydraulic cylinder by adjusting the motor speed, thereby avoiding throttling regulation and improving overall energy efficiency [4]. Qu et al. applied an open-circuit VSD working system with an

All Open Access articles are peer-reviewed, distributed under the Creative Commons Attribution-Non Commercial 4.0 International

integrated motor-pump unit in a skid steer loader, achieving a steady-state energy efficiency of up to 59.9% [5]. Guo et al. proposed a VSD steering system for wheel loaders, which reduced energy consumption by 22.8% compared with conventional systems [6].

Although the VSD working system significantly improves energy efficiency, it still has certain inherent limitations due to its system configuration: 1) The high-magnitude and transient load demands characteristic of working hydraulic system requires substantial installed power when relying solely on motor-pump actuation. 2) The frequent load cycle variation compels the motor-pump unit to respond rapidly, often operating outside its optimal efficiency range. 3) The concurrent demands for high dynamic response, sustained energy efficiency, and high peak power result in increased system cost [7-10].

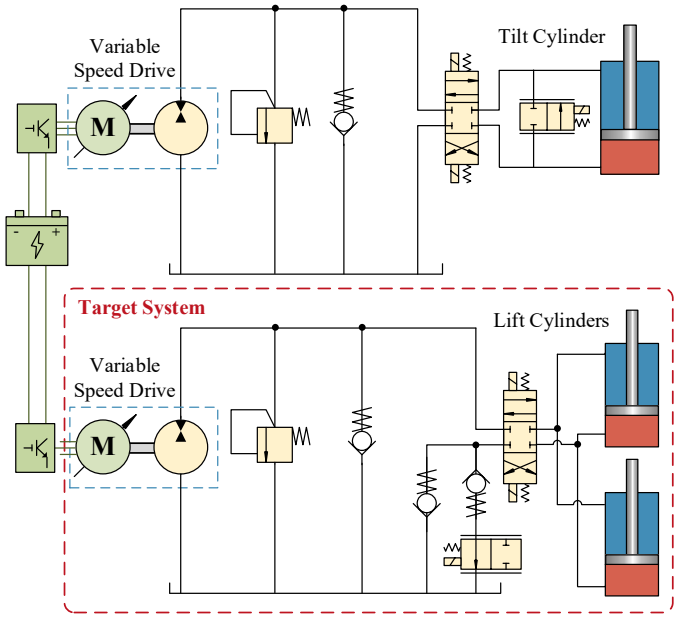

Fig. 1.1. The electro-hydrostatic variable speed drive (VSD) system (baseline system)

Compared with purely electric drive systems, electro-hydraulic hybrid drive systems integrate a secondary energy storage component, which expands the controllable dimensions and enables flexible energy distribution and conversion between different power sources, thereby facilitating improved overall performance [11-13]. Some recent studies have focused on electro-hydraulic hybrid control strategies for VSD working systems. Kang et al. proposed using an accumulator as a built-in regulator to enhance the dynamic performance of the VSD system, aiming to achieve faster response and broader frequency bandwidth [14]. Shang et al. introduced an energy recovery module into the variable-speed system, which disabled the generator mode of the motor under forward load conditions [15]. This configuration allowed the elimination of the system's power resistor and reduced electric motor heating temperature by 39%. Seo et al. employed a secondary control part in the VSD system, consisting of a high-pressure accumulator, a servo valve and mode-switching valves, to reconfigure the hydraulic circuit according to operational modes [16].

Therefore, an electro-hydraulic hybrid variable speed drive system (EH-VSD) is proposed for the working function of electric wheel loaders. Unlike VSD system that relies solely on motor speed regulation, the proposed solution incorporates a high-pressure accumulator in parallel configuration. The electro-hydraulic parallel design leverages the respective advantages of both components: the electric motor and pump unit (VSD unit) supplies the average power demand, while the accumulator responds to peak load requirements. This configuration effectively reduces the installed power, leading to a more compact and lightweight system, making it more suitable for powertrain layout design and contributing to lower electric drive costs. Meanwhile, the proposed system still utilizes the variable speed drive to maintain the throttle-free advantage.

The main contribution of this study is to propose an electro-hydraulic hybrid variable speed drive system (EH-VSD) to downsize the electric drive system. An energy management strategy based on the dynamic programming is developed to ensures the VSD unit operates within its high-efficiency region, which further improves the energy efficiency of the system. The comparison between proposed system and baseline system (VSD) is conducted in terms of system performance, installed power and energy efficiency. The rest of the paper is organized as follows: Section 2 presents system mathematical modelling and working modes, section 3 shows control strategy and optimization method, section 4 shows simulation study and comparison, and section 5 concludes the study.

2. SYSTEM CONFIGURATION

2.1. System overview

The schematic of the electro-hydraulic hybrid variable speed drive (EH-VSD) working system is illustrated in Fig. 2.1. In the working system of a wheel loader, the lift function accounts for over 80% of the total energy consumption and is characterized by high load power [17]. Therefore, this study focuses on the lift function as a representative case to investigate the performance of the proposed EH-VSD system.

The system's power sources consist of a VSD unit and a high-pressure hydraulic accumulator module. The VSD unit is composed of a lithium iron phosphate ($LiFePO_4$) battery pack, an inverter, a permanent magnet synchronous motor (PMSM), and a hydraulic pump. The PMSM is selected for its fast dynamic response, making it well-suited for variable-speed operation. A fixed-displacement, unidirectional hydraulic pump is employed in the system. The high-pressure accumulator module serves as a secondary power source, supplying additional energy to the system when required. The proportional valve 1 (PV1) is used to regulate the flow discharged from the accumulator and also allows the hydraulic pump to operate independently. Both the hydraulic pump and the accumulator adopted in the proposed system are commercially available hydraulic components.

The hydraulic system adopts an open-circuit configuration, in which the low-pressure pipeline and the pump inlet are directly connected to the hydraulic reservoir. The system switches between different operating modes using a directional valve (DV), with specific control strategies detailed in Section III. The proportional valve 2 (PV2) is employed to control the lowering speed of the hydraulic cylinder and remains fully open in the left position during other working modes. The check valve 1 (CV1) ensures unidirectional rotation of the hydraulic pump by preventing backflow from the accumulator, thereby

avoiding interference with pump operation. The check valves 2 (CV2) and 3 (CV3) are used to control the flow direction between the hydraulic cylinder and hydraulic reservoir, enabling appropriate flow paths for different working modes. A relief valve (RV) is included as a protective component to prevent system pressure from exceeding the designated working pressure.

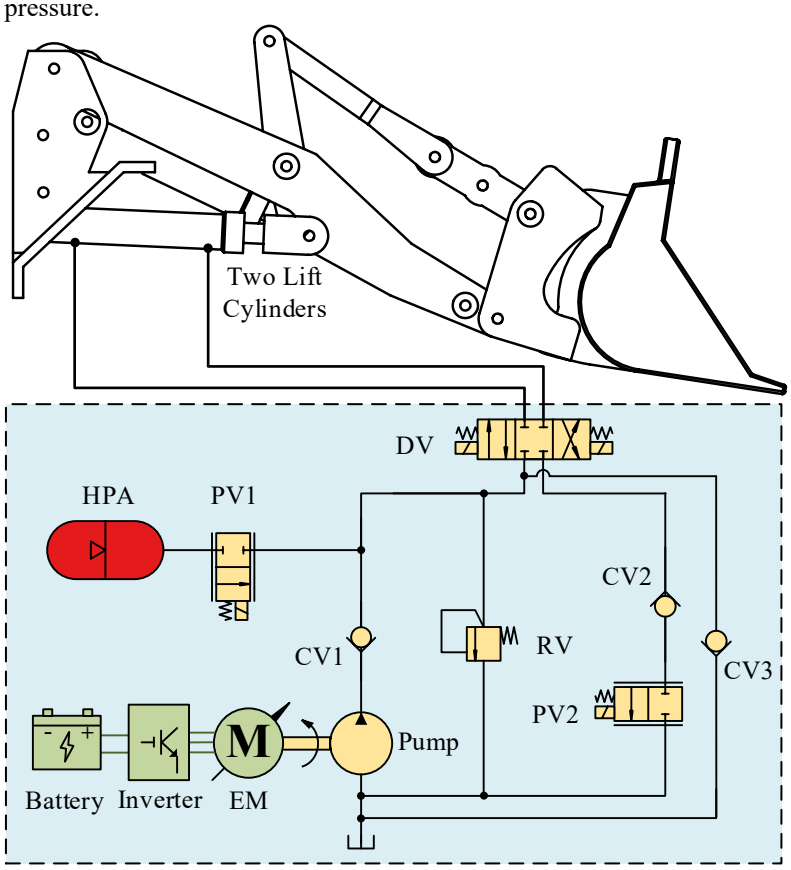

Fig. 1.1. The proposed electro-hydraulic hybrid variable speed drive (EH-VSD) working system

2.2. System Modelling

1) Electric Motor/Generator: The electric motor is modelled using a d–q axis framework, where the direct axis (d) aligns with the rotor flux, and the quadrature axis (q) is orthogonal to it. This empirical model for the permanent magnet synchronous motor (PMSM) captures the motor's dynamic behaviour during rapid acceleration and deceleration and allows for adjustable step sizes in real-time simulations.

According to the generalized form of Ohm's law, the d- axis and q-axis components of the stator voltage space vector, u_d and u_q, are expressed as:

$$\begin{cases} u_d = R_s I_d - \omega_e \psi_q + \dot{\psi}_d \\ u_q = R_s I_q + \omega_e \psi_d + \dot{\psi}_q \end{cases} \tag{4}$$

where R_s is stator winding resistance and ω_e is the angular velocity of the rotor.

The d–q components of the flux linkage, ψ_d and ψ_q, are given by:

$$\begin{cases} \psi_d = L_d I_d + \psi_{pm} \\ \psi_q = L_q I_q \end{cases} \tag{5}$$

where L_d and L_q are stator cyclic inductances along the d-q axis, I_d and I_q are corresponding stator currents, and ψ_{pm} is permanent magnet flux linkage.

The electromagnetic torque, T_{em}, is calculated by:

$$T_{em} = \frac{3}{2} N\left(\psi_d I_q - \psi_q I_d\right) \tag{6}$$

where p is the number of pole pairs.

The dynamic equation of the motor shaft is described by:

$$\left(J_{em} + J_p\right)\dot{\omega_{em}} = T_{em} - T_p - T_f \tag{7}$$

where J_{em} and J_p are the shaft inertia of electric motor and pump, T_p is the torque of pump and T_f is viscous friction torque.

2) Fixed Displacement Pump: The fixed-displacement pump model incorporates the variation of component efficiencies with operating speed and pressure. It determines the output torque and flow rate based on an efficiency map that reflects these dependencies. The shaft torque T_p, and inlet flow rate Q_p, of the pump are given by:

$$\begin{cases} T_p = \dfrac{D_p(p_H - p_L)}{\eta_m^a} \\ Q_p = D_p \omega_p \eta_v^a \end{cases} \tag{9}$$

where D_p is full displacement of pump, p_H and p_L are the high and low pressure sides of the pump, η_m and η_v are mechanical and volumetric efficiencies which are pressure and shaft speed-dependent, a is mode factor of pump, ω_p is the shaft speed of pump and is equal to the electric motor speed $\omega_p = \omega_{em}$.

3) Accumulator: During the loading cycle, both the charging and discharging of the accumulator are relatively short. Therefore, the accumulator is modelled using the isothermal gas law, assuming a constant operating temperature. The pressure of the accumulator, p_{acc}, is given by:

$$p_{acc} = p_0 \left(\frac{V_0}{V_{acc}}\right)^{\gamma} \tag{10}$$

where p_0 is pre-charge pressure, V_0 and V_{acc} are initial and current gas volume and γ is polytropic index of gas.

The current gas volume of the accumulator is determined by the integral of the flow rate over time. The flow rate, Q_{acc}, is considered positive during discharge and negative during charging. The gas volume, V_{gas}, is expressed as:

$$V_{acc} = V_0 + \int Q_{acc} dt \tag{11}$$

The hydraulic state of charge (SOC) of the accumulator, SOC_{acc}, is defined as:

$$SOC_{acc} = \frac{p_{acc} - p_{min}}{p_{max} - p_{min}} \tag{12}$$

where p_{min} and p_{max} are the maximum and minimum allowable accumulator pressure.

4) Proportional Valve: A proportional valve is used to regulate the flow rate from the high-pressure accumulator and another one controls the lowering speed of the lift cylinder. The flow rate across the directional valve, Q_v, is:

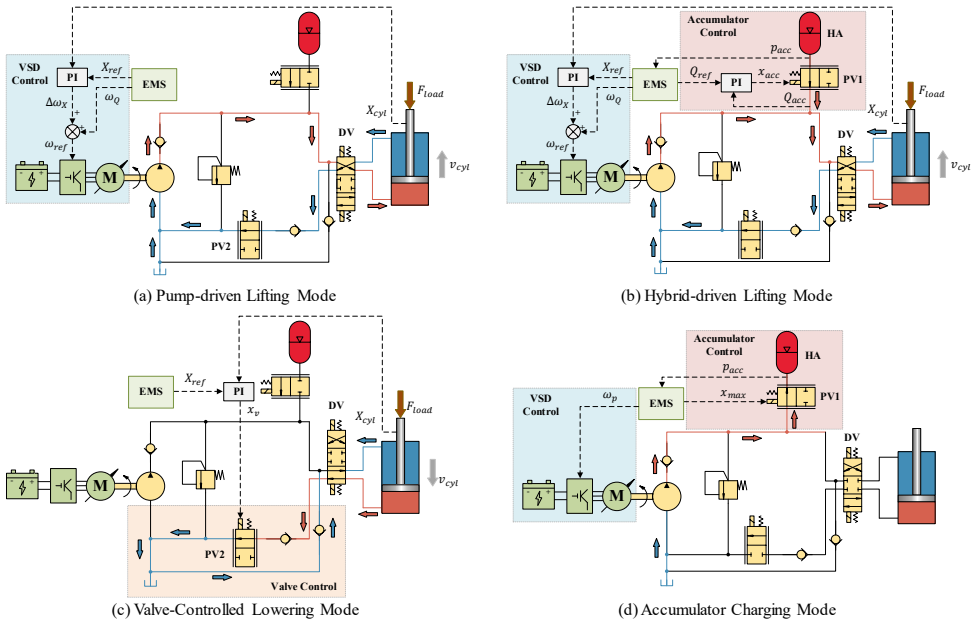
$$Q_v = c_q A_v x_v \sqrt{\frac{2|\Delta p|}{\rho}} \tag{13}$$

where c_q is flow coefficient, A_v is throttling area of proportional valve, x_v is the valve opening ratio, Δp is the pressure difference of valve inlet and outlet, ρ is hydraulic fluid density.

5) Hydraulic Cylinder: The dynamic behaviour of cylinder can be described by a set of well-established mathematical equations:

$$\begin{cases} Q_A - A\dot{x_{cyl}} = \frac{V_A}{E_h}\dot{p_A} \\ a\dot{x_{cyl}} - Q_a = \frac{V_a}{E_h}\dot{p_a} \\ p_A A - p_a a - F_{load} - Bv = m\ddot{x_{cyl}} \end{cases} \tag{16}$$

where p_A and p_a are pressure in the piston and rod chambers, A and a are the effective area of piston and rod sides, Q_A and Q_a are flow rate of piston and rod chamber, V_A and V_a are control volumes of piston and rod chambers, E_h is the effective bulk modulus of hydraulic fluid, F_{load} is the external load force on the piston, B is viscous friction coefficient, x_{cyl} is piston displacement and m is equivalent mass of piston.



2.3. Working Mode

The proposed EH-VSD system operates in four working modes: pump-driven lifting mode, hybrid-driven lifting mode, valve-controlled lowering mode, and accumulator charging mode. The overall system operation is coordinated by an energy management strategy (EMS), as illustrated in Fig. 2.2.

(a) Pump-driven Lifting Mode: In this mode, the control strategy integrates feedforward speed estimation with position PI feedback to achieve accurate cylinder motion control. Based on the cylinder velocity in the given loading cycle, the EMS calculates the theoretical rotational speed of the VSD unit, which serves as the feedforward term for the electric motor speed command. In parallel, a position PI feedback controller computes a speed compensation from the position difference between the actual cylinder position and reference given by EMS. The feedforward and feedback components are combined to ensure

precise cylinder position control. The baseline VSD system also employs this same control approach, regulating cylinder position through motor speed adjustment.

(b) Hybrid-driven Lifting Mode: In the hybrid mode, the flow rate outputs of the VSD unit and the high-pressure accumulator are determined in advance by the dynamic programming–based optimization method (to be described in the following subsection), and EMS assigns the corresponding reference control signals to each module. The high-pressure accumulator is regulated using proportional control, where the opening of PV1 is determined by the PI controller based on the error between the theoretical and actual flow rates, ensuring accurate control of the accumulator's output power. The VSD unit continues to employ the feedforward and feedback control strategy, with the feedback loop ensuring precise lift cylinder position tracking.

(a) Pump-driven Lifting Mode (b) Hybrid-driven Lifting Mode

(c) Valve-Controlled Lowering Mode (d) Accumulator Charging Mode

Fig. 2.2. Working modes of the EH-VSD working system

(c) Valve-Controlled Lowering Mode: In this mode, a hydraulic cylinder position PI controller is employed. The PI controller regulates the opening of the proportional valve based on the error between the theoretical position provided by the EMS and the actual actuator position, achieving controlled lowering of the cylinder through outlet throttling. Furthermore, not utilizing the VSD unit for energy recovery in this mode offers additional benefits: (i) the hydraulic pump does not need to operate in bidirectional rotation, so a unidirectional pump can be utilized, thereby reducing component cost, (ii) the electric motor avoids operating in generator mode, which would otherwise cause significant power losses and increase motor temperature, negatively affecting its operating condition.

(d) Accumulator Charging Mode: In this mode, the proportional valve of the accumulator module is kept fully open to avoid additional throttling losses. The EMS regulates the VSD unit speed according to the optimization results obtained from the dynamic programming,

ensuring that both the motor and hydraulic pump operate within their high-efficiency regions. Once SOC_acc reaches its maximum value (i.e., the initial state), the proportional valve of the accumulator module is closed, and the VSD unit returns to standby mode.

3. SYSTEM CONTROL STRATEGY

3.1. Overview

Compared with the VSD working system, the proposed EH-VSD system incorporates two power sources: the VSD unit and the high-pressure hydraulic accumulator. The inclusion of the accumulator provides an additional degree of freedom for system control, and certain parts of the system configuration differ from the conventional design. Consequently, different working modes must be assigned according to the wheel loader's loading cycle. Multiple power sources enable power-split operation within the system. The accumulator not only reduces the installed power requirement but also facilitates optimal system-level control aimed at improving energy efficiency. The power distribution between the VSD unit and the accumulator has a significant impact on both installed power and system energy efficiency, making it necessary to perform optimization of power distribution.

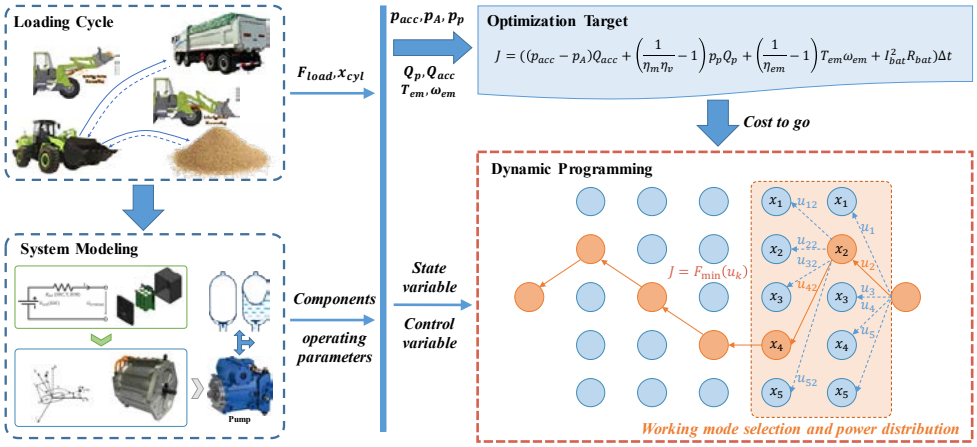


Fig. 3.1. Control schematic of the mode-based control strategy of proposed powertrain

The control strategy and power distribution optimization framework for the proposed EH-VSD system are illustrated in Fig. 3.1. First, the loading cycle of wheel loader are analyzed to determine the control strategy and optimization boundary. Then, based on the loading cycle and the system mathematical model established in section 2, a cost function is formulated to define the optimization objectives. Finally, the dynamic programming is then applied to select the working mode of system and achieve the globally optimal power distribution parameters, thereby maximizing energy efficiency under the minimum installed power constraint.

3.2. Optimization Method

Dynamic programming (DP) is commonly used to solve global optimization problems by decomposing them into a series of simpler sub-problems [18, 19]. Under a known loading

cycle, DP discretizes the cycle and solves the problem step-by-step, reducing computational complexity by storing and reusing solutions of sub-problems [20, 21].

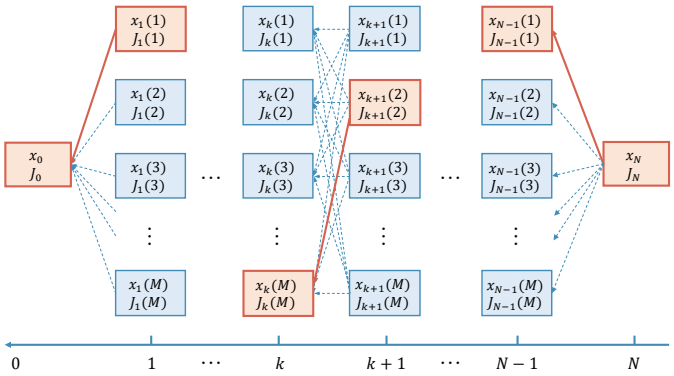

Fig. 3.2. Dynamic programming for the power distribution optimization method

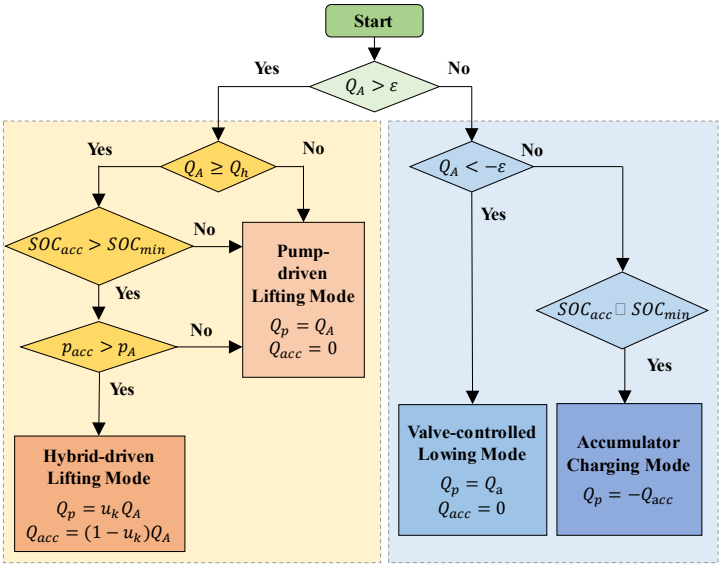

Fig. 3.3. Working mode selection within the dynamic programming

This study focuses on the EH-VSD working system to investigate the optimal power distribution between VSD unit and high-pressure accumulator. The objective is to reduce the installed power while improving overall system energy efficiency. The time horizon is discretized into N equally spaced intervals. Appropriate state and control variables are selected and discretized into an M-dimensional grid. A performance objective function is formulated based on the system's energy losses. Under constraints on initial and terminal states as well as component operational limits, a backward recursion algorithm is used to find the global optimum. Subsequently, a forward pass calculates the power-optimal control inputs.

In addition to the conventional optimal power distribution, a working mode selection strategy is integrated into the dynamic programming framework to ensure proper system

operation and reduce the computational load of the DP process. The control logic of this strategy is consistent with that described in Section 2, where one of four operating modes is selected based on the required flow rate of the working system in the loading cycle.

4. SIMULATION STUDY

4.1. Simulation Parameters

The simulation study is conducted on Matlab and Amesim platforms. Matlab is used for control strategy and optimization method, while Amesim is applied for component model verification and simulation operation. The main parameters of the proposed EH-VSD system are designed according to the existing electric wheel loader working system with all components commercially available. The battery pack is a 456 Ah lithium iron phosphate type, whose open-circuit voltage and internal resistance vary with battery SOC. When the SOC decreases, the battery voltage drops while the internal resistance rises.

Table 3.1

Main parameters of proposed EH-VSD system

	Property	Value	Unit
Battery	Normal capacitance	456	Ah
	Normal voltage	618	V
	Normal Initial resistance	20	mΩ
Electric motor	Max. speed	3000	rpm
	Max. torque	450	Nm
Hydraulic pump	Geometric displacement	100	cc/rev
	Max. speed	3000	rpm
	Max. pressure	30	MPa
Hydraulic accumulator	Volume	25	L
	Max./Min. pressure	32/12	MPa
	Efficiency	85%	\
Proportional valve	Valve coefficient	0.7	\
	Natural frequency	80	Hz
Hydraulic pipeline	Length	3	m
	Diameter	20	mm
	Relative roughness	0.002	\
	Hydraulic fluid viscosity	46	mm^2/s
Hydraulic cylinder	Diameter of piston	150	mm
	Diameter of rod	90	mm
	Piston stroke	815	mm
	Viscous friction coefficient	2000	N/(m/s)

Permanent magnet synchronous motor (PMSM) is adopted, with maximum speed and torque limited to 3000 rpm and 450 Nm respectively. A unidirectional fixed-displacement pump of 100 cc/rev is employed with a maximum pressure of 30 MPa, and a 25 L high-pressure accumulator operates within pressure range of 12–32 MPa.

The electric motor–pump unit (VSD unit) used in this study adopts efficiency maps obtained from manufacturer data and test bench measurements. The operating efficiency depends on motor torque (related to pump pressure) and rotational speed. Therefore, optimizing the operating points of the VSD unit can effectively improve system energy efficiency.

4.2. Simulation Results and Performance Comparison

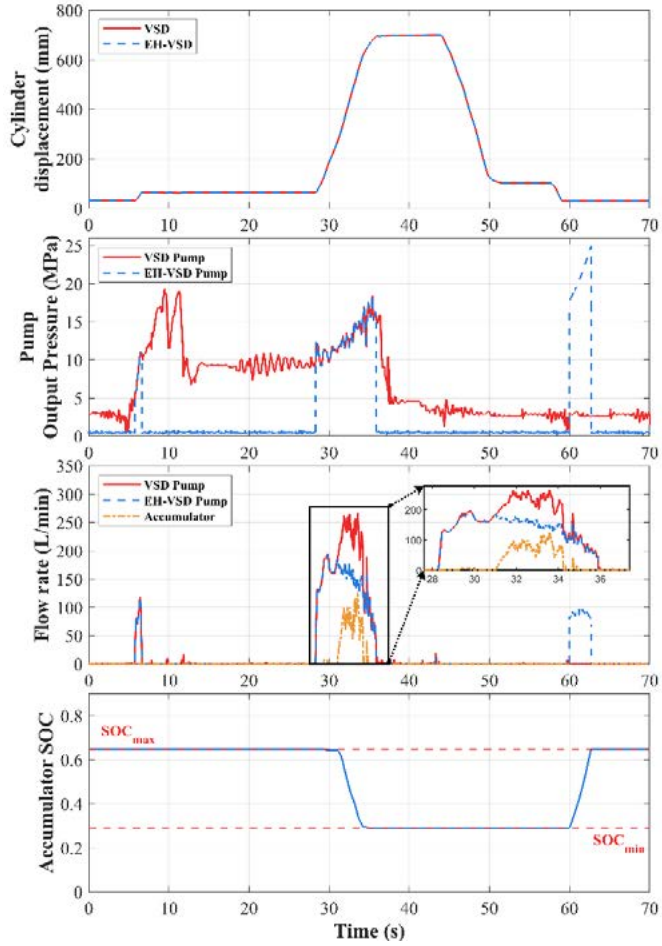

Fig. 4.1. Comparison of hydraulic components performance between systems

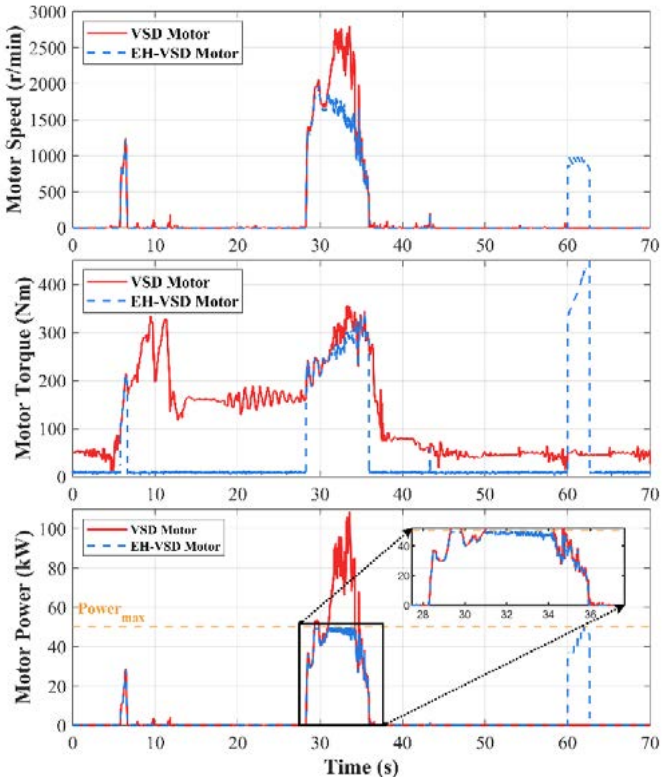
The performance of hydraulic components in both the baseline VSD system and the proposed EH-VSD system is shown in Fig. 4.1. In both cases, the hydraulic cylinders accurately follow the reference signal to complete the loading task. In VSD system, the pump outlet pressure remains nearly consistent with the load pressure. In the EH-VSD system, due to the check valve at the pump outlet, pressure is generated only when the pump works, and it closely matches the load pressure. After the loading cycle, the pump also charges the accumulator, during which outlet pressure follows the accumulator pressure.

The flow rate output highlights the differences between the two systems. In the VSD system, the hydraulic pump alone supplies the flow required for cylinder lifting. In contrast, the EH-

VSD system combines the outputs of the pump and accumulator, where the pump provides a nearly constant flow and the accumulator compensates for the remaining demand, thereby reducing the pump's power output. During cylinder lowering, the VSD and EH-VSD system adopt throttling, eliminating the need for pump operation. The accumulator SOC remains within its operating range, starting from a maximum of 0.65, decreasing to 0.3 after the hybrid lifting mode, and then being recharged by the VSD unit to its initial state in preparation for the next cycle.



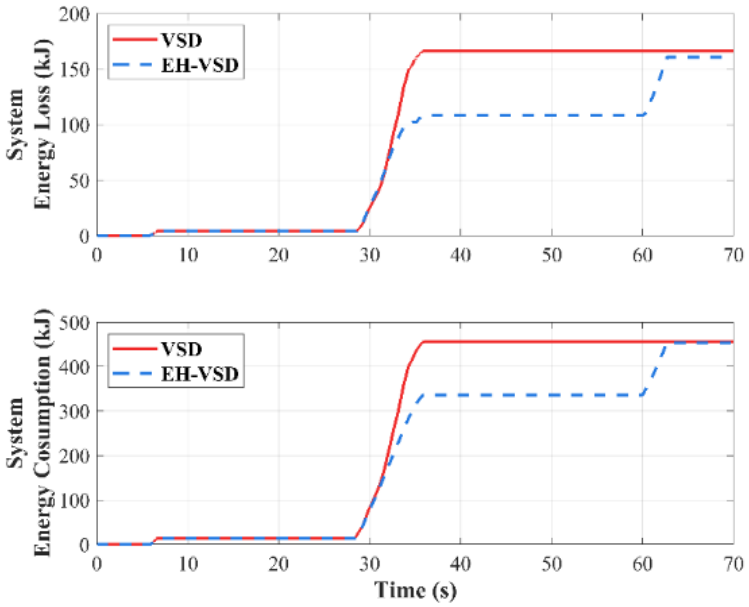


Fig. 4.2. Comparison of electric motor performance between systems

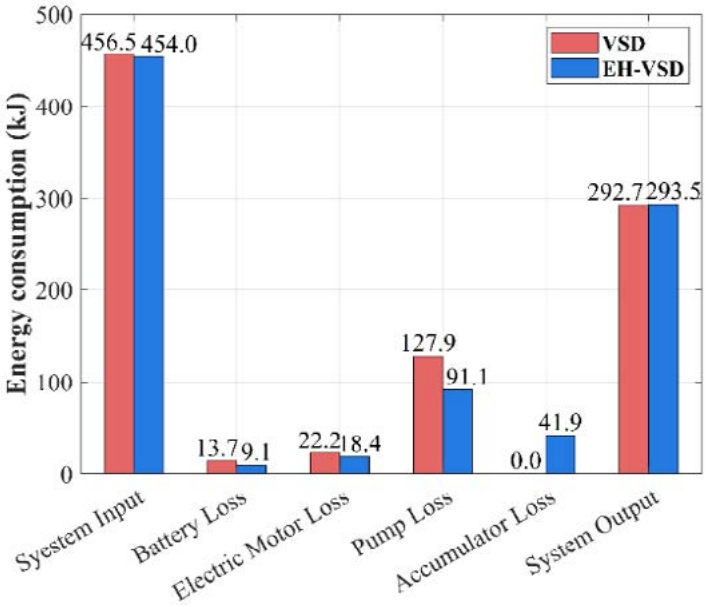

Fig. 4.2. compares the motor performance of the two systems. The motor speeds are nearly identical, except that the EH-VSD shows a lower speed during lifting since part of the flow is supplied by the accumulator. The motor torque follows a similar trend to the pump pressure, consistent with Eq. (7) and (9). The motor power of the EH-VSD system remains below the power limit of 50 kW in both lifting and charging modes, while the VSD system must supply the entire load independently, reaching a peak power of 110 kW. This represents a 54.5% reduction in installed power, confirming the feasibility of the proposed strategy in which the motor provides average power and the accumulator delivers peak power.

Fig. 4.3 compares the energy consumption of the EH-VSD and VSD systems to evaluate energy efficiency. Fig. 4.3 (a) shows system energy loss and consumption during one loading cycle. In the lifting mode, the EH-VSD system exhibits lower energy loss, attributed to the optimized power distribution strategy. During accumulator charging, EH-VSD incurs

additional loss from the VSD unit, bringing the total loss close to that of the VSD system. The final energy consumption of both systems is nearly identical, and VSD system is even higher.

(a) System energy loss and consumption

(b) Energy consumption of components

Fig. 4.3. The energy consumption comparison between VSD and EH-VSD system in one loading cycle

Fig. 4.3 (b) illustrates the component-level energy losses, including battery, motor, pump, accumulator, and other hydraulic elements (merged into pump loss). The VSD system requires higher input energy than the EH-VSD system. The EH-VSD system exhibits lower losses in the battery, motor, and pump, thereby improving overall efficiency. Although EH-VSD has accumulator charging/discharging and throttling loss, these have been minimized through optimization.

Table 4.1

Performance comparison between VSD and EH-VSD systems

	VSD	**EH-VSD**	**Comparison**
Installed Power	110 kW	50 kW	**-54.5%**
Energy Consumption	456.5 kJ	454.0 kJ	**-0.6%**
Energy Efficiency	64.1%	64.6%	**+0.5%**

As shown in Table 4.1, the performance of the two systems is compared for a single loading cycle. The proposed EH-VSD system reduces installed motor power by 54.5%, energy consumption by 0.6%, and improves energy efficiency by 0.5% compared with the VSD system, significantly enhancing overall operational performance. The EH-VSD system achieves a significant reduction in installed power while maintaining a high energy efficiency comparable to that of the VSD system, effectively avoiding substantial throttling losses.

5. CONCLUSIONS

In this paper, an electro-hydraulic hybrid variable speed drive system (EH-VSD) is proposed to downsize the electric motor of electric wheel loader working function. A high-pressure accumulator in parallel configuration assists the VSD unit under high load condition, to reduce system installed power. An energy management strategy based on the dynamic programming is developed to ensures the VSD unit operates within its high-efficiency region, improving the energy efficiency of the system. The comparison between proposed system and baseline system, and comparative simulation of different accumulator parameters are conducted in terms of system performance, installed power and energy efficiency.

Simulation results show that the installed power of EH-VSD system reduces by 54.5% compared to VSD system (from 100 kW to 50 kW). The EH-VSD system achieves a significant reduction in installed power while maintaining a high energy efficiency comparable to that of the VSD system, effectively avoiding substantial throttling losses.

The proposed EH-VSD system significantly reduces the installed power while maintaining energy efficiency. However, the complexity of system will increase due to the addition of components, heightened requirements for electro-hydraulic control precision, and the incorporation of additional control algorithms. Furthermore, this paper has only conducted simulation studies for a single cycle. Although the methodology can be applied to other

scenarios, further experimental validation across additional cycles is required to demonstrate the universality of system and control strategy.

Future work will focus on three aspects: 1) optimizing the system configuration to realize boom energy regeneration; 2) optimizing accumulator parameters to further improve energy efficiency; and 3) conducting experiments on a test bench or machine to evaluate the actual performance.

Biographies

Yihan Qiao received B.S. degree in mechanical engineering from Zhejiang University, Hangzhou, China, in 2022. He is currently pursuing his Ph.D. degree in mechanical

engineering at Zhejiang University, Hangzhou, China. His main research focuses on electro-hydraulic hybrid variable speed drive system for wheel loader.

Jiaming Wu received B.S. degree in mechanical engineering from Zhejiang University, Hangzhou, China, in 2019. He is currently pursuing his Ph.D. degree in mechanical engineering at Zhejiang University, Hangzhou, China. His main research focuses on modeling and control of electro-hydrostatic actuator system for off-road vehicles.

Feng Wang received B.S., M.S., and Ph.D. degrees in mechanical engineering from Zhejiang University, Hangzhou, China, in 2003, 2005, and 2009. In 2009 he became a Postdoctoral Associate in the Department of Mechanical Engineering at University of Minnesota, Minneapolis, MN, USA, where he joined the NSF Engineering Research Center for Compact and Efficient Fluid Power (CCEFP). In 2016 he became an Assistant Professor in the School of Mechanical Engineering at Zhejiang University, Hangzhou, China, where he joined the State Key Laboratory of Fluid Power and Mechatronics Systems. His research interests include modeling and control of intelligent hydraulic powertrains for heavy-duty vehicles and large utility wind turbines.

Bing Xu received Ph.D. degree in mechanical engineering from Zhejiang University, Hangzhou, China, in 2001. He is currently a Professor in the school of mechanical engineering and also the Director of the State Key Laboratory of Fluid Power Transmission and Control at Zhejiang University. He has authored or co-authored more than 200 journal and conference papers, and authorized 49 patents. His research interests include fluid power components and systems, mechatronic systems design and motion control for mobile machinery. Prof. Xu is a Chair Professor of the Yangtze River Scholars Program and a science and technology innovation leader of the Ten Thousand Talent Program.

Motion Control of Multi-DOF Hydraulic Manipulator Driven by Independent Metering System with Friction Compensation

Abstract.

Multi-degree-of-freedom hydraulic manipulators are widely used in heavy-duty machinery, due to the advantages of hydraulic transmission. While previous research focused on output force and power, recent developments have shifted toward control performance and energy efficiency. However, precise control remains challenging for hydraulic manipulators compared to electric manipulators, due to the complexities of hydraulic transmission and multi-body dynamics. Nonlinear model-based control strategies and independent metering techniques have shown promise in overcoming these challenges. This paper investigates the motion control of a multi-DOF hydraulic manipulator driven by an independent metering system. A hydraulic circuit based on independent metering is designed, and the system's dynamics are modeled. To address nonlinearities, uncertainties, and friction in the system, an adaptive robust control strategy is proposed. Friction, which plays a significant role in degrading control performance, is compensated using the LuGre model-based approach. The proposed method is evaluated through simulations and experiments on a 4-DOF hydraulic manipulator test rig. Quantitative analysis, including the Integral of Time-weighted Absolute Error (ITAE) and maximum tracking errors, verifies that the proposed strategy achieves improved tracking performance and energy efficiency compared to traditional control methods.

1. INTRODUCTION

Multiple degrees of freedom (multi-DOF) hydraulic manipulators are typically installed on heavy-duty machinery like excavators [1] and Autonomous Underwater Vehicles (AUVs) [2] due to the benefits offered by hydraulic transmission systems. Historically, the primary focus regarding hydraulic manipulators has been on high output force/power [3], with limited attention given to studying control performance. This is because most machines were traditionally operated by operators controlling the valve orifices directly, without the application of closed-loop control systems. Nowadays, the control performance has emerged as a primary concern for hydraulic manipulators, given that fully-autonomous or semi-autonomous off-road machinery represents a significant research focus in numerous countries within the framework of intelligent development [4].

Unlike electric manipulators utilized in industrial applications, which employ servo motors to control the joints and therefore achieve higher control performance relatively easily, multi-DOF hydraulic manipulators typically utilize cylinders to drive the rotary joints instead of hydraulic motors [4]. As a result, precise control of hydraulic manipulators is more challenging due to the complex nature of hydraulic transmission and the multi-body mechanism. The dynamics of multi-DOF hydraulic manipulator is highly nonlinear with various uncertainties [5]. To attain high precision, nonlinear model-based control methods such as adaptive control or robust control have been proven effective [6, 7]. These control strategies aim to compensate for the nonlinear dynamics as accurately as possible and incorporate robust feedback mechanisms to address uncertainties and disturbances. Notably, friction represents a key nonlinear property within the dynamics of hydraulic manipulators [8]. Friction exhibits a complex relationship with velocity, particularly at low speeds [9]. Due to the kinematics of the hydraulic manipulator, when the end-effector is moving continuously and relatively fast, some joints may experience frequent stop-and-go or low speed motions. Inadequate compensation for such behaviors can lead to significant peak errors in the joints and degrade overall control performance.

Typically, the friction force is represented as a combination of Coulomb and viscous terms [10]. This model is accurate when the velocity is relatively high and can be easily integrated into model compensation control. However, as the velocity decreases, the discrepancy between this model and the actual behavior can be increased, since the real friction force exhibits a pronounced Stribeck effect at low speeds [11, 12]. Thus, extra attention should be paid to make more effective compensation for the nonlinear friction in order to enhance the control performance of multi-DOF hydraulic manipulator. Among the existing models, LuGre friction model [13] has been demonstrated to be effective in various actuation systems such as linear motors [14], PMSM servo systems [15] and hydraulic cylinders [16]. However, few studies can be found about applying LuGre model in hydraulic manipulators. Considering the complex dynamics of hydraulic manipulator itself, designing a model-based controller is still challenging.

In addition to control precision, energy efficiency is also important for hydraulic manipulators [4]. In most hydraulic manipulators, each hydraulic cylinder is controlled by a single proportional or servo valve. The hydraulic circuit is quite straightforward, and such four-way valve ensures the stability of the internal dynamics within the hydraulic system [10]. However, the inlet and outlets orifices of the actuator is coupled strongly by the mechanical linkage of the valve spool. This linkage restricts the control to a single control input for a given actuator, which makes it unfeasible for energy saving. In the field of electro-hydraulics, independent metering technique has been a solution for addressing energy efficiency concerns [17]. With in independent metering systems, each actuator is

controlled by two independent valves at least, which enables independent metering of the inlet and outlet orifices. This additional control input facilitates simultaneous energy savings through strategic control design. Although in many researches direct pump control becomes a good choice when energy saving is a major concern [18], the control performance of independent metering system can be much better since the actuator is still controlled by the high-response proportional or servo valves [19]. Implementing independent metering systems in hydraulic manipulators could offer both superior control performance and improved energy efficiency. However, the corresponding control flexibility should be handled properly by the controller [20].

To achieve high precise motion tracking performance while improve the energy efficiency, motion control of the hydraulic manipulator driven by an independent metering system is studied. The hydraulic circuit is designed based on the independent metering technique and the dynamics of the system is modelled. Then, the desired load force ensuring the tracking performance is synthesized based on the adaptive robust control theory [10], additionally considering nonlinear friction compensation. To address the flexibility of the independent metering configuration, a mode selection method is proposed to determine the control objective for each cylinder chamber. Motion and pressure controllers are then designed for both chambers. Finally, the control performance is evaluated theoretically and validated through comparative simulations and experiments.

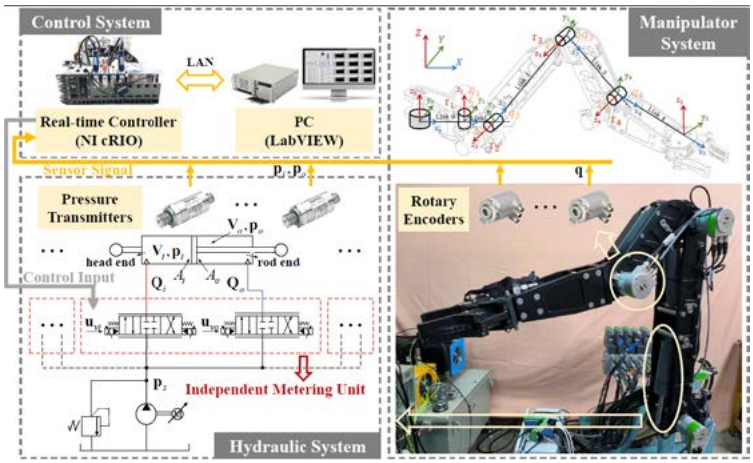

Figure 1: The common mechanism of multi-DOF hydraulic manipulator

2. HARDWARE CONFIGURATION AND PROBLEM FORMULATION

2.1. Hardware Configuration

A hydraulic manipulator with cylinders driving the joints is given in Fig. 1, illustrating the common mechanism of multi-DOF hydraulic manipulator. The corresponding coordinates are defined following the typical processes. Usually, each cylinder is controlled by a single four-way proportional or servo valve [4]. Instead, in this study, the independent metering technique is implemented in the hardware configuration. For example, for the n-th cylinder, two proportional four way valves, namely V_{in} and V_{on} are used coordinately to control the inlet and outlet flows, denoted as Q_{in} and Q_{on}, respectively. These two valves

collectively form an independent metering unit as shown in Fig. 1. It is important to mention that in independent metering systems, controlling the pump to match the flow required by the actuator is also crucial for energy savings. However, in this study, our primary focus will be on the control of independent metering valves.

2.2. Modeling of Hydraulic Manipulator

The model of the hydraulic manipulator is constructed as

$$\begin{aligned} &M(q)\ddot{q} + C(q,\dot{q})\dot{q} + G(q) = \tau + D_F \\ &\tau = J_h(q)F_L - T_f, F_L = A_i P_i - A_o P_o \end{aligned} \tag{1}$$

where $q \in \mathbb{R}^n$ is the joint angle. $M(q) \in \mathbb{R}^{n\times n}$, $C(q,\dot{q}) \in \mathbb{R}^{n\times n}$, and $G(q) \in \mathbb{R}^n$ denote the inertia matrix, the centripetal and Coriolis matrix, and the gravity terms, respectively. $D_F \in \mathbb{R}^n$ is the lumped modeling error including external disturbances and other hard-to-model terms, such as the non-uniform mass distribution across each link of the hydraulic manipulator. $J_h(q) \in \mathbb{R}^{n\times n}$ represents the nonsingular joint Jacobian matrix and $T_f \in \mathbb{R}^n$ means the friction torque. $F_L \in \mathbb{R}^n$ denotes the load force, with $A_i \in \mathbb{R}^{n\times n}$ and $A_o \in \mathbb{R}^{n\times n}$ being the head and rod-end ram areas of each cylinder. $P_i \in \mathbb{R}^n$ and $P_o \in \mathbb{R}^n$ represent the pressure of the two chambers, whose dynamics can be further expressed as

$$\begin{aligned} &V_i(x_L)\beta_{ei}^{-1}\dot{P}_i = -A_i\dot{x}_L + Q_i + D_{Qi} \\ &V_o(x_L)\beta_{eo}^{-1}\dot{P}_o = A_o\dot{x}_L - Q_o - D_{Qo} \end{aligned} \tag{2}$$

where $\dot{x}_L = J_h\dot{q}$, with x_L being the cylinder displacement. $\beta_{ei} \in \mathbb{R}$ and $\beta_{eo} \in \mathbb{R}$ denote the effective bulk modulus of the two chambers. $V_i(x_L) \in \mathbb{R}^{n\times n}$ and $V_o(x_L) \in \mathbb{R}^{n\times n}$ are the total compressible volumes of the head and rod end, respectively. $D_{Qi} \in \mathbb{R}^n$ and $D_{Qo} \in \mathbb{R}^n$ denote the lumped modeling errors, which include leakages in the hydraulic circuit and other minor nonlinear characteristics. Owing to the independent metering unit, Q_i and Q_o are two independent control inputs. In practice, Q_i and Q_o need to be reasonably distributed to obtain control signals for each valve core. Note that the dynamic response of the valve is much higher than other parts of the system, so only the static mapping of Q_i and Q_o to the valve control signal is considered. Therefore, this step will be omitted in the modeling process in this paper, and the general problem of controlling the motion of hydraulic manipulator with Q_i and Q_o will be studied.

The friction torque T_f is given by

$$T_f = Z\sigma_s + \dot{Z}\bar{\sigma}_m(\dot{q}) + \breve{\dot{q}}f_v, \dot{Z} = \dot{q} - \left|\dot{q}\right| g^{-1}(\dot{q})Z \tag{3}$$

where $Z \in \mathbb{R}^{n\times n}$ means the internal friction state and $\breve{\dot{q}} = diag(\dot{q})$. $\sigma_s \in \mathbb{R}^n$, $\bar{\sigma}_m(\dot{q}) = h_m(\dot{q})\sigma_m \in \mathbb{R}^n$, and $f_v \in \mathbb{R}^n$ are the stiffness, a velocity dependent damping coefficient, and the viscous friction coefficient, respectively. $g(\dot{q}) \in \mathbb{R}^{n\times n}$ is a positive diagonal matrix describing the Stribeck effect, in which

$$g_i(\dot{q}_i) = \alpha_{ci} + (\alpha_{si} - \alpha_{ci})e^{-(\dot{q}_i/\dot{q}_{si})^2} \tag{4}$$

with $\sigma_{si}\alpha_{si}$ and $\sigma_{si}\alpha_{ci}$ corresponding to the static friction and the Coulomb friction, respectively. $\dot{q}_{si}$ is the Stribeck velocity.

In addition, though the lumped modeling error $D_\bullet$ in (1) and (2) is unknown and time-varying, it can be split into the nominal value $D_{\bullet n}$ with slow variation and the bounded deviation value $\Delta D_\bullet$, i.e., $D_\bullet$ can be further denoted by

$$\begin{aligned} D_F &= D_{Fn} + \Delta D_F \\ D_{Qi} &= D_{Qin} + \Delta D_{Qi} \\ D_{Qo} &= D_{Qon} + \Delta D_{Qo} \end{aligned} \tag{5}$$

Property 1. The inertia matrix $M(q)$ is a positive definite symmetric matrix, and satisfies

$$\underline{\lambda}_M I_n \le M(q) \le \overline{\lambda}_M I_n \tag{6}$$

with $\underline{\lambda}_\bullet$ and $\overline{\lambda}_\bullet$ being the minimum and maximum eigenvalues of $\bullet$, respectively.

Property 1. The matrix $N(q,\dot{q}) = \dot{M}(q) - 2C(q,\dot{q})$ is skew-symmetric and

$$\dot{M}(q) = C(q,\dot{q}) + C^T(q,\dot{q}) \tag{7}$$

2.3. Dynamics parameterizing

For the convenience of subsequent controller derivation, the model in Section 2.1 can be parameterized as

$$\begin{aligned} M\ddot{q} + C\dot{q} &= J_h F_L - G - T_f(Z, \vartheta_{s1}) + \theta_4 + \Delta D_F \\ V_i(x_L)\theta_5 \dot{P}_i &= -A_i \dot{x}_L + Q_i + \theta_6 + \Delta D_{Qi} \\ V_o(x_L)\theta_7 \dot{P}_o &= A_o \dot{x}_L - Q_o - \theta_8 - \Delta D_{Qo} \end{aligned} \tag{8}$$

where $\vartheta_{s1} \triangleq [\theta_1^T, \theta_2^T, \theta_3^T, \theta_4^T]^T$, $\vartheta_{s2} \triangleq [\theta_5^T, \theta_6^T]^T$, and $\vartheta_{s3} \triangleq [\theta_7^T, \theta_8^T]^T$, in which θ_j means the parameter set of the j^{th} dynamics parameter at each joint, that is

$$\begin{aligned} \theta_j &= [\pi_1(j), \cdots, \pi_i(j), \cdots, \pi_n(j)]^T \\ \pi_i &= [\sigma_{si}, \sigma_{mi}, f_{vi}, D_{Fni}, , \beta_{ei}^{-1}, D_{Qini}, \beta_{eo}^{-1}, D_{Qoni}]^T \end{aligned} \tag{9}$$

with $\pi_i(j)$ being the j^{th} element of π_i. $T_f(\dot{q}, \vartheta_{s1}) = \phi_f^T \vartheta_{s1}$, and $\phi_f^T = \left[Z, \dot{Z}\, h_m, \breve{\dot{q}}, 0_{n\times 1} \right]$ is a linear regression matrix.

Assumption 1. The bounds of parametric uncertainties and uncertain nonlinearities are known, i.e.,

$$\vartheta_{si} \in \Omega_{\vartheta_{si}} \triangleq \{\vartheta_{si} : \vartheta_{si\min} \le \vartheta_{si} \le \vartheta_{si\max}\}$$
$$|\Delta D_F| \le \delta_F, |\Delta D_{Qi}| \le \delta_{Qi}, |\Delta D_{Qo}| \le \delta_{Qo} \tag{10}$$

where $\vartheta_{si\min}$, $\vartheta_{si\max}$, δ_F, δ_{Qi}, and δ_{Qo} are known scalars.

2.4. Control Objectives

Since independent metering technique is used for hydraulic manipulator, the controller should achieve high tracking performance while effectively managing the additional flexibility to enhance energy efficiency. The dual design objectives can be specifically described as:

1) High precision motion control: given a set of desired trajectories $q_d(t)$, the primary objective is to synthesize the valve spool voltage u_v, so that each joint angle $q(t)$ can track $q_d(t)$ as closely as possible, especially under low-speed conditions.

2) Low energy consumption: utilize the dual independent control valves for each actuator to maintain chamber pressures at low levels to conserve energy.

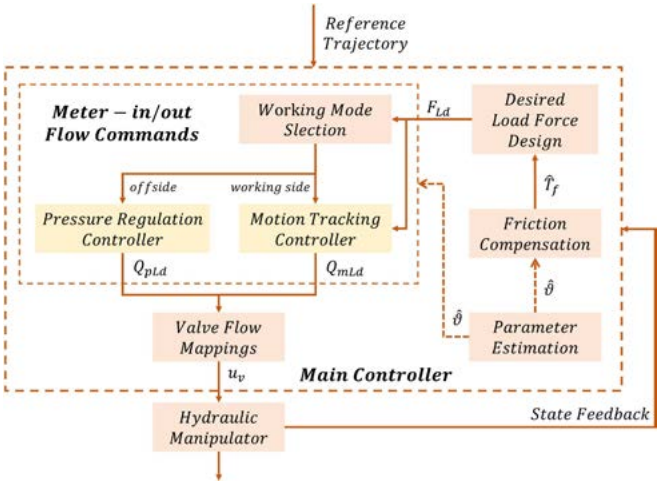

Figure 2: The overall control framework.

3. CONTROLLER DESIGN

In order to achieve the dual control objectives, the working mode selection is applied following the standard procedures proposed in [21]. In the selected working mode, the offside (to keep the chamber at a low pressure) and working side(motion tracking) independently control the pressure of the two chambers based on adaptive robust control theory [10]. The specific control framework is shown in Fig. 2.

The following notations are used throughout this paper: $\hat{\bullet}$ denotes the estimate of $\bullet$ and $\tilde{\bullet} = \hat{\bullet} - \bullet$ denotes the parameter estimation error.

3.1. Desired Load Force Design

This subsection aims to achieve motion tracking of the hydraulic manipulator and calculate the desired load force of the hydraulic cylinder F_{Ld} so that the angle tracking error $e_1 = q - q_d$ can be kept as small as possible.

Define a switching-function-like quantity

$$e_2 = \dot{e}_1 + K_1 e_1 = \dot{q} - \dot{q}_{eq}, \dot{q}_{eq} \square \dot{q}_d - K_1 e_1 \tag{11}$$

with K_1 being a positive gain matrix. As long as the $e_2 \to 0$, the tracking error e_1 will be very small or converge to zero.

Differentiating (11) and noting (8), it has

$$\begin{aligned} M\dot{e}_2 + Ce_2 = J_h F_{Ld} + J_h e_3 - G - T_f(Z, \vartheta_{s1}) \\ +\theta_4 + \Delta D_F - (M\ddot{q}_{eq} + C\dot{q}_{eq}) \end{aligned} \tag{12}$$

with $e_3 = F_L - F_{Ld}$.

Considering that Z is unmeasurable, a dual observer based on mapping functions is designed as

$$\begin{aligned} \dot{\hat{z}}_1 &= \mathrm{Proj}_{\hat{z}_1}\left\{ x_2 - \frac{|x_2|}{g(x_2)}\hat{z}_1 - \gamma_1 e_2 \right\} \\ \dot{\hat{z}}_2 &= \mathrm{Proj}_{\hat{z}_2}\left\{ x_2 - \frac{|x_2|}{g(x_2)}\hat{z}_2 + \gamma_2 \frac{h(x_2)|x_2|}{g(x_2)} e_2 \right\} \end{aligned} \tag{13}$$

The virtual control force F_{Ld} can be designed as

$$\begin{aligned} F_{Ld} &= F_{Lda} + F_{Lds} \\ F_{Lda} &= F_{Lda1} + F_{Lda2},\ F_{Lds} = F_{Lds1} + F_{Ldas2} \\ \cdot F_{Lda1} &= J_h^{-1}\left(M\ddot{q}_{eq} + C\dot{q}_{eq} + G + \hat{T}_f(\square \hat{Z}, \hat{\vartheta}_{s1}) - \hat{\theta}_4 \right)\cdot \\ F_{Lds1} &= -J_h^{-1} K_{2s1} e_2, F_{Lds2} = -J_h^{-1} K_{2s2} e_2 \end{aligned} \tag{14}$$

in which K_{2s1} is a sufficiently large nonlinear gain matrix.

Consolidate the model compensation errors resulting from uncertain nonlinearities and physical parameter estimation discrepancies, and then separate them into a static component d_1 and a high-frequency component $\square d_1^*(t)$

$$d_1 + \square d_1^*(t) \square \Delta D_F - \phi_F^T \tilde{\vartheta}_{s1} \tag{15}$$

Then, design fast dynamics compensation F_{Lda2} as

$$F_{Lda2} = -J_h^{-1}\hat{d}_1, \dot{\hat{d}}_1 = \mathrm{Proj}_{\hat{d}}(\gamma_F e_2) \tag{16}$$

in which γ_F is a positive constant matrix, and $\mathrm{Proj}_{\hat{d}}(\bullet)$ is a projection mapping.

K_{2s2} is a nonlinear robust feedback gain chosen large enough such that F_{Lds2} satisfies the following robust performance conditions:

$$
\begin{aligned}
&(i)\ \ e_2^T J_h F_{Lds2} \le 0 \\
&(ii)\ e_2^T (J_h F_{Lds2} - \tilde{d}_1 + \tilde{d}_1^* \\
&\quad + \theta_1 \bar{Z}_1 - \theta_2 h_m \left|\dot{q}\right| g^{-1} \bar{Z}_2) \le \eta_1
\end{aligned} \tag{17}
$$

with $\eta_1 > 0$ being an arbitrarily small parameter.

Using (14) and (16), the resulting error dynamics of e_2 can be written as

$$
\begin{aligned}
M\dot{e}_2 + Ce_2 = &-K_{2s1}e_2 + \theta_1 \bar{Z}_1 - \theta_2 h_m \left|\dot{q}\right| g^{-1} \bar{Z}_2 \\
&+ J_h e_3 + \left(J_h F_{Lds2} - \tilde{d}_1 + \bar{d}_1^*\right)
\end{aligned} \tag{18}
$$

3.2. Pressure Regulation Controller

Hydraulic cylinders need to generate the desired load force mentioned above to achieve motion control goals, but the independent form of the load port allows for independent control of the pressure in both chambers, resulting in countless combinations of chamber pressures. According to the direction of the load force, when a forward load force is required, the pressure in the rod end chamber is controlled at a small value, while when a reverse load force is required, the pressure in the head chamber is controlled at a small value p_c, which can effectively achieve the goal of maintaining low pressure [21]. This subsection takes the rod end chamber as the offside as an example to design a pressure regulation controller. The pressure design for the head chamber follows the same procedure and is omitted here.

Define the tracking error of pressure as $e_{3p} = P_o - p_c$. The error dynamics would be the same as the pressure dynamics because p_c is constant

$$
\theta_7 \dot{e}_{3p} = V_o^{-1} \left(A_o \dot{x}_L - Q_o - \theta_8 - \Delta D_{Qo}\right) \tag{19}
$$

with Q_o being the control input, the proposed control law is given by

$$
\begin{aligned}
Q_{oLd} &= Q_{oLda} + Q_{oLds} \\
Q_{oLda} &= Q_{oLda1} + Q_{oLda2} \\
Q_{oLds} &= Q_{oLds1} + Q_{oLdas2} \\
Q_{oLda1} &= A_o \dot{x}_L - \hat{\theta}_8, \ \ Q_{oLda2} = V_o \hat{d}_p \\
Q_{oLds1} &= K_{os1} V_o e_{3p}, \ \ Q_{oLds2} = K_{os2} V_o e_{3p}
\end{aligned} \tag{20}
$$

where Q_{oLda1} is the model compensation term and $\hat{d}_p$ is a fast dynamics compensation with $d_p + \bar{d}_p^*(t) \in V_o^{-1}\left(\tilde{\theta}_8 - \Delta D_{Qo}\right)$ and $\dot{\hat{d}}_p = \mathrm{Proj}_{\hat{d}}(\gamma_{Qo} e_{3p})$. $K_{os1} > 0$ and K_{os2} is a nonlinear feedback gain chosen to satisfy the following condition for performance robustness to model uncertainties:

$$
\begin{aligned}
&(i)\ \ -e_{3p}^T V_o^{-1} Q_{oLds2} \le 0 \\
&(ii)\ e_{3p}^T \left(-V_o^{-1} Q_{oLds2} - \tilde{d}_p + \bar{d}_p^*\right) \le \eta_p
\end{aligned} \tag{21}
$$

with $\eta_p > 0$ being an arbitrarily small parameter.

Substituting control law (20) into (19), the error dynamics can be written as

$$\theta_7 \dot{e}_{3p} = -K_{os1} e_{3p} + \left(\bar{d}_p^* - \tilde{d}_p - V_o^{-1} Q_{oLds2} \right) \tag{22}$$

3.3. Motion Tracking Controller

The pressure regulation controller has already calculated the control flow Q_{oLd}. Furthermore, it is necessary to calculate the control flow rate based on the desired load force to achieve accurate motion tracking in the closed-loop system.

The error between the real load force and the desired load force is $e_{3m} = F_L - F_{Ld}$, whose derivative is

$$\begin{aligned} \theta_5 \dot{e}_{3m} &= \theta_5 \dot{F}_L - \theta_5 \dot{F}_{Ld} \\ &= -(V_i^{-1} A_i^2 + V_o^{-1} A_o^2) \dot{x}_L + V_i^{-1} A_i Q_i + V_o^{-1} A_o Q_o \\ &\quad + V_i^{-1} A_i \theta_6 + V_o^{-1} A_o \theta_8 + A_i \Delta D_{Qi} - A_o \Delta D_{Qo} - \dot{F}_{Ld} \end{aligned} \tag{23}$$

where $\dot{F}_{Ld}$ can be further expressed as the incalculable part $\dot{F}_{Ldi}$ and calculable part $\dot{F}_{Ldc}$.

Similar to Q_{oLd}, Q_{iLd} in (23) can be generated as

$$\begin{aligned} &Q_{iLd} = Q_{iLda} + Q_{iLds} \\ &Q_{iLda} = Q_{iLda1} + Q_{iLda2} \\ &Q_{iLds} = Q_{iLds1} + Q_{iLdas2} \\ &Q_{iLda1} = V_i A_i^{-1} [(V_i^{-1} A_i^2 + V_o^{-1} A_o^2) \dot{x}_{\mathrm{L}} - V_o^{-1} A_o Q_o \\ &-V_i^{-1} A_i \hat{\theta}_6 - V_o^{-1} A_o \hat{\theta}_8 + \dot{F}_{\mathrm{Ldc}} + \mathrm{Y}_{Qm}] \\ &Q_{iLda2} = -V_i A_i^{-1} \hat{d}_m \\ &Q_{iLds1} = -k_{\mathrm{is1}} V_i A_i^{-1} e_{3m},\ Q_{iLds2} = -k_{\mathrm{is2}} V_i A_i^{-1} e_{3m} \end{aligned} \tag{24}$$

with k_{is1} being a gain matrix and $\mathrm{Y}_{Qm} = -\omega_1 \omega_2^{-1} J_h e_2$. $\hat{d}_m$ is a fast dynamics compensation with $\dot{\hat{d}}_m = \mathrm{Proj}_{\hat{d}}(\gamma_{Qi} e_{3m})$. k_{is2} is a nonlinear robust feedback gain chosen large enough such that Q_{Lds2} satisfies the following robust performance conditions:

$$\begin{aligned} &(i)\ \ e_{3m}^T Q_{iLds2} \le 0 \\ &(ii)\ e_{3m}^T \left(V_o^{-1} A_o Q_{iLds2} - \tilde{d}_2 + \bar{d}_2^* \right) \le \eta_m \end{aligned} \tag{25}$$

with $\eta_m > 0$ being an arbitrarily small parameter.

Substituting control law (24) into (23), the error dynamics can be written as

$$\dot{e}_{3m} = -k_{\mathrm{is1}} z_3 + \left(V_o^{-1} A_o Q_{Lds2} - \tilde{d}_2 + \bar{d}_2^* \right) + \mathrm{Y}_{Qm} \tag{26}$$

3.4. Parameter Estimation

The parameter estimation law is given as

$$\dot{\hat{\vartheta}}_{si} = \mathrm{sat}_{\hat{\vartheta}}(\mathrm{Proj}_{\hat{\vartheta}}(\Gamma_i \tau_i)) \tag{27}$$

The projection function $\mathrm{Proj}_{\hat{\vartheta}}(\bullet)$ is defined as

$$\mathrm{Proj}_{\hat{\vartheta}}(\bullet)=\begin{cases}\bullet, & \hat{\vartheta}\in\Omega_{\vartheta}\ \text{or}\ n_{\hat{\vartheta}}^{T}\bullet\le 0\\ \left(I-\Gamma\dfrac{n_{\hat{\vartheta}}n_{\hat{\vartheta}}^{T}}{n_{\hat{\vartheta}}^{T}\Gamma n_{\hat{\vartheta}}}\right)\bullet, & \hat{\vartheta}\in\partial\Omega_{\vartheta}\ \text{and}\ n_{\hat{\vartheta}}^{T}\bullet\ge 0\end{cases} \tag{28}$$

where Ω_{ϑ}, $\partial\Omega_{\vartheta}$, and $n_{\hat{\vartheta}}$ are the interior and the boundary of Ω_{ϑ} and the outward unit normal vector at $\hat{\vartheta}\in\partial\Omega_{\vartheta}$.

Define regressors as

$$\begin{aligned}\phi_1^T &= \left[-Z_d, -\dot{Z}_d\ h_m, -\dot{q}, I_{n\times 1}\right]\\ \phi_2^T &= [-\dot{P}_i, V_i^{-1}]^T\\ \phi_3^T &= [-\dot{P}_o, -V_o^{-1}]^T\\ u_1 &= J_h F_L - M\ddot{q} - C\dot{q} - G\\ u_2 &= V_i^{-1}(-A_i\dot{x}_L + Q_i)\\ u_3 &= V_o^{-1}(A_o\dot{x}_L - Q_o)\end{aligned} \tag{29}$$

A stable filter $H_f(s)$ with a relative degree no less than one is used to handle the sensor noise. Noting (29) we can get

$$u_{if} = -\phi_{if}^T\vartheta_{is} \tag{30}$$

Define the prediction out and prediction error as

$$\begin{aligned}\hat{u}_{if} &= \phi_{if}^T\hat{\vartheta}_{is}\\ \dot{\varsigma}_i &= \hat{u}_{if} - u_{if} = \phi_{if}^T\tilde{\vartheta}_{is}\end{aligned} \tag{31}$$

$\Gamma_i(t)$ is updated by

$$\dot{\Gamma}_i=\begin{cases}\alpha\Gamma_i-\Gamma_i\phi_{if}\phi_{if}^T\Gamma_i, & \text{if } \lambda_{\max}(\Gamma_i(t))\le\rho_M\\ 0, & \text{else}\end{cases} \tag{32}$$

in which ρ_M is the upper bound of $\Gamma_i(t)$, α is the forgetting factor, and $\nu\ge 0$. The adaptation function $\tau_i=\phi_{if}\dot{\varsigma}_i$.

Theorem 1. All signals in the system controller are bounded. Furthermore, the positive-definite function V_s defined by

$$V_s=\frac{1}{2}e_1^Tw_1K_1^2e_1+\frac{1}{2}e_2^Tw_1Me_2+\frac{1}{2}e_{3m}^T\theta_5e_{3m}+\frac{1}{2}e_{3p}^Tw_2\theta_7e_{3p} \tag{33}$$

is bounded above by

$$V_s(t)\le\exp(-\lambda_s t)V_s(0)+\frac{\eta_s}{\lambda_s}\left[1-\exp\left(-\lambda_s t\right)\right] \tag{34}$$

with $\lambda_s=\min\left\{\underline{\lambda}_{K_1}, 2\underline{\lambda}_{K_{2s1}}/\overline{\lambda}_M, 2\underline{\lambda}_{K_{is1}}/\theta_{5max}, 2\underline{\lambda}_{K_{os1}}/\theta_{7max}\right\}$ and $\eta_s=w_1\eta_1+w_2\eta_m+\eta_p$. In addition, if there is only parameter uncertainties in the system after a finite time, the

closed-loop system can achieve asymptotic tracking performance, i.e., the tracking errors $e_1 \to 0 \quad \text{as} \, t \to \infty$.

4. SIMULATIONS AND EXPERIMENTS

To verify the feasibility and effectiveness of the proposed control strategy, both simulations and experiments were conducted. The simulations were designed to evaluate the controller performance under controlled and reproducible conditions, while the experiments further validated its applicability in real hardware environments.

4.1. Simulations

In the simulation, the multi-DOF coupling effect, sensor measurement noise, and the dynamic process of the valve simulated by a second-order system are all considered, to make it more practical. The noises of the angle encoder is set as $1\times10^{-4} rad$, which is consistent with reality.

Two controllers were compared to highlight the advantages of the proposed method as follows:.

C1: the proposed controller with the LuGre model compensation, enabling better handling of nonlinear friction, particularly at low velocities. The control law can be represented by (14), (20), (24).

C2: the proposed controller with the Coulomb and viscous friction model, which is widely used [22]. The only difference from C1 is that the friction compensation term is composed of $\hat{T}_f = S_a(\dot{q})\hat{\theta}_3 + \dot{q}\,\hat{\theta}_4$.

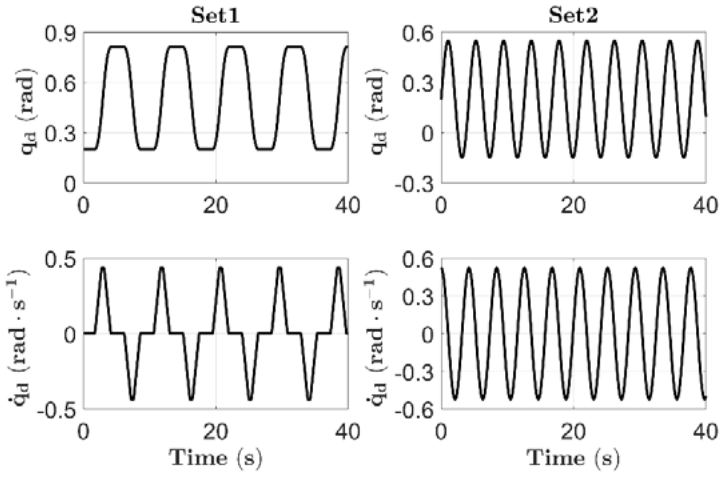

Figure 3: The reference trajectories.

Two sets of experiments, as show in Fig.3, were set up as follows:

Set1: Slow point-to-point(P2P) tracking experiment. The desired trajectory was from 0.2rad to 0.81rad, with the maximum angular velocity 0.43rad/s, which includes various motion states such as starting, accelerating, constant speed, and decelerating.

Set2: Slow SINE curve tracking experiment. The desired trajectory was set as $q_d(t) = 20\sin(1.5t)\,\text{rad}$.

In the simulation, all joints are controlled by the proposed method to track the reference trajectory simultaneously. For clarity, the analysis here focuses solely on the swing joint. To rigorously evaluate the tracking accuracy, quantitative metrics including the maximum tracking error e_{max} and the Integral of Time-weighted Absolute Error (ITAE) were introduced. The ITAE index is particularly significant as it penalizes long-duration errors, thereby reflecting the steady-state accuracy and convergence speed.

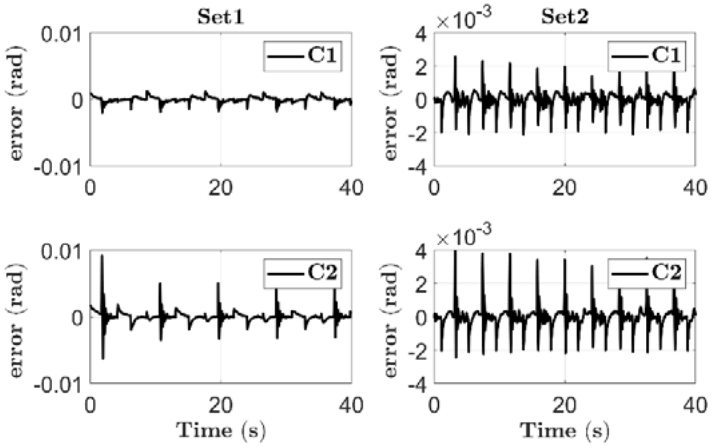

Figure 4: The tracking errors of C1 and C2.

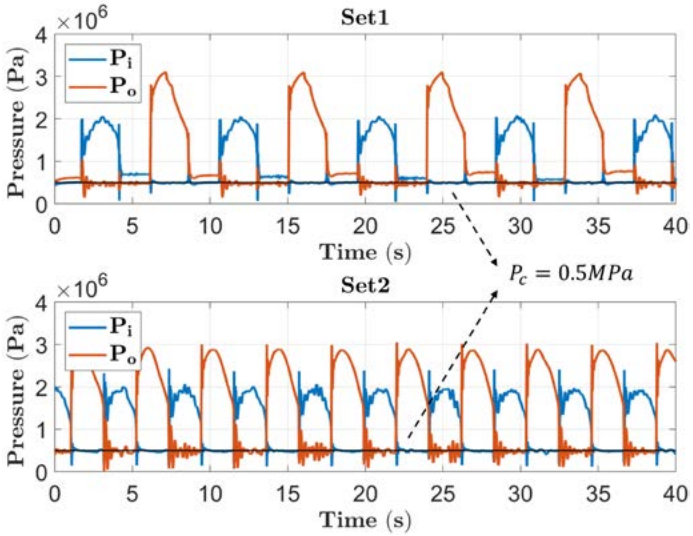

Figure 5: The pressure regulation results of C1.

The experiment results are shown in Fig. 4, and Table 1 is a summary of the comparison results. In the Point-to-Point motion (Set1), which involves frequent acceleration and deceleration phases, the proposed adaptive robust controller (C1) demonstrated remarkable performance. Specifically, C1 reduced the maximum tracking error e_{max} by 77.73% (from 0.0092 rad to 0.0020 rad) compared to the traditional controller (C2). This substantial reduction indicates that the proposed LuGre model-based friction compensation effectively

suppresses the error spikes caused by the Stribeck effect during zero-speed crossings. Furthermore, the ITAE index was reduced by 27.44%, confirming improved global tracking capability. Similarly, in the continuous Sine wave tracking (Set2), C1 consistently outperformed C2, achieving a 41.94% reduction in peak error and a 13.87% reduction in ITAE. These quantitative improvements validate that the proposed strategy not only handles nonlinear friction more effectively but also achieves higher precision across different motion trajectories. In addition, the pressure regulation results of C1 are show in Fig. 5, where the pressures of both chambers are regulated at a low level, which means the energy efficiency can be further improved by the independent metering technique.

Table 1: Quantitative comparison of tracking performance metrics.

Motion Set	Metric	C1	C2	Improvement
Set 1 (P2P)	e_{max} (rad)	0.0020	0.0092	77.73%
	ITAE ($rad \cdot s$)	0.2313	0.3188	27.44%
Set 2 (Sine)	e_{max} (rad)	0.0025	0.0044	41.94%
	ITAE ($rad \cdot s$)	0.2537	0.2946	13.87%

4.2. Experiments

The experimental validation was conducted on a customized 4-DOF hydraulic manipulator test rig (as shown in Fig. 1). The system is powered by a variable displacement pump station with a supply pressure of 10 MPa. The joint angles are measured by high-resolution rotary encoders, and the cylinder pressures are monitored by pressure sensors installed at both chambers to provide feedback for the pressure regulation loop. Real-time control algorithms are implemented on a NI cRIO system with the control frequency being 300 Hz. Compared with the simulation, additional real-world effects such as valve hysteresis, signal noise, and load fluctuations were present. The experimental results, as shown in Fig. 6, confirm that the proposed method effectively improves trajectory tracking accuracy, validating its potential for practical implementation in hydraulic manipulators.

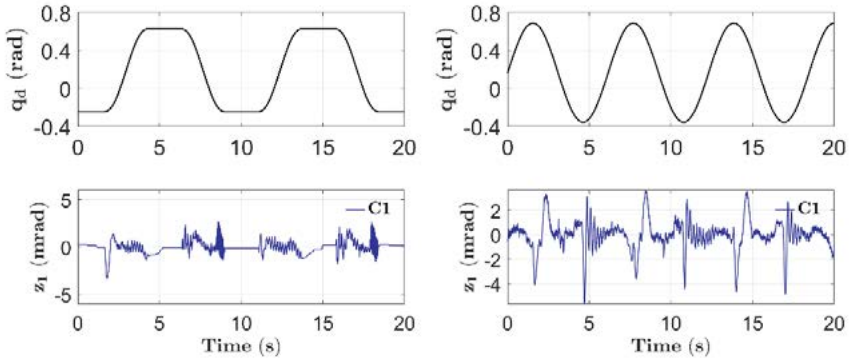

Figure 6: The experiment results of C1.

5. CONCLUSION

This paper presented a motion control strategy for a multi-DOF hydraulic manipulator driven by an independent metering system. An adaptive robust controller with LuGre

friction compensation was developed to handle system nonlinearities and uncertainties while improving energy efficiency. Both simulation and experimental results verified that the proposed method achieves high tracking accuracy and maintains low chamber pressures, demonstrating its potential for efficient and precise hydraulic manipulation.

Abstract

Servo-valve controlled hydraulic cylinders are widely used in various industrial applications. These systems show highly nonlinear dynamic behavior which poses significant challenges for control system design. This paper develops two novel adaptive control frameworks for cylinder position and load pressure control to enhance the robustness and stability of these systems. The frameworks are specifically designed to address common issues such as parametric uncertainties, unexpected external disturbances and component wear. Key contributions are the development of a single, adaptive control design for the entire operation range as well as the introduction of an algorithm for seamless transition between adaptive position and load pressure control which improves the frameworks' overall performance and practicality. The proposed control frameworks are validated and tested through both numerical simulations and experiments conducted on a 4-roll plate bending machine. Finally, an experimental comparison between the proposed adaptive controllers and conventional linear and nonlinear controllers is presented. The results demonstrate an improvement in accuracy for both position and load pressure control.

Keywords: industrial hydraulics, 4-roll plate bending machine, adaptive control, Model Reference Adaptive Control (MRAC), valve control, position control, load pressure control

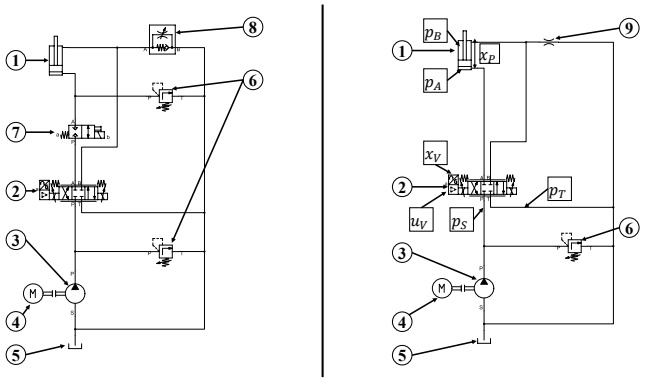
1. Introduction

Hydraulic drives are key components in many industries including robotics, manufacturing, forestry and earthwork. Due to their excellent energy- and power-density, they are often deployed for heavy-duty tasks like metal forming or excavation. These systems commonly operate under harsh and varying environmental conditions over extended periods, leading to significant changes in system behavior throughout a machine's lifetime. This variability presents a considerable challenge for control system design.

All Open Access articles are peer-reviewed, distributed under the Creative Commons Attribution-Non Commercial 4.0 International

To accomplish common control tasks like position and load pressure regulation, linear controllers are predominantly used. Their widespread adaptation is due to their conceptual simplicity, ease of implementation and sole reliance on readily available pressure and position measurements [1, 2]. While manually tuned PID based controllers remain common, more sophisticated linear control techniques, such as state-space control, are becoming more popular. For instance, [3] presents methods for system modeling and their application to linear control design, while [4] describes a method to improve feedforward control by combining physical modeling with measurement-based system identification during commissioning.
Additionally, extensive research has been conducted to address the challenges posed by the highly nonlinear dynamics of hydraulic systems. Different applications of nonlinear control techniques can be found for example in [5, 6, 7, 8, 9, 10]. However, these control designs suffer from drawbacks like the reliance on high-fidelity system models [5, 6] or require a fixed, repeatable process [10]. The development of high-fidelity system models is often resource- and time-intensive, making them less accessible to small and medium sized enterprises and manufacturers of special-machinery. This disadvantage is further exacerbated by the aforementioned parametric uncertainties, which reduce model accuracy and, consequently, the performance of model based control designs. The type and magnitude of these parameter variations are difficult to estimate during the design phase, thus motivating the application of robust and adaptive control techniques.
Since the 1950s, adaptive control has been an ongoing subject of research due to its capabilities in rejecting unforeseen disturbances such as structural damage, component wear or changes in the machine configuration. Today, a wide range of different approaches exist which can be broadly categorized into model-based and data-driven techniques [11]. Purely data-driven methods show increasingly promising results in hydraulic system control as seen in [12] and [13]. However, they often lack physical interpretability which poses a challenge for industrial applications as commissioning and maintenance tasks become increasingly complex and opaque. Therefore, despite this extensive research, a control architecture which simultaneously addresses the challenges of parametric uncertainty and external disturbances while maintaining physical interpretability remains a research gap. This work thus aims to develop two novel, adaptive control frameworks that address this gap. A particular emphasis is placed on the practical integration and applicability of these methods within existing industrial control frameworks.

2. System model



Mathematical system models simplify the development of controller designs and enable an assessment of open- and closed-loop behavior and performance. Especially state-space models are widely used in control theory as they provide an intuitive and physically meaningful system description. These models combine a set of coupled, first order differential equations to describe system dynamics with algebraic equations to determine the system outputs [14]:

$$\begin{aligned} \dot{\underline{x}} &= \underline{f}(\underline{x}, \underline{u}, \underline{\Theta}, t) \\ \underline{y} &= \underline{g}(\underline{x}, \underline{u}, \underline{\Theta}, t) \end{aligned} \tag{2.1}$$

The determination of required system equations is demonstrated using the hydraulic plant shown in Table 2.1. First, the original system is considered. It includes a pressure relief valve on the piston side and a check valve on the rod side of the cylinder. While the pressure relief

valve protects the cylinder from overpressure, the check valve prevents underpressure. Both phenomena are typically caused by external disturbances. However, if the control system performs adequately, both components remain inactive and are therefore irrelevant for the control design. Furthermore, the seat valve can also be neglected because it remains open during the entire control cycle. This leads to the simplified hydraulic scheme shown on the right side of Table 2.1.

Table 2.1: Schematic representation of the hydraulic drive used for bottom roller movement in a 4-roll plate bending machine.
Left: Original system; **Right**: Simplified model for control design

Position	Designation	Position	Designation
1	Differential cylinder	6	Pressure relief valve
2	4/3 proportional valve	7	2/2 seat valve
3	Hydraulic pump	8	Throttle and check valve
4	Electric motor	9	Throttle
5	Hydraulic tank		

To further simplify the model, it is assumed that the supply and tank pressure, p_{S} and p_{T}, are piecewise constant. The resulting model thus requires mathematical descriptions of a 4/3 proportional valve, a differential cylinder and an orifice.
Applying Newtons second law to the cylinder piston one obtains [2]:

$$\ddot{x}_{\mathrm{P}} = \frac{1}{m} \cdot (A_{\mathrm{A}} \cdot p_{\mathrm{A}} - A_{\mathrm{B}} \cdot p_{\mathrm{B}} - F_{\mathrm{f}}(\dot{x}_{\mathrm{P}}) - m \cdot g - F_{\mathrm{ext}}) \tag{2.2}$$

The friction force is given by:

$$F_{\mathrm{f}}(\dot{x}_{\mathrm{P}}) = \sigma \cdot \dot{x}_{\mathrm{P}} + \mathrm{sign}(\dot{x}_{\mathrm{P}}) \cdot \left[F_{\mathrm{c0}} + F_{\mathrm{s0}} \cdot \exp\left(-\frac{\|\dot{x}_{\mathrm{p}}\|}{c_{\mathrm{s}}} \right) \right] \tag{2.3}$$

The external forces vary between different applications of the hydraulic cylinder. For the controller design of a 4-roll plate bending machine, the external forces can be approximated as a mechanical hard stop:

$$F_{\mathrm{ext}}\left(x_{\mathrm{P}}\right) = \begin{cases} 0, & x_{\mathrm{P}} \leq a \\ k \cdot (x_{\mathrm{P}} - a), & x_{\mathrm{P}} > a \end{cases} \tag{2.4}$$

Using the continuity equation, the pressure dynamics of the cylinder chambers are obtained:

$$\dot{p}_{\mathrm{A}} = \frac{E\left(p_{\mathrm{A}}\right)}{V_{\mathrm{A}}\left(x_{\mathrm{P}}\right)} \cdot \left(Q_{\mathrm{A}}\left(p_{\mathrm{A}}, x_{\mathrm{V}}\right) - Q_{\mathrm{L,i}}\left(p_{\mathrm{A}}, p_{\mathrm{B}}\right) - Q_{\mathrm{L,e,A}}\left(p_{\mathrm{A}}\right) - A_{\mathrm{A}} \cdot \dot{x}_{\mathrm{P}}\right) \tag{2.5}$$

$$\dot{p}_{\mathrm{B}} = \frac{E\left(p_{\mathrm{B}}\right)}{V_{\mathrm{B}}\left(x_{\mathrm{P}}\right)} \cdot \left(Q_{\mathrm{B}}\left(p_{\mathrm{B}}, x_{\mathrm{V}}\right) + Q_{\mathrm{L,i}}\left(p_{\mathrm{A}}, p_{\mathrm{B}}\right) - Q_{\mathrm{L,e,B}}\left(p_{\mathrm{B}}\right) + A_{\mathrm{B}} \cdot \dot{x}_{\mathrm{P}}\right) \tag{2.6}$$

The chamber volumes and leakage flow rates are defined as:

$$V_{\mathrm{A}}\left(x_{\mathrm{P}}\right) = V_{0,\mathrm{A}} + A_{\mathrm{A}} \cdot x_{\mathrm{P}} \quad \text{and} \quad V_{\mathrm{B}}\left(x_{\mathrm{P}}\right) = V_{0,\mathrm{B}} + A_{\mathrm{B}} \cdot \left(S - x_{\mathrm{P}}\right)$$
$$Q_{\mathrm{L,i}}\left(p_{\mathrm{A}}, p_{\mathrm{B}}\right) = k_{\mathrm{L,i}} \cdot \left(p_{\mathrm{A}} - p_{\mathrm{B}}\right) \quad \text{and} \quad Q_{\mathrm{L,e,A/B}}\left(p_{A/B}\right) = k_{\mathrm{L,e,A/B}} \cdot \left(p_{A/B} - p_0\right)$$

The flow rates for both cylinder chambers are given by:

$$Q_{\mathrm{A}}\left(p_{\mathrm{A}}, x_{\mathrm{V}}\right) = Q_{\mathrm{V,A}}\left(p_{\mathrm{A}}, x_{\mathrm{V}}\right) \quad \text{and} \quad Q_{\mathrm{B}}\left(p_{\mathrm{B}}, x_{\mathrm{V}}\right) = Q_{\mathrm{O}}\left(p_{\mathrm{B}}\right) + Q_{\mathrm{V,B}}\left(p_{\mathrm{B}}, x_{\mathrm{V}}\right)$$

With the flow rates through the orifice and 4/3 proportional valve:

$$Q_{\mathrm{O}}\left(p_{\mathrm{B}}\right) = k_{\mathrm{O}} \cdot \operatorname{sign}\left(p_{\mathrm{T}} - p_{\mathrm{B}}\right) \cdot \sqrt{\left\|p_{\mathrm{T}} - p_{\mathrm{B}}\right\|} \tag{2.7}$$

$$Q_{\mathrm{V,A}}\left(p_{\mathrm{A}}, x_{\mathrm{V}}\right) = k_{\mathrm{V,A}} \cdot \begin{cases} \operatorname{sign}\left(p_{\mathrm{S}} - p_{\mathrm{A}}\right) \cdot \sqrt{\left\|p_{\mathrm{S}} - p_{\mathrm{A}}\right\|} \cdot x_{\mathrm{V}}, & x_{\mathrm{V}} \geq 0 \\ \operatorname{sign}\left(p_{\mathrm{T}} - p_{\mathrm{A}}\right) \cdot \sqrt{\left\|p_{\mathrm{T}} - p_{\mathrm{A}}\right\|} \cdot \left(-x_{\mathrm{V}}\right), & x_{\mathrm{V}} < 0 \end{cases} \tag{2.8}$$

$$Q_{\mathrm{V,B}}\left(p_{\mathrm{B}}, x_{\mathrm{V}}\right) = k_{\mathrm{V,B}} \cdot \begin{cases} \operatorname{sign}\left(p_{\mathrm{T}} - p_{\mathrm{B}}\right) \cdot \sqrt{\left\|p_{\mathrm{T}} - p_{\mathrm{B}}\right\|} \cdot x_{\mathrm{V}}, & x_{\mathrm{V}} \geq 0 \\ \operatorname{sign}\left(p_{\mathrm{S}} - p_{\mathrm{B}}\right) \cdot \sqrt{\left\|p_{\mathrm{S}} - p_{\mathrm{B}}\right\|} \cdot \left(-x_{\mathrm{V}}\right), & x_{\mathrm{V}} < 0 \end{cases} \tag{2.9}$$

To further simplify the model for control design, the following assumptions are made:

- No leakage flows $Q_{\mathrm{L,i}} = Q_{\mathrm{L,e,A/B}} = 0$
- The bulk modulus is constant $E\left(p_{\mathrm{A}}\right) = E\left(p_{\mathrm{B}}\right) = \mathrm{cst}.$
- The dynamic behavior of the valve spool is neglected $x_{\mathrm{V}} = u_{\mathrm{V}}$
- The valve has no overlap
- Only viscous friction is considered $F_{\mathrm{f}}\left(\dot{x}_{\mathrm{P}}\right) = \sigma \cdot \dot{x}_{\mathrm{P}}$

Defining the state vector $\underline{x} = \begin{bmatrix} x_{\mathrm{P}} & \dot{x}_{\mathrm{P}} & p_{\mathrm{A}} & p_{\mathrm{B}} \end{bmatrix}^{\intercal}$, the disturbance as $d = F_{\mathrm{ext}}$ and the input as $u = u_{\mathrm{V}}$ and combining equations 2.2, 2.5 and 2.6 one obtains the state-space representation:

$$\dot{\underline{x}} = \begin{pmatrix} x_2 \\ \frac{1}{m} \cdot \left(A_{\mathrm{A}} \cdot x_3 - A_{\mathrm{B}} \cdot x_4 - m \cdot g - \sigma \cdot x_2\right) \\ \frac{E}{V_{\mathrm{A}}(x_1)} \cdot \left(Q_{\mathrm{A}}\left(x_3, u\right) - A_{\mathrm{A}} \cdot x_2\right) \\ \frac{E}{V_{\mathrm{B}}(x_1)} \cdot \left(Q_{\mathrm{B}}\left(x_4, u\right) + A_{\mathrm{B}} \cdot x_2\right) \end{pmatrix} + \begin{pmatrix} 0 \\ -\frac{1}{m} \\ 0 \\ 0 \end{pmatrix} \cdot d \tag{2.10}$$

While measurements of the cylinder position and both chamber pressures are available, the output equation differs based on the current control task:

$$y_{\mathrm{Pos}} = x_1 \qquad y_{\mathrm{Load}} = x_3 - \frac{A_{\mathrm{B}}}{A_{\mathrm{A}}} \cdot x_4 \tag{2.11}$$

3. Controller design

This section presents two different methods to design adaptive controllers for cylinder and load pressure control. Both designs are based on a direct MRAC approach.

3.1. Direct model reference adaptive control (MRAC)

Direct MRAC aims at preserving desirable system behavior in the presence of unexpected parametric variations or disturbances. Therefore, it compares the behavior of a reference model against the real plant. Controller parameters are directly adapted based on the observed error between reference model and plant. Figure 3.1 shows the core components of a direct MRAC approach which are the aforementioned reference model, the adaptation law, the adaptive controller and the base controller.

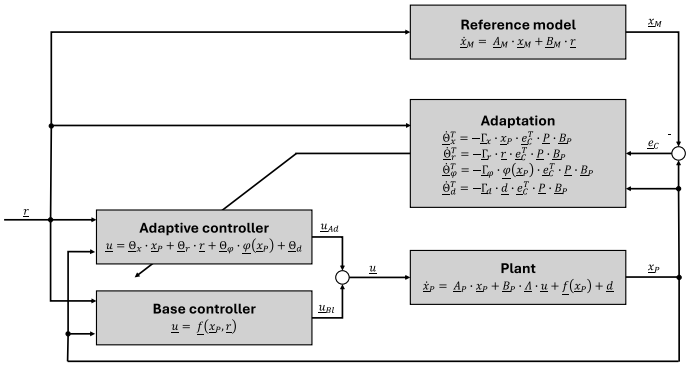


Figure 3.1: Block diagram of direct-MRAC based on the work of [15]

The base controller is designed to stabilize the plant during nominal conditions. If the plant is expected to be linear, the base controller can be designed as [16]:

$$\underline{u} = \underline{M}_{\mathrm{u}} \cdot \underline{r} + \underline{K} \cdot (\underline{M}_{\mathrm{x}} \cdot \underline{r} - \underline{x}) \tag{3.1}$$

Applying this control input to the nominal plant dynamics results in a design method for the reference model:

$$\dot{\underline{x}}_{\mathrm{M}} = \underbrace{\left(\underline{\hat{A}}_{\mathrm{P}} - \underline{\hat{B}}_{\mathrm{P}} \cdot \underline{K}\right)}_{\underline{A}_{\mathrm{M}}} \cdot \underline{x}_{\mathrm{M}} + \underbrace{\underline{\hat{B}}_{\mathrm{P}} \cdot (\underline{M}_{\mathrm{u}} + \underline{K} \cdot \underline{M}_{\mathrm{x}})}_{\underline{B}_{\mathrm{M}}} \cdot \underline{r} \tag{3.2}$$

If the real system deviates from the reference model, the adaptation mechanism becomes active. The choice of the adaptation mechanism and the appropriate control law depends on the nature of the expected disturbances. A general approach can be seen in Figure 3.1. However, if the disturbance is expected to be highly nonlinear, the following control law is sufficient:

$$\underline{u}_{\mathrm{Ad}} = \underline{\Theta}_{\varphi} \cdot \underline{\varphi}\left(\underline{x}_{\mathrm{P}}\right) + \underline{\Theta}_{\mathrm{d}} \tag{3.3}$$

The regressor vector $\underline{\varphi}\left(\underline{x}\right)$ can either be derived from physical system knowledge or by approximation, commonly using a single hidden layer neural network [17].

3.2. Type I: Feedback linearization

For the application of direct MRAC, models with a nearly linear behavior are preferred. Furthermore, control design for this type of models is comparatively straightforward as a broad variety of well-founded control design methods is available. While methods for linear systems distinguish themselves with verifiable, global stability and robustness measures [16], design methods for nonlinear systems are often cumbersome, require simplifications or provide only limited insight into the closed-loop system behavior. This motivates the application of feedback linearization, a technique that transforms a nonlinear system into a linear one, thereby enabling the use of well established linear control methods for nonlinear systems. This is achieved by a state transformation $\underline{z} = \underline{\Phi}(\underline{x})$. If the state transformation $\underline{\Phi}(\underline{x})$ is a local diffeomorphism around a workpoint $\underline{x}_0$ and the system description is affine in $\underline{u}$, application of the state transformation renders the system linear in the new state description $\underline{z}$ [18].
In order to use feedback linearization, the nonlinear system has to be expressed in the form:[1]

$$\begin{aligned} \dot{\underline{x}} &= \underline{f}(\underline{x}) + \underline{g}(\underline{x}) \cdot u \\ y &= h(\underline{x}) \end{aligned} \tag{3.4}$$

To determine the new state variables $\underline{z}$, the output equation is differentiated in time until the r-th derivative of y shows a direct dependency on u. Defining the states $\underline{\xi} = \begin{bmatrix} y & \dot{y} & \dots & y^{(r-1)} \end{bmatrix}^\mathsf{T}$ and the new input $v = y^{(r)}$, a linear model is obtained:

$$\begin{aligned} \dot{\underline{\xi}} &= \underbrace{\begin{pmatrix} 0 & 1 & 0 & \dots & 0 \\ 0 & 0 & \ddots & \ddots & 0 \\ 0 & \dots & 0 & \ddots & 0 \\ 0 & & \dots & 0 & 1 \\ 0 & & \dots\dots & & 0 \end{pmatrix}}_{\tilde{\underline{A}}} \cdot \underline{\xi} + \underbrace{\begin{pmatrix} 0 \\ \vdots \\ \vdots \\ 0 \\ 1 \end{pmatrix}}_{\tilde{\underline{b}}} \cdot v \\ y &= \underbrace{\begin{bmatrix} 1 & 0 & \dots & 0 \end{bmatrix}}_{\tilde{\underline{c}}} \cdot \underline{\xi} \end{aligned} \tag{3.5}$$

Controller design for the system given by Equation 3.5 can be done for example by using pole-placement or linear quadratic regulation (LQR). To obtain the input to the nonlinear system, following transformation based on the Lie-derivatives has to be applied [18]:

$$u = \frac{v - L_{\underline{f}}^{r} h(\underline{x})}{L_{\underline{g}} L_{\underline{f}}^{r-1} h(\underline{x})} \tag{3.6}$$

However, Equation 3.5 only represents the entire, original system if the relative degree r equals the number of states. Otherwise, the system possesses $(n_x - r)$ states $\underline{\eta}$ which are not influenced by the control input and thus can not be stabilized by the control system. Therefore, these states have to be inherently stable to guarantee stability of the entire system. Determination of the zero dynamics can be achieved through two distinct approaches [18]:

[1] The following discussion focuses on SISO-systems. For discussions of the MIMO case refer e.g. to [18] or [19]

1. Solving the partial differential equations $\frac{\partial \eta_i}{\partial t} = \frac{\partial \Phi_{r+i}(\underline{x})}{\partial \underline{x}} \cdot \left(\underline{f}(\underline{x}) + \underline{g}(\underline{x}) \cdot u\right)$
2. Selecting them arbitrarily and checking if $\det\left(\frac{\partial \underline{\Phi}(\underline{x})}{\partial \underline{x}}\right) \neq 0$

Table 3.1: Results of feedback linearization for position and load pressure control applied to the state space system described by equations 2.10 and 2.11

	Position	**Load pressure**
Controllable states	$\xi_1 = x_1$ $\xi_2 = x_2$ $\xi_3 = \frac{1}{m} \cdot (A_\mathrm{A} \cdot x_3 \ - A_\mathrm{B} \cdot x_4 - m \cdot g - \sigma \cdot x_2)$	$\xi_1 = x_3 - \frac{A_\mathrm{B}}{A_\mathrm{A}} \cdot x_4$
Zero dynamics	$\eta_1 = x_3 - \frac{A_\mathrm{B}}{A_\mathrm{A}} \cdot x_4$ $\eta_2 = x_3$	$\eta_1 = x_1$ $\eta_2 = x_2$ $\eta_3 = \frac{1}{m} \cdot (A_\mathrm{A} \cdot x_3 \ - A_\mathrm{B} \cdot x_4 - m \cdot g - \sigma \cdot x_2)$ $\eta_4 = x_3$
Linear system	$\dot{\underline{\xi}} = \begin{pmatrix} 0 & 1 & 0 \\ 0 & 0 & 1 \\ 0 & 0 & 0 \end{pmatrix} \cdot \underline{\xi} + \begin{pmatrix} 0 \\ 0 \\ 1 \end{pmatrix} \cdot v$	$\dot{\xi} = v$
Lie-derivatives	$L_{\underline{f}}^r h(\underline{x}) = \frac{1}{m} \cdot$ $\big[- \frac{E}{V_A(x_1)} \cdot A_A^2 \cdot x_2$ $- \frac{E}{V_B(x_1)} \cdot A_B \cdot (Q_O(x_4) + A_B \cdot x_2)$ $- \frac{\sigma}{m} \cdot (A_A \cdot x_3 - A_B \cdot x_4 - mg - \sigma \cdot x_2) \big]$ $L_{\underline{g}} L_{\underline{f}}^{r-1} h(\underline{x}) = \frac{1}{m} \cdot$ $\big[\frac{E}{V_\mathrm{A}(x_1)} \cdot A_\mathrm{A} \cdot Q_{\mathrm{V,A,nom}}(x_3)$ $- \frac{E}{V_\mathrm{B}(x_1)} \cdot A_\mathrm{B} \cdot Q_{\mathrm{V,B,nom}}(x_4) \big]$	$L_{\underline{f}}^r h(\underline{x}) =$ $- \frac{E}{V_A(x_1)} \cdot A_A \cdot x_2$ $- \frac{A_B}{A_A} \cdot \frac{E}{V_B(x_1)} \cdot [Q_O(x_4) + A_B \cdot x_2]$ $L_{\underline{g}} L_{\underline{f}}^{r-1} h(\underline{x}) =$ $\frac{E}{V_\mathrm{A}(x_1)} \cdot Q_{\mathrm{V,A,nom}}(x_3)$ $- \frac{A_\mathrm{B}}{A_\mathrm{A}} \cdot \frac{E}{V_\mathrm{B}(x_1)} \cdot Q_{\mathrm{V,B,nom}}(x_4)$
Interpretation	• States represent position, velocity and acceleration • Control input represents jerk • Cylinder pressures are not controllable. They result from the current velocity and external load.	• System is scalar and represents load pressure dynamics. • Other states are only considered during input transformation

Unfortunately, the system description in Equation 2.10 is not affine in the control variable as the flow rate through the proportional valve is more involved. However, equations 2.8 and 2.9 can be rewritten as:

$$Q_{\mathrm{V,A}}(x_3, u) = Q_{\mathrm{V,A,nom}}(x_3, u) \cdot u \quad \text{and} \quad Q_{\mathrm{V,B}}(x_4, u) = Q_{\mathrm{V,B,nom}}(x_4, u) \cdot u \quad (3.7)$$

With:

$$\begin{aligned} Q_{\mathrm{V,A,nom}}\left(x_3,u\right) &= k_{\mathrm{V,A}}\cdot\begin{cases}\mathrm{sign}\left(p_{\mathrm{S}}-x_3\right)\cdot\sqrt{\|p_{\mathrm{S}}-x_3\|}, & u\geq 0\\ -\mathrm{sign}\left(p_{\mathrm{T}}-x_3\right)\cdot\sqrt{\|p_{\mathrm{T}}-x_3\|}, & u<0\end{cases}\\ Q_{\mathrm{V,B,nom}}\left(x_4,u\right) &= k_{\mathrm{V,B}}\cdot\begin{cases}\mathrm{sign}\left(p_{\mathrm{T}}-x_4\right)\cdot\sqrt{\|p_{\mathrm{T}}-x_4\|}, & u\geq 0\\ -\mathrm{sign}\left(p_{\mathrm{S}}-x_4\right)\cdot\sqrt{\|p_{\mathrm{S}}-x_4\|}, & u<0\end{cases}\end{aligned} \tag{3.8}$$

Using Equation 3.7, the system becomes affine in the control variable if $u>0$ or if $u<0$. Thereby, if the system description is separated around $u=0$, it satisfies Equation 3.4 which justifies the usage of feedback linearization.
An overview of the feedback linearized systems can be found in Table 3.1. It can be seen that the zero dynamics of the position and load pressure controller are selected in a way that both scenarios use the same transformed state representation.
Combining feedback linearization with model reference adaptive control leads to the control scheme shown in Figure 3.2a. In this context, the adaptive controller acts on the transferred states. Thereby, it needs to compensate for uncertainties and deviations in the state and input transformation. These errors are usually nonlinear. Therefore, the control law given by Equation 3.3 is used for MRAC. As the proposed position and load pressure controller share the same state representation and act on the same system, both control systems are affected by the same disturbances and uncertainties. For this reason, a transfer of adapted controller gains between both controllers is desirable.
To transfer the gains between both controllers, it is further assumed that they share the same regressor vector $\underline{\varphi}\left(\underline{x}\right)$. Based on the idea of bumpless transfer, it is assumed that at the time of controller switching t_s both controllers should produce the same output:

$$u_{\mathrm{Pos}}\left(t_{\mathrm{s}}\right)\overset{!}{=}u_{\mathrm{Load}}\left(t_{\mathrm{s}}\right) \tag{3.9}$$

Separating the output of the base and adaptive controller in Equation 3.6 one obtains:

$$u_i\left(t_{\mathrm{s}}\right)=\underbrace{\frac{v_{\mathrm{Bl},i}-L_{\underline{f}}^{r_i}h_i\left(\underline{x}\right)}{L_{\underline{g}}L_{\underline{f}}^{r_i-1}h_i\left(\underline{x}\right)}}_{\text{Base controller}}+\underbrace{\frac{v_{\mathrm{Ad},i}}{L_{\underline{g}}L_{\underline{f}}^{r_i-1}h_i\left(\underline{x}\right)}}_{\text{Adaptive controller}} \tag{3.10}$$

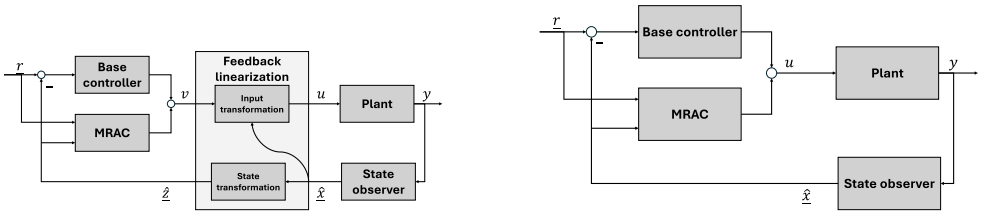
Combining equations 3.3, 3.9 and 3.10 and solving for the adaptive control input of the load pressure controller results in:

$$\begin{aligned}&\underline{\Theta}_{\varphi,\mathrm{Load}}\cdot\underline{\varphi}\left(\underline{x}\right)+\Theta_{\mathrm{d,Load}}=\\ &\frac{L_{\underline{g}}L_{\underline{f}}^{r_{\mathrm{Load}}-1}h_{\mathrm{Load}}\left(\underline{x}\right)}{L_{\underline{g}}L_{\underline{f}}^{r_{\mathrm{Pos}}-1}h_{\mathrm{Pos}}\left(\underline{x}\right)}\cdot\underline{\Theta}_{\varphi,\mathrm{Pos}}\cdot\underline{\varphi}\left(\underline{x}\right)+\Delta u_{\mathrm{Bl}}+\frac{L_{\underline{g}}L_{\underline{f}}^{r_{\mathrm{Load}}-1}h_{\mathrm{Load}}\left(\underline{x}\right)}{L_{\underline{g}}L_{\underline{f}}^{r_{\mathrm{Pos}}-1}h_{\mathrm{Pos}}\left(\underline{x}\right)}\cdot\Theta_{\mathrm{d,Pos}}\end{aligned} \tag{3.11}$$

With:

$$\Delta u_{\mathrm{Bl}}=L_{\underline{g}}L_{\underline{f}}^{r_{\mathrm{Load}}-1}h_{\mathrm{Load}}\left(\underline{x}\right)\cdot\left[\frac{v_{\mathrm{Bl,Pos}}-L_{\underline{f}}^{r_{\mathrm{Pos}}}h_{\mathrm{Pos}}\left(\underline{x}\right)}{L_{\underline{g}}L_{\underline{f}}^{r_{\mathrm{Pos}}-1}h_{\mathrm{Pos}}\left(\underline{x}\right)}-\frac{v_{\mathrm{Bl,Load}}-L_{\underline{f}}^{r_{\mathrm{Load}}}h_{\mathrm{Load}}\left(\underline{x}\right)}{L_{\underline{g}}L_{\underline{f}}^{r_{\mathrm{Load}}-1}h_{\mathrm{Load}}\left(\underline{x}\right)}\right]$$

Using coefficient comparison results in:



$$\underline{\Theta}_{\varphi,\mathrm{Load}} = \frac{L_{\underline{g}} L_{\underline{f}}^{r_{\mathrm{Load}}-1} h_{\mathrm{Load}}\left(\underline{x}\right)}{L_{\underline{g}} L_{\underline{f}}^{r_{\mathrm{Pos}}-1} h_{\mathrm{Pos}}\left(\underline{x}\right)} \cdot \underline{\Theta}_{\varphi,\mathrm{Pos}} \tag{3.12}$$

$$\Theta_{\mathrm{d,Load}} = \Delta u_{\mathrm{Bl}} + \frac{L_{\underline{g}} L_{\underline{f}}^{r_{\mathrm{Load}}-1} h_{\mathrm{Load}}\left(\underline{x}\right)}{L_{\underline{g}} L_{\underline{f}}^{r_{\mathrm{Pos}}-1} h_{\mathrm{Pos}}\left(\underline{x}\right)} \cdot \Theta_{\mathrm{d,Pos}} \tag{3.13}$$

Equations 3.12 and 3.13 represent the exchange of obtained knowledge based on adaptation. As these mappings are bijective, transfer in both directions is possible by inverting.

3.3. Type II: Linear replacement model

The main purposes of Type II adaptive control are the preservation of controller performance for industrial applications while simultaneously relying on minimum model knowledge. Therefore, it incorporates arbitrary, existing control frameworks by identification of the closed loop system after commissioning and uses the identified system as reference model. The block diagram of the resulting control scheme can be seen in Figure 3.2b. Compared to the scheme of Type I, Type II is distinguished by a reduced complexity as it avoids the additional state transformation.

(a) Adaptive control type I

(b) Adaptive control type II

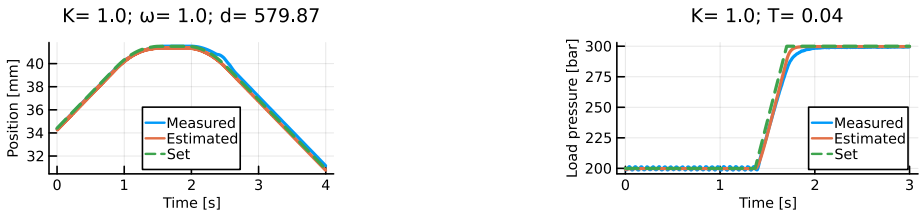


Figure 3.2: Block diagrams of adaptive control frameworks

Additionally, Type II adaptive control integrates smoothly into existing commissioning routines as can be seen by the following, recommended sequence:

1. Commissioning of the known control framework
2. Collecting data from the closed-loop system
   - The collected data should represent system behavior over the entire operating range.
   - Data collection requires movement in closed loop mode.
   - The set and actual values of the controlled output should be recorded.
3. Identification of a black box model using for example least squares or maximum likelihood estimation
4. Defining the identified model as reference model for direct MRAC
5. Parametrization of the adaptation behavior

Examples for the results of system identification can be seen in Figure 3.3. Hereby, the positioning behavior of the actuator is modeled as a PT2 element while the pressure dynamics are approximated as PT1 model. Since the identified model does not incorporate

any information about the underlying system physics, all deviations from the nominal performance are compensated by adaptation of the controller. This complicates error tracking as intended system variations like changing supply pressures have to be compensated by the base controller. Otherwise they appear as disturbance to the adaptive controller and lead to adaptation of the control law.

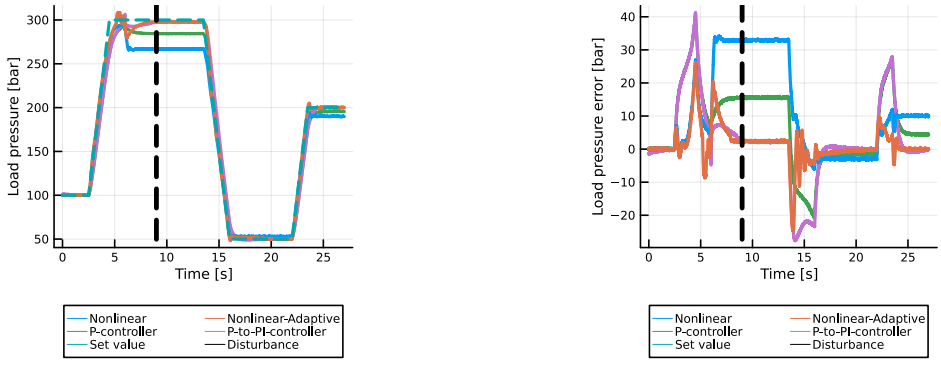
(b) Identified PT1 load pressure model

Figure 3.3: Results of closed-loop system identification

4. Simulation results

Simulation based design is nowadays standard in research and industry as it provides a cost and time efficient way to validate and test new concepts. Furthermore, it allows for system evaluation under wide parametric variations or under safety critical conditions. For this work, an open-source simulation environment developed in *julia* [20] is used, leveraging the *DifferentialEquations.jl* [21] and *ModellingToolkit.jl* [22] packages for acausal, symbol-based modeling and control design.
For evaluation of the control performance the following test scenarios are evaluated:

1. Load pressure control with suddenly increasing cylinder leakage
2. Position and load pressure control with different supply pressure control schemes
3. Switching between adaptive position and load pressure control



All scenarios use a common system model which is based on the experimental setup presented in Section 5. The nominal parameter values are listed in Table 4.1.

Table 4.1: Nominal parameters of the simulated cylinder

Parameter	**Unit**	**Value**	**Parameter**	**Unit**	**Value**
Piston side area A_A	mm^2	3848.5	Piston rod side area A_B	mm^2	1885.0
Piston stroke S	mm	85.0	Viscous friction coefficient σ	$\frac{N}{\frac{mm}{s}}$	192.0
Piston mass m_P	kg	2.96	Load mass m_L	kg	475.6
Flow rate coefficient valve k_V	$\frac{l}{min \cdot \sqrt{bar}}$	0.338	Flow rate coefficient orifice k_O	$\frac{l}{min \cdot \sqrt{bar}}$	0.0
Flow rate coefficient internal lekage $k_{L,i}$	$\frac{l}{min \cdot bar}$	0.0	Flow rate coefficient external lekage $k_{L,e}$	$\frac{l}{min \cdot bar}$	0.0
Supply pressure p_S	bar	310.0	Tank pressure p_T	bar	2.0
Bulk modulus E	bar	18000.0			

The first scenario examines the control performance of Type I adaptive control under unexpected disturbances. Therefore, an additional 2-way valve is introduced between the piston

and ring side of the cylinder. Activating the 2-way valve leads to an unexpected flow rate between both piston chambers which has to be compensated by the controller. To evaluate the performance of the adaptive controller, it is compared against a P-controller, a P-to-PI switching control structure, where the integral action is added in proximity of the target value, and a nonlinear controller based on feedback linearization. Figure 4.1 shows the results. All designs show a good tracking behavior during the first 9 s. At this point, the disturbance is introduced by opening the 2-way valve. This leads to an immediate decline of control performance for all four designs. The nonlinear controller, in particular, shows the strongest reaction to the disturbance and fails to recover which leads to a sustained steady-state error for the rest of the simulation run. As the adaptive controller is based on the nonlinear controller, it also shows a strong initial reaction to the disturbance. However, due to the adaptation mechanism, it quickly recovers its performance. During the following setpoint changes, the system with adaptive control shows the smallest control deviations. Especially during the transition phases, nonlinear control designs show a significantly improved performance compared to the linear controllers.

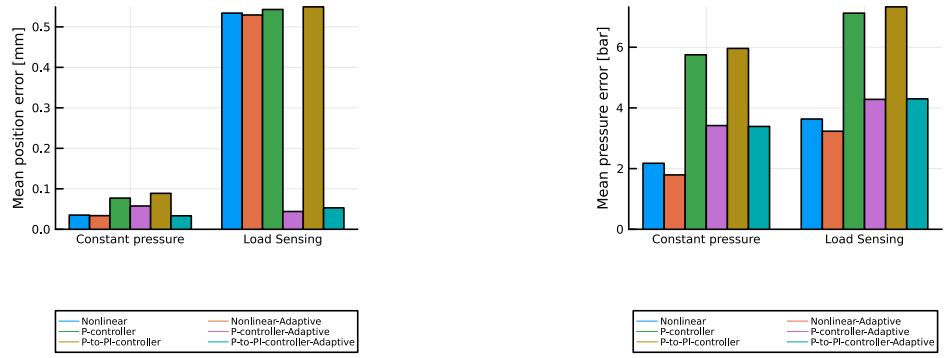
(a) Trajectory

(b) Tracking error

Figure 4.1: Performance of different load pressure controller designs under the influence of an unexpected disturbance caused by a cylinder leakage

In summary, it can be said that nonlinear control designs improve the control performance during nominal conditions. However, their dependence on a sophisticated system model makes them vulnerable against unexpected disturbances or model errors. These disadvantages can be compensated by a nonlinear controller with adaptation, as described in Section 3.2, resulting in the increased performance shown in Figure 4.1.
To further investigate the applicability of adaptive controllers in industrial settings, the second scenario is considered. For this scenario, a total of six different control designs are benchmarked. Similar to the designs of scenario 1, feedback control is achieved using a P-controller, a P-to-PI switching controller and a nonlinear controller based on feedback linearization. Additionally, all three foundational controllers are enhanced by an adaptive layer and the linear position controllers are augmented by a model-based feedforward structure which inverts equations 2.8 and 2.9 to calculate the necessary control input.
During this scenario, the system is disturbed by a varying supply pressure. This represents common practical applications where systems lack a pressure accumulator or utilize load-

sensing, which actively modulates the supply pressure. To quantify the influence of changing supply pressures, two control schemes are evaluated:

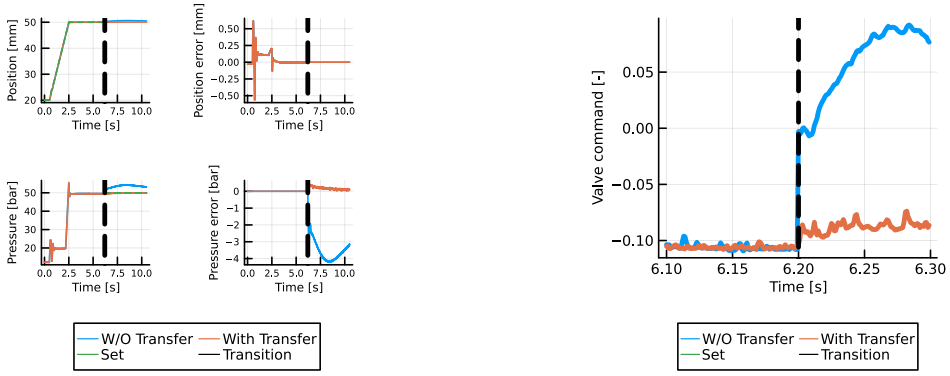


1. **Constant pressure**: The supply pressure is constantly hold at $310\,\mathrm{bar}$.
2. **Load-Sensing**: Supply pressure is adapted based on the highest moving actuator pressure.

The setpoint trajectories are generated to replicate the operation of the CNC-interface of the test machine in Section 5 and are illustrated in Figure 4.2. Notably, the position setpoint is designed to induce an external force on the cylinder at a position of $40\,\mathrm{mm}$, simulating the contact force between bottom and top rollers of the machine.

(a) Position (b) Load pressure

Figure 4.2: Setpoint trajectories used for controller comparison



(a) Position (b) Load pressure

Figure 4.3: Simulated performance of different control designs

Figure 4.3 presents the mean absolute control deviations for both the load pressure and position controllers. It is evident that supply pressure variations significantly degrade control performance. This effect is especially pronounced in the linear controllers without adaptation as they lack an effective mechanism to compensate for supply pressure variations. Consequently, extending these controllers with a Type II adaptive framework leads to a substantial improvement in accuracy by compensating for these variations. The performance of the adaptive position controllers under load-sensing distinctively highlights this effect. Because

load-sensing stabilizes the difference between supply and cylinder pressure, the valve flow rate becomes primarily dependent on the control input alone. This reduces system complexity which in turn facilities faster adaptation and improved convergence, leading to enhanced control performance. In contrast, the adaptive enhancement has a reduced influence on the nonlinear controller's performance, as the adaptation process is already significantly affected by the underlying structure of feedback linearization.
In summary, adaptive and nonlinear controllers are both capable of improving accuracy, particularly under varying supply pressures. The Type II adaptive controller design is especially promising, as it significantly enhances the performance of conventional linear controllers.
Finally, the third scenario is examined. As discussed in Section 3.2, transfer of adaptation gains between position and load pressure control is a common and essential task. To validate the increase in controller performance by introduction of the transfer algorithm, the same control task is simulated with and without the switching algorithm. The 2-way valve between both cylinder chambers is open for the entire simulation. During the first $6.2\,\mathrm{s}$, position control is active and adapts for the unexpected flow rate between the cylinder chambers. Thereafter, the controller mode switches from position to pressure control. Results can be seen in Figure 4.4. As expected, the transfer of controller gains significantly reduces the initial control transient after switching, as the previously acquired knowledge about the system's behavior is leveraged by the new controller.

(a) Trajectories and tracking errors

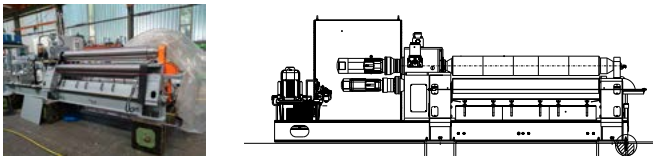
(b) Control input

Figure 4.4: Trajectories and control deviations using adaptation transfer

5. Experimental results

An experimental campaign was designed and executed to validate the novel control approaches by comparing different controller designs. All experiments were conducted on a **4-roll plate bending machine** (HAEUSLER, VRM-2000x23) which can be seen in Figure 5.1. Both side rollers and the bottom roller can be moved linearly using hydraulic actuators while the top and bottom roller are rotary driven by electric motors. Linear movement is conducted via two servo-valve controlled differential cylinders per roller which operate in leader-follower control to synchronize their movements. The required oil for all hydraulic actuators is provided by a **gear pump** (Bosch Rexroth, PGH2-2X/005RE07VU2). As the

pump provides a constant flow rate, supply pressure is adjusted between 20 bar to 310 bar via a proportional pressure relief valve. For process and CNC-control, the machine is equipped with a state of the art PLC developed at HAEUSLER AG. The hardware consists of a **4/3-way proportional valve** (Bosch Rexroth, 4WRPEH6C3B02L-3X/M/24A1), an **absolute position encoder** (Baumer, EAL580-B) in combination with a **draw-wire sensor** (MICRO-EPSILON, WDS-2000-P60-M-SO-HAE) and two **pressure transducers** (IFM, PA 9020) per linear axis. Thereby, the machine is capable to perform high precision interpolation-movements between all axes, allowing for the production of complex work pieces with high radius transition requirements.



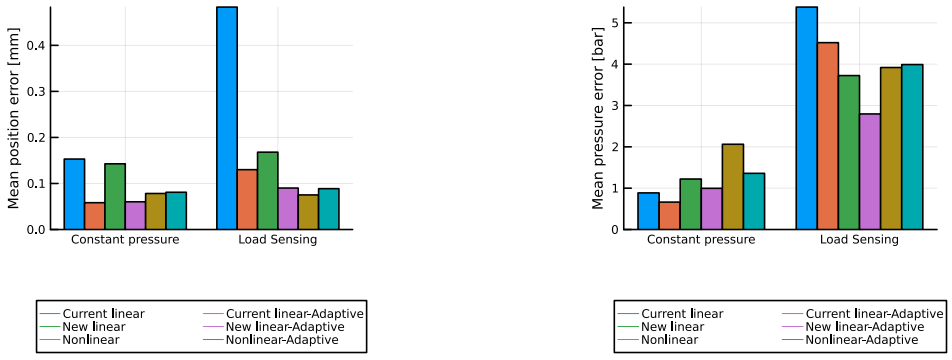


Figure 5.1: Test machine (HAEUSLER, VRM-2000x23) at HAEUSLER AG

For the experimental survey, a total of six different control approaches were benchmarked. These were based on three foundational controllers: the **currently implemented machine controller**, a **newly designed linear switching P-to-PI controller** (derived from scenarios 1 and 2 in Section 4), and a **nonlinear controller based on feedback linearization**. The primary difference between the default machine controller and the new linear controller lies in their feedforward structures. Where the new linear controller employs a model-based feedforward structure described in Section 4, the default machine controller utilizes a one-dimensional characteristic curve that maps the cylinder velocity to the control input. All three foundational controllers were enhanced by an adaptive layer. The two linear controllers were extended using the Type II adaptive framework (see Section 3.3), while the nonlinear controller was augmented with the Type I adaptive framework (see Section 3.2).

(a) Position

(b) Load pressure

Figure 5.2: Controller performance metrics of the experimental campaign

To validate controller robustness and performance, each control approach was tested under two supply pressure conditions —constant pressure and an active load-sensing system—

mirroring the simulation setup of scenario 2 in Section 4. The experiments were repeated three times per controller and supply pressure scheme, with results averaged to mitigate the influence of outliers.
A comparative evaluation of the controller performances is shown in Figure 5.2. The experimental results generally concur with the simulation outcomes presented in Figure 4.3, thereby, validating the conclusion that both the supply pressure and the adaptive control scheme have a significant influence on performance. A notable discrepancy between the experimental and simulated results is the reduced performance improvement of Type II adaptive position control. This reduction is likely attributable to non-modeled nonlinearities present in the physical system.
In summary, the experimental campaign successfully validated the capabilities of both adaptive and nonlinear controllers to improve accuracy and robustness under real-world conditions.

6. Conclusion

This work presented two novel approaches for the adaptive control of servo-valve controlled hydraulic cylinders. Performance of these designs was analyzed and validated through both numerical simulations and an extensive experimental campaign on a production-grade 4-roll plate bending machine.
The results demonstrate that the proposed adaptive control frameworks significantly enhance accuracy and robustness against a wide range of external disturbances and parametric uncertainties, including external forces, increasing leakages or varying supply pressures. The adaptive gain transfer mechanism, a key contribution of this work, was also validated through simulation, showing improved accuracy and a smooth transition during the crucial switching phase between position and load pressure control.
The experimental campaign, comparing the novel adaptive controllers against conventional linear and nonlinear designs, underscores the practical applicability of the proposed methods. Notably, it was shown that an adaptive enhancement of existing, industrial linear controllers, specifically using the Type II approach, can lead to a significant and verifiable improvement in control accuracy. This finding highlights a clear path for integrating advanced adaptive control into real-world industrial applications without requiring a complete overhaul of existing control systems.

Marcel Steidle received his bachelor's and master's degrees in Mechanical Engineering from the Technical University of Munich (TUM) in 2017 and 2019, respectively. He is currently an automation engineer at Haeusler AG Duggingen, where he is also pursuing his doctoral degree in cooperation with the the Chair of Fluid Mechatronic Systems at TU Dresden. His research focuses on adaptive control and methods for system and parameter identification in industrial hydraulic systems. Additionally, he explores opportunities to improve the energy efficiency of plate roll bending machines.

Patrick Stadler earned a Bachelor's degree in 2016 and a Master's degree in 2018 in Mechanical Engineering from ETH Zürich, with a focus on robotics and control system design. Since 2019, he has been working at Haeusler AG in Duggingen, applying scientific knowledge to enhance industrial applications.

Jürgen Weber received his Dipl.-Ing. and Dr.-Ing. in Mechanical Engineering from the Technical University of Dresden (TU Dresden) in 1986 and 1991, respectively. His early career was spent in academia, serving as a scientific assistant and senior engineer at TU Dresden's Institute for Machine Tools and Institute for Hydraulics and Pneumatics until 1997.

Following a 13-year period in the industry, where he held various leadership roles in hydraulic systems and advanced development, he returned to academia in 2010. He was appointed an University Professor and Director of the Institute of Fluid Power at TU Dresden. In 2018, he took on an additional leadership role as the Director of the Institute of Mechatronic Engineering. Since 2022, he has been the CEO of Construction Future Lab gGmbH, a startup focused on the digitization of construction machinery, further bridging his academic and industrial expertise.

Design Overview and Performance Assessment of an Integrated Electro-Hydraulic Actuator (iEHA)

Abstract.

The recent electrification trend in mobile and aerospace applications is increasing interest in electro-hydraulic actuators (EHAs), which are essentially primary-controlled hydraulic cylinders with an electric prime mover. EHAs can achieve high energy efficiency, a desirable feature particularly for electrified vehicles. Moreover, when implemented in a self-contained arrangement, EHAs are particularly attractive, as they can serve as an alternative to electromechanical actuators, leveraging the typical advantages of hydraulics. However, existing EHA designs have a structure unsuitable for most mobile applications and do not fully leverage the benefits of component integration.

This paper proposes an innovative design for an integrated Electro-Hydraulic Actuator (iEHA) based on aggressive component integration. The electric prime mover and the hydraulic machine are encapsulated in the cylinder head, while the reservoir is integrated alongside the walls of the hydraulic cylinder. The internal flow connections allow the differential flow between the cylinder and reservoir to circulate through the electric machine, thereby enabling optimal heat removal from the electric machine. The paper details the design morphology, the hydraulic and cooling circuit, and the sizing of the internal components, with supporting simulation results.

Keywords. EHA, iEHA, Electrification, Thermal Analysis.

1. INTRODUCTION

Self-contained EHAs have been introduced decades ago for critical controls in aerospace applications, with clear reliability advantages over electromechanical actuators, EMAs [1]. Their usage can eliminate long hydraulic lines and reduce leakages. Most importantly, their high energy efficiency, comparable to that of electromechanical actuators [2], makes their use particularly attractive for electrified off-road vehicles. EHAs also consistently reduce the space-claims actuation system, even compared to EMAs [3]. In EHA, high efficiency is achieved through a throttle-less implementation of the primary control concept [4, 5], in which the electric machine and hydraulic machines (i.e., E-Pump) are regulated to precisely match the hydraulic cylinder's flow demand.

Additionally, several EHA concepts also enable energy recuperation during overrunning loads [6]. These positive, energetic features of EHAs have promoted the implementation of "distributed EHA", as conceptually represented in Fig. 1.1, in which all components of the EHA system are distributed across different locations within the machine. Examples include the systems by Qu et al. in [7, 8], which also demonstrate the flexibility of the distributed arrangement, enabling both open-circuit and closed-circuit primary-controlled configurations. However, these implementations do not exploit the potential advantages of component integration, such as reduced overall space requirements and leakage. Such benefits are clearly desirable for off-road machinery and clearly motivated efforts such as the implementation proposed by Pietrzyk et al. [9].

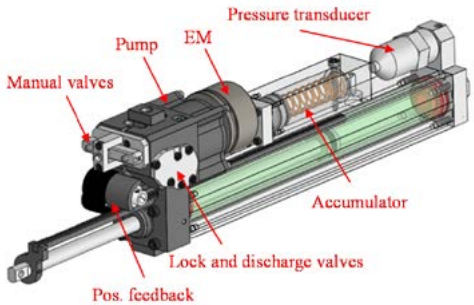

Figure 1.1. – Self-contained Electro Hydraulic Actuator designed by Altare et al. [10]

A clear challenge in deploying self-integrated EHAs in mobile applications, such as off-road machinery, is related to the design morphology. In fact, the typical design of a compact EHA resembles that of Fig. 1.1, where all the critical EHA elements are widely exposed to the surrounding environment. This arrangement is clearly unfavourable in harsh applications with a high risk of impact, such as construction equipment.

Integrated EHA typically require closed-circuit configurations of the hydraulic system, as in Fig. 1.2, that leverage pressurized reservoirs (usually low-pressure accumulators) for a flexible installation arrangement. In such a circuit, the cylinder extension and retraction always require flow corresponding to the displaced rod volume (usually referred to as differential flow). Creating control complexities and increasing the requirements on the hydraulic control system [11]. State-of-the-art EHAs do not leverage this differential flow for useful functions, such as heat dissipation, as in the proposed solution.

The present paper proposes a novel integrated design methodology for EHAs, particularly suitable for mobile applications. The study covers the design and the integration of the EHA, including component sizing and thermal behaviour analysis through simulations. The paper also discusses practical aspects of design integration and concludes with a summary of findings and conclusions.

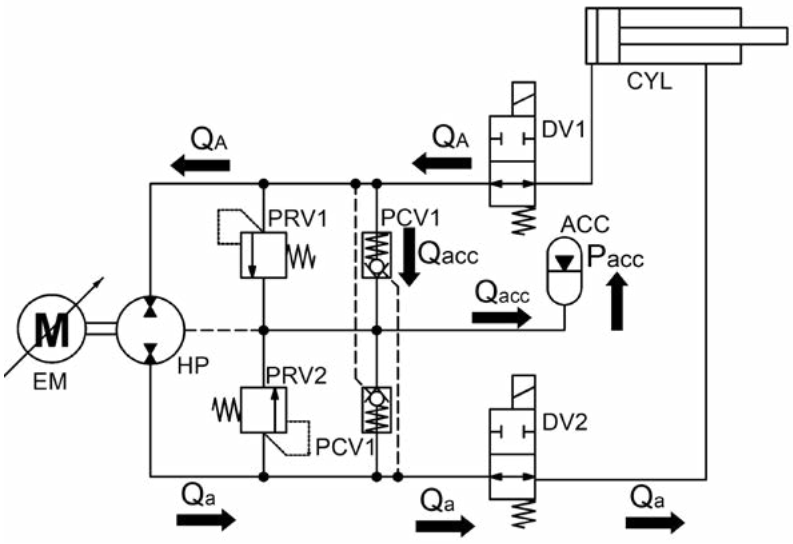

Figure 1.2. Closed-circuit EHA

The remainder of this paper is divided into the following sections. Section 2 presents the proposed electro-hydraulic actuator, including an overview and rationale, as well as its basic functioning, with isometric views and CAD details such as the cooling path. Section 3 describes the reference application and the choice of points for EHA functioning. Section 4 covers the basic component sizing, detailing the methods and final parameters for the electric machine, hydraulic machine, and Accumulator, along with the implications of the bypass valve. Section 5 provides practical information on design integration. Section 6 assesses the thermal behaviour through numerical simulations for the iEHA and cooling analysis for the electric motor. Finally, Section 7 concludes the paper by summarising the findings and conclusions.

2. INTEGRATED ELECTRO-HYDRAULIC ACTUATOR DESIGN

The principle of the proposed design is to maximize component integration, bringing the conventional architecture conceptually represented in Fig. 2.1(a) to a resulting architecture of Fig. 2.1(b). The Accumulator is concentric to the cylinder, and the E-pump is placed behind the cylinder on the same axis. Finally, the valve manifold is placed between the cylinder and the E-pump. The valve manifold not only serves as the point where all the valves are mounted but also as the part that provides hydraulic connections to all the components of the actuator. The proposed architecture leverages the known advantages for integrating electric and hydraulic machines (E-Pumps), in terms of magnet mass of the electric machine and overall dimension [12, 13,14], with additional advantages of integrating the pressurized reservoir within the hydraulic actuator. Additionally, an internal manifold valve integrates the hydraulic circuit, allowing for recirculation of the differential flow within the E-Pump. These features will be further detailed in the following subsections.

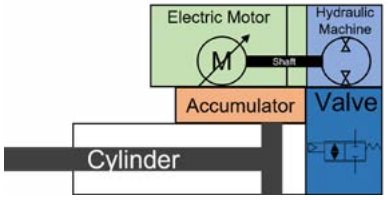

Figure 2.1(a). Traditional EHA design

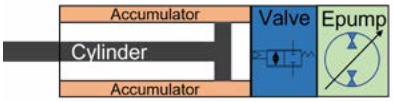

Figure 2.1(b). Proposed iEHA design

2.1. *Accumulator Design*

The low-pressure Accumulator is arranged concentric to the cylinder, similarly to a multi-chamber cylinder arrangement as commercialized by [15]. A ring-type piston is used to implement an original form of piston-type gas accumulator as shown in Fig. 2.2. Such a design not only reduces spatial requirement, but it is also adaptable to different piston strokes, as the volume requirement of the Accumulator linearly scales with the stroke length. The Accumulator uses the outer surface of the cylinder as one running surface, and a concentric cylinder running the entire length of the cylinder serves as the outer running surface for the Accumulator.

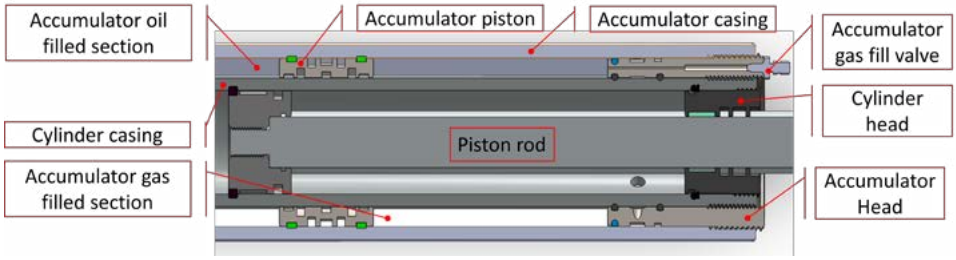

Figure 2.2: Accumulator design

2.2. *E-pump Design*

This section covers the design of the E-pump. The E-pump is designed based on the previous work by Pan and Zappaterra [13]. To enable energy recovery during assistive loading conditions, a four-quadrant hydraulic pump is required. Due to space constraints, a fixed-displacement pump is preferred, which also allows us to maintain a simple, compact design.

Considering the requirement of noise reduction, an internal gear pump is selected. And since internal gear pumps provide better filling and less noise [16] than external gear machines, a more compact design is possible. Moreover, using an internal gear pump offers a key advantage: the external gear can be directly driven, as illustrated in Fig. 2.3, resulting in a more compact E-pump design. In addition to its compactness, the internal gear pump can be designed so that the journal bearing supporting the external gear of the pump can also support the rotor of the electric motor [17]. Finally, the pump sizing is determined by the required flow rate derived from the cylinder specifications and the electric motor's maximum operating speed. Based on this, an internal gear machine with a 13-tooth pinion and a 19-tooth external gear was chosen.

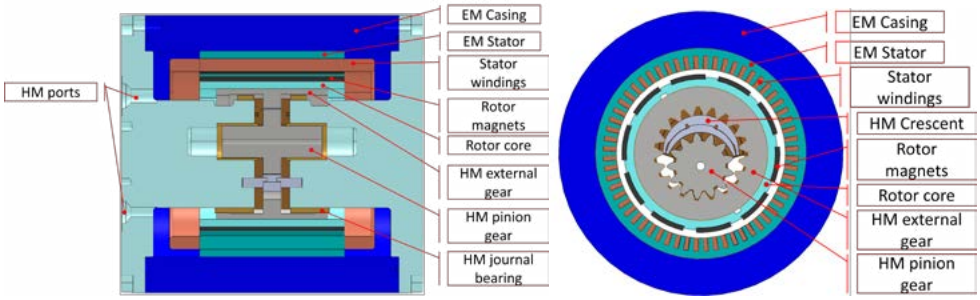

Figure 2.3(a). Radial cross-section Figure 2.3(b). Axial cross-section

Figure 2.3: E-pump design

A novel design feature of the E-pump design is using the differential flow to and from the Accumulator to cool the electric motor, as illustrated in Fig.2.5. The E-pump is designed so that the accumulator flow passes over the stator of the electric motor, thus cooling it. The flow path of the oil has been optimized using simulation to make sure that there are no hot spots in the stator. The heat energy transferred into the oil is later radiated into the atmosphere by the accumulator [18]. The E-pump design also discharges the drain flow into the differential flow.

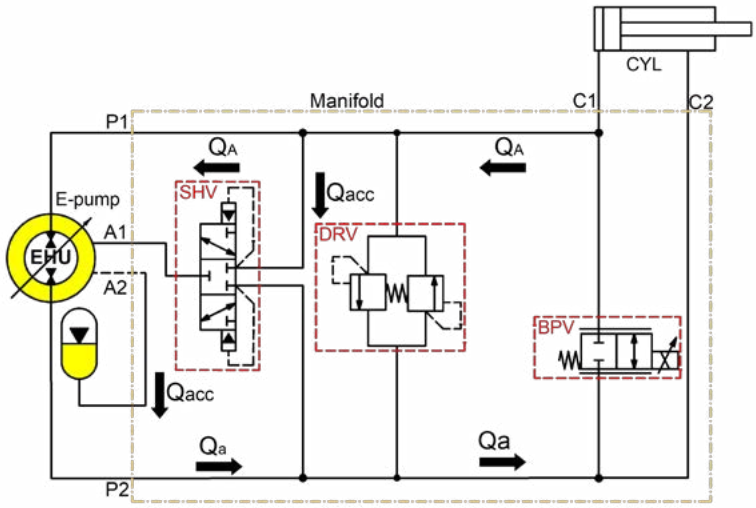

Figure 2.4 ISO schematic of the proposed EHA

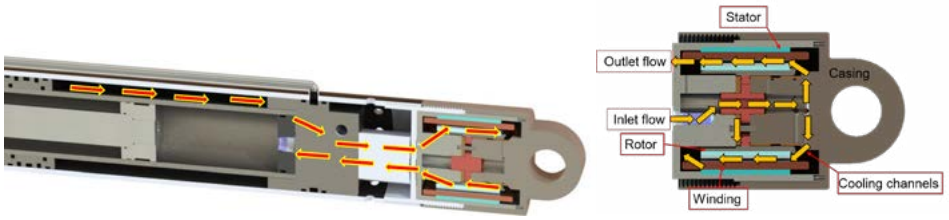

Figure 2.5. EHA Cooling flow path

2.3. Hydraulic circuit and valve manifold design

As illustrated in Fig. 2.4, the EHA was designed with three valves, of which one is a solenoid-operated proportional valve. This architecture represents the most minimalist implementation of a primary controlled circuit, where the low-pressure circuit is handled by an inverse shuttle valve (SHV) similar to that discussed in [19]. The circuit also includes a bypass valve (BPV) to improve control at low actuator velocities without running the E-pump at low RPMs. Moreover, as described in [20], the BPV also allows achieving high retraction velocities without increasing the E-pump's displacement, so that its displacement can be optimised to meet the maximum extension velocity requirement. To prevent any over-pressurisation events, a dual-acting version of an adjustable pressure relief valve (PRV) called the DRV was used. The DRV consists of 2 antiparallelly arranged pressure relief valves that are adjusted using a single screw. The final of the manifold design is shown in Fig. 2.6.

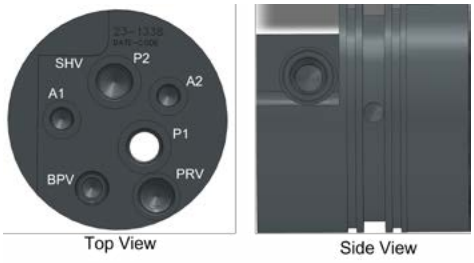

Figure 2.6: Manifold design

3. SIZING CONSIDERATIONS

The design sizing was based on considering the boom function of a mini excavator available in the market. The design data were obtained based on the cylinder size, velocity, and force required for the boom operation of a reference machine operated by an expert operator. Using this known data, a drive cycle was generated (shown in Fig. 3.3), and a basic assumption was made on the speed and torque requirements of the electric motor. Here, a design process, as shown in Fig. 3.1, was used to design and optimize the sizes of the electric motor, hydraulic pump, and manifold.

Figure 3.1: Designing procedure

After the initial design considerations were completed, particular attention to the packing of the integrated cylinder was taken into account. The valve locations impact how much they stick out for the manifold; this directly impacts the overall length of the cylinder. This is further complicated by the fact that the BPV, which requires exposure to air flow as it is solenoid-operated and requires cooling.

3.1. EHA operating points

As illustrated in Fig. 3.2, the design of the EHA components is based on a reference cycle to which the reference machine will be regularly subjected, as shown in Fig. 3.3. The electric motor power was selected based on the peak power in the reference drive cycle being run for a sustained period of time without leading to overheating.

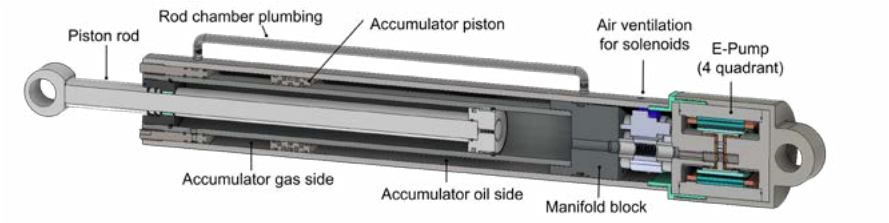

Figure 3.2 Design Overview

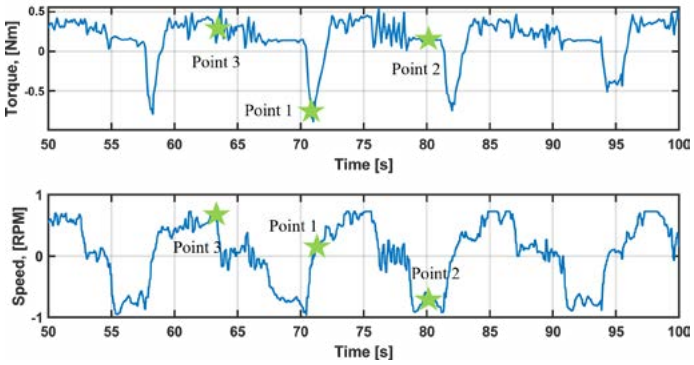

Figure 3.3 Operating points

4. BASIC COMPONENT SIZING

As detailed in Chapter 3, sizing begins with selecting a reference machine. Thus, the cylinder details are driven by the cylinder on the reference machine. The cylinder size then drives the volume of the Accumulator. The max velocity and the details of the cylinder drive the HM sizing. The HM size then determines the EM size. The sizing methodology used ensures that the EM's power rating accounts for all losses of earlier stages and can sustainably provide the power required for the reference drive cycle. Table 4.1 provides the normalized and relative cylinder details.

Parameters	*Symbol*	*Value*
Normalized Stroke length	S_l	1
Relative Piston Diameter	-	$S_l/7.1$
Relative Rod Diameter	-	$S_l/13.4$

Table 4.1 Normalized/ relative cylinder details

4.1. Electric motor sizing methodology & Final parameters

A Permanent Magnet Synchronous Motor (PMSM) was selected, as it offers very high power density. Furthermore, since the rotor of a PMSM comprises a set of magnets, the rotor core can be made hollow, allowing the hydraulic machine to nest inside the rotor.

The EM design was performed using GOSET software from Sudhoff [21]. This software is written in MATLAB and uses a multi-objective design approach to generate the EM design parameters based on the selected input parameters. The software generates a Pareto-optimal curve to select the optimal design. The software then uses the chosen design to develop the final EM design.

Parameters	*Symbol*	*Value*	*Units*
Nominal DC supply voltage	V_{DC}	800	[V]
Maximum motor speed	n_s	9500	[RPM]
Nominal motor torque	$\tau_{m,nom}$	25	[Nm]
Maximum motor torque	$\tau_{m,max}$	40	[Nm]

Table 4.2 EM input parameters

The input parameters are provided in Table 4.2. The input parameters are based on a drive cycle generated (Fig. 3 .3) using the methodology detailed earlier in this chapter, and on the choice of the battery and the inverter. Three points of interest from the drive cycle were selected based on the action being performed and the electric motor's instantaneous requirements. These 3 points cover the three most common modes of operation at regular loading conditions. Points 1 & 3 are a normal raising or quadrant one in Fig. 4.1. At point 1, the cylinder is starting to accelerate, and thus the EM speed is low, but the torque is at $\tau\ m$, max, But, at point 1, the cylinder is extending at high velocity and at no appreciable load. This requires a high EM speed and low torque. Point 2 is assistive retraction or quadrant four in Fig. 4.1. Here, the boom is lowering due to gravity, and thus energy recovery is possible. The final design parameters for the EM as detailed in Table 4.3

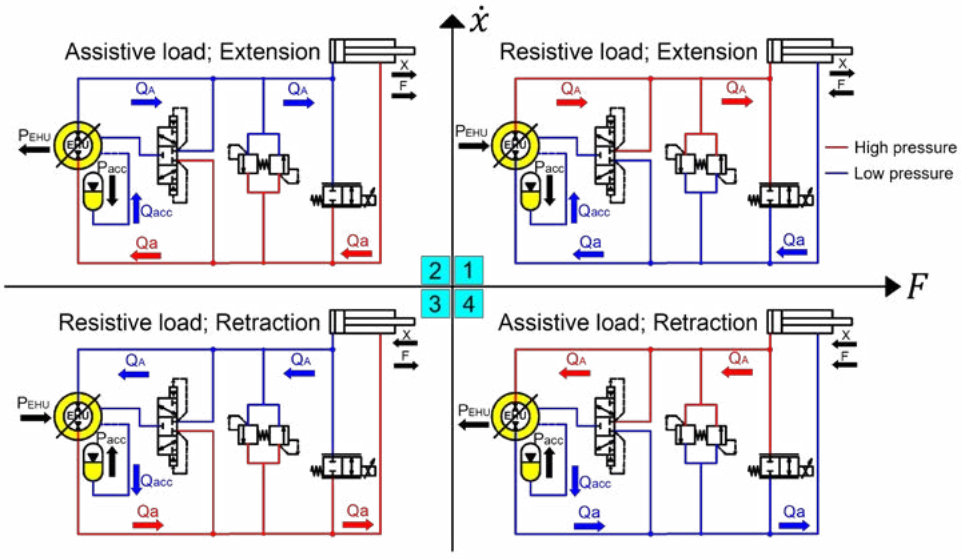

Figure 4.1 Operating modes of the EHA

Parameters	*Symbol*	*Value*	*Units*
Maximum motor speed	$n_{s,\,max}$	9500	[RPM]
Maximum motor torque	$\tau_{m,max}$	40	[Nm]

Table 4.3 Final EM parameters

4.2. Hydraulic machine sizing & Final parameter

The primary factor driving the design of the hydraulic machine is the maximum operating speed. The hydraulic machine is integrated into the rotor of the electric machine, resulting in a 1:1 gear ratio. Based on the conclusion from Zappaterra et al.[8] and Pietrzyk et al.[7]. An internal gear machine was determined to be suitable for this purpose.

The size of the hydraulic machine is determined by using Eqns.4.1 & 4.2. Based on the max velocity of the actuator during extension and the max rotational speed of the electric motor ($n_{s,\,max}$).

$$Q_A = \dot{x} \cdot A_A \tag{4.1}$$

$$V_D = \frac{Q_A \cdot \eta_v}{n_{s,max}} \tag{4.2}$$

In addition, the pump diameter is constrained by the electric motor's rotor diameter. This means that beyond a certain point, the length of the pump's gear set must increase to increase the displacement. Table 4.4 shows the final parameter for the hydraulic machine.

Parameters	*Symbol*	*Value*	*Units*
HM displacement	V_D	8	[cc]

Table 4.4. Final HM parameter

4.3. Accumulator sizing & Final parameters

Since a closed-circuit design was selected, an accumulator provides the differential flow of the cylinder. Hence, this is the primary driving factor for sizing the Accumulator. The cylinder's annular volume is derived from Eqn 4.3

$$V_a = A_a \cdot S_l \tag{4.3}$$

Based on the annular volume and the minimum and maximum accumulator pressures, the accumulator size is calculated using Eqns 4.4 & 4.5

$$\Delta V = V_0 \cdot p_0^{\frac{1}{\gamma}} \cdot \frac{p_2^{\frac{1}{\gamma}} - p_1^{\frac{1}{\gamma}}}{p_2^{\frac{1}{\gamma}} * p_1^{\frac{1}{\gamma}}} \tag{4.4}$$

$$V_0 = \frac{(\frac{p_2}{p_1})^{\frac{1}{\gamma}} \cdot \Delta V}{(\frac{p_0}{p_1})^{\frac{1}{\gamma}} \cdot \left[(\frac{p_2}{p_1})^{\frac{1}{\gamma}} - 1\right]} \tag{4.5}$$

The input parameters for the sizing of the accumulator are derived based on the cylinder details and are detailed in Table 4.5, and the final accumulator sizing is detailed in Table 4.6.

Parameters	*Symbol*	*Value*	*Units*
Charge gas	-	Nitrogen	[-]
Polytropic index	γ	1.4 @ 20°C	[-]
Precharge pressure	p_0	5.2	[bar]
Minimum working pressure	p_1	6.0	[bar]
Required volume	ΔV	3.44	[Liters]

Table 4.5 Accumulator input parameters

Parameters	*Symbol*	*Value*	*Units*
Accumulator volume	V_0	3.6	[Liters]
Maximum accumulator pressure	p_2	8.92	[bar]

Table 4.6 Accumulator final parameters

4.4. Bypass valve implications

The bypass valve is used in two scenarios. The primary use is to reduce the size of the hydraulic machine while achieving the same fast retraction velocity. The bypass valve is opened in quadrant 4 of Fig. 4.1(assistive retraction), which diverts some flow from the piston side chamber to the rod side of the cylinder. The secondary use is to allow high-velocity operation, especially when the hydraulic machine's speed falls below the minimum required to achieve this velocity.

5. DESIGN INTEGRATION

As mentioned, in the existing EHA designs, the components are externally connected to each other. This design aims to integrate all the components and place them on the same axis as the cylinder. For this reason, the majority of the components are cylindrical and are stacked. The Accumulator was designed to be concentric to the cylinder to increase the integration. The concentric cylinder would also allow the outer surface of the cylinder to be used as the inner running surface for the accumulator piston. Stacking/placing the manifold behind the cylinder will enable it to act as both the piston end cap of the cylinder and one of the end caps for the Accumulator, while providing fluid paths to both. The E-pump is placed/ stacked behind the manifold, and a connector connects the E-pump to the manifold. This connector also provides the space required for the valves. Since the outer running surface of the Accumulator is exposed to the environment, it can be used as a radiator for the heat generated. This eliminates the need for an additional external cooling system. Fig. 3.1 shows a near-complete design of the iEHA.

6. SIMULATION – THERMAL BEHAVIOUR & RESULTS

To access the thermal behaviour of the EHA, thermal simulations were conducted using two software packages. Simcenter's Amesim and Dassault Systèmes's SolidWorks were used to run thermal simulations of the complete EHA and the electric machine, respectively.

These simulations were performed using drive cycles generated to mimic the three loading points from Fig 3.3. The thermal simulation time period was set to a minimum of 9000 seconds for each drive cycle.

To ensure consistency between the two simulation methods. The boundary conditions

(mainly the oil flowrate and oil pressure used to cool the E-Pump) and other parameters were obtained by first running the Amesim simulations using the generated drive cycles, capturing the data, and then using this data as inputs to the SolidWorks simulations.

6.1. Hydrothermal simulation using Amesim

As illustrated in Fig. 6.1, a thermal simulation model that considered both electrical and hydraulic characteristics was built and simulated, using the hydraulic equations from Chapter 4 for the hydraulic system. Further equations shown in this chapter were used to simulate thermal energy in electrical and hydraulic systems. Specifically, Eqs. 6.1 & 6.2 were used to build a discretized thermal model of the EM, accounting for energy loss due to electrical resistance and Eddy currents. The heat exchange between the oil and the EM is also simulated using a thermohydraulic flow model with heat transfer, and the contact areas were determined from the EM's 3D CAD. In addition, the accumulator oil flow path through the EM for cooling purposes was considered, along with the flow path lengths and diameters. Furthermore, the accumulator components used consider the design's features, and the design's dimensions are used to calculate the external surface area of the Accumulator in contact with the environment. A conservative wind speed and temperature were also considered.

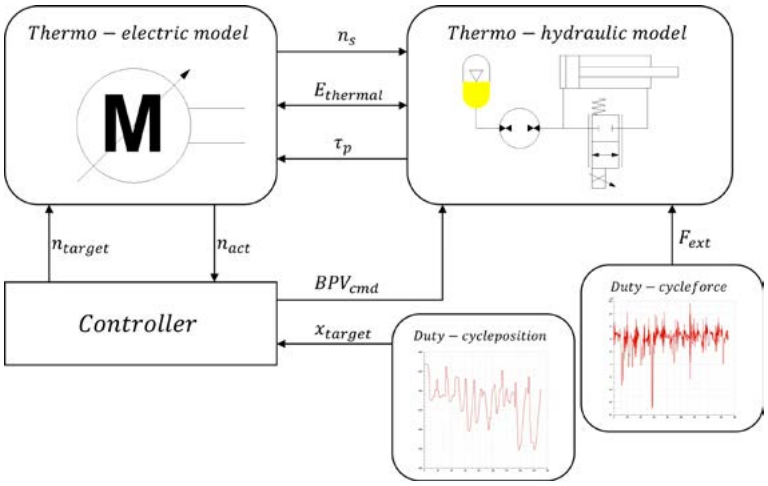

Figure 6.1 Simulation block diagram

$$dh_1 = \frac{t_2 - t_1}{TR} \tag{6.1}$$

$$\frac{dT}{dt} = \frac{\sum_{i=1}^{N} dh_i}{TC} \tag{6.2}$$

For the thermo-electric motor simulation, a lumped parameter RC model was built in Amesim. Fig. 6.2 illustrates an equivalent RC lumped parameter model. The thermal resistances (TR; illustrated by the black resistors in Fig. 6.2) and their heat flow rates are calculated using Eqn. 6.1. The thermal capacitances (TC) and the rate of change of temperature are computed using Eqn. 6.2. The EM lumped parameter model also accounts for the cooling oil flow and models the heat exchange using thermo-hydraulic flow with a heat exchange component in Amesin (THFHE; illustrated as red resistors in Fig. 6.2).

$$P_{frict}^{P} = (\tau \cdot \omega) - (Q_{in} \cdot \Delta p) \quad (6.3)$$

$$P_{frict}^{M} = (Q_{out} \cdot \Delta p) - (\tau \cdot \omega) \quad (6.4)$$

$$hgf = tcgf \cdot (T_g - T_l) \quad (6.5)$$

$$dh = k_{Heat} \cdot h_{conv} \cdot A_{ce} \cdot (T_l - T_w) \quad (6.6)$$

Furthermore, the thermo-hydraulic components we used for the hydraulic machine, cylinder and the Accumulator. As such, the friction in the pump/ motor is calculated using Eqn. 6.3 in pumping mode and Eqn. 6.4 in motoring mode. The heat exchange in the Accumulator is calculated using Eqn. 6.5. Finally, the heat exchange between the air and the Accumulator is calculated using Eqn. 6.6.

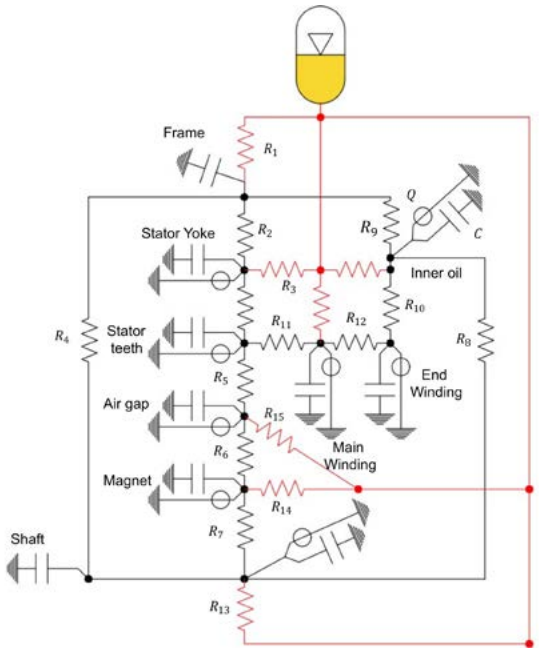

Figure 6.2 Equivalent EM lumped parameter model

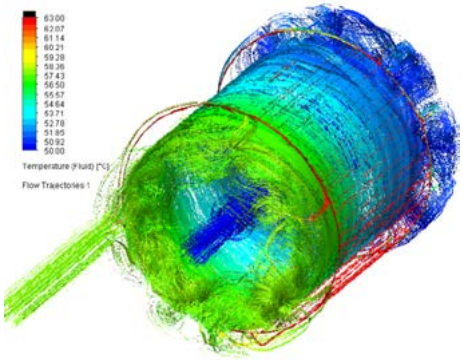

6.2. Thermal behaviour simulation using Amesim & SolidWorks

In addition to the hydrothermal simulation in Amesim. A thermal simulation in SolidWorks was performed to verify the proper/ complete cooling of the EM. This simulation was performed on the standalone E-pump design with properties identical to those of the integrated E-pump design. The primary objective of simulating EM cooling using both a lumped-parameter Amesim model and a SolidWorks model was to verify that the lumped-parameter model accurately simulates the losses and temperatures of the EM. The secondary objective of the flow simulation was to verify the even cooling of the EM stator. The results and the subsequent comparison of the temperatures are shown in the Table. 6.1. The average temperature difference between the models was 1.6°C, and the maximum temperature difference was 4.0°C. Since the windings generate most of the heat and are the main priority, a total temperature reduction of 4.0°C (5.27%) is promising.

Location	*Amesim*	*SolidWorks*	*ΔT*
Winding	76.0	72.0	4.0
Stator	71.0	71.5	0.5
Magnet	54.0	54.0	0
Rotor core	53.6	54.2	0.6
Fluid at the outlet	54.1	57.0	2.9
Average deviation			1.6

Table 6.1 Temperature comparison

The secondary reason for this simulation was to ensure even & sufficient cooling of the EM. To access this, a further simulation was performed at multiple cylinder velocities to account for the varying cooling oil flow rates. As illustrated in Fig. 6.3, the fluid can evenly cool the EM, resulting in a maximum stator temperature of 76 °C. Fig. 6.4 also illustrates the temperature distribution in the EM. It can be observed that the maximum temperature deviation in the windings is 9.29°C.

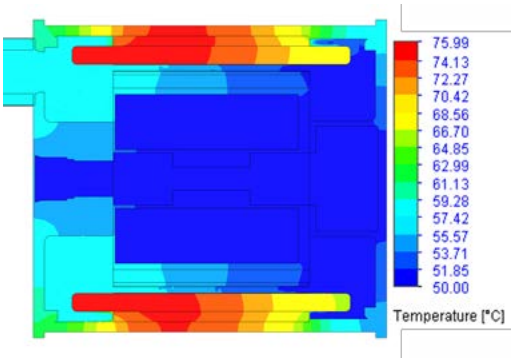

Figure 6.3 SolidWorks thermal & flow simulation Figure 6.4 SolidWorks – Simulated temperature distribution

7. CONCLUSION

In conclusion, this paper proposes an innovative design for an integrated Electro-Hydraulic Actuator (iEHA) by aggressively integrating the components of a linear hydraulic actuation system. The paper focuses on the design challenges of integrating the electric prime mover (EM), hydraulic pump, valve manifold, and Accumulator into a single-cylinder unit. Particular attention is given to key design areas. Such as the integration of the EM and the hydraulic pump (the E-pump), the concentric design approach for the cylinder and the Accumulator, and the utilization of differential flow to cool the E-pump.

Furthermore, the system's sizing is supported by two thermal simulation methods. A lumped-parameter model built in Siemens Amesim to verify the iEHA's design approach, with a particular focus on the E-pump's thermals. Additionally, a CFD simulation in Dassault Systèmes' SolidWorks confirmed the feasibility of the E-pump's cooling approach. These results demonstrate that the system temperature remains within acceptable limits and that the cooling architecture provides adequate flow to cool the E-pump evenly.

Though this paper focuses on simulation, the current work involves testing prototypes of the E-pump, the manifold, and the control system. In the future, the plan is to build a complete

iEHA prototype based on lessons learned from both simulations and the prototyping phase. Once proven, the proposed iEHA concept could find wide application in several electrified areas, such as aerospace and electrified mobile machines, where efficiency is critical.

Abstract.

As hydraulic components continue to evolve toward higher power densities and efficiencies, their structural design must meet increasingly demanding performance and reliability requirements. This often requires a targeted, sustainable use of material, particularly in highly stressed regions. This demands the assessment of the components' load limits, which are determined by cyclic pressure impulse tests.

During operation most components fail due to fatigue cracks, which have severe consequences. Thus, detailed knowledge of crack-growth behaviour is essential. Crack-propagation depends on the material properties and, above all, on the local stress amplitudes at the crack tip. The latter is changed in fluid power applications since the viscous oil interacts with the crack faces. This study aims to investigate the effect on a large scale. To make experimental investigation more efficient and economical, non-destructive, online monitoring of the crack development is employed. This work focuses on crack detection by acoustic emission (AE) methods, including the measurement setup and the evaluation of the acquired AE signals, while addressing common challenges such as background noise and data handling.

Keywords. Fatigue cracks, non-destructive testing, acoustic emission, pressure peaks

1. INTRODUCTION

As hydraulic components continue to evolve toward higher power densities and efficiencies, their structural design must meet increasingly demanding performance and reliability requirements. Achieving high power density often involves operating at elevated pressures or exploiting a weight-optimized design. Both require a targeted, sustainable use of material, particularly in highly stressed regions, which demands a precise understanding of the components' load limits.

A key failure mechanism is the initiation of fatigue cracks, which can have severe consequences, especially under cyclic internal pressure loading. Consequently, detailed knowledge of crack-growth behaviour is essential. Crack-propagation rates depend on the material properties and, above all, on the local stress amplitudes at the crack tip. [1] Furthermore, in oil environments, two opposing effects alter the stress amplitude compared with classical fracture-mechanics tests in air. On one hand, the crack faces are additionally loaded by the hydrostatic pressure of the oil, which increases the stress amplitude. Therefore, the crack propagates faster than without oil. However, there is an effect known as oil-

All Open Access articles are peer-reviewed, distributed under the Creative Commons Attribution-Non Commercial 4.0 International

induced crack closure [2], which is illustrated in **Figure 1-1**. This effect is due to the viscous behaviour of the oil, which is particularly noticeable at high pressure drop rates. In this case, the oil cannot flow out of the crack sufficiently fast after the end of the load. The trapped oil prevents the crack faces from fully reclosing, sustaining residual internal pressure that lowers the effective stress amplitude (while the peak stress remains unchanged) and consequently extends component life. [3]

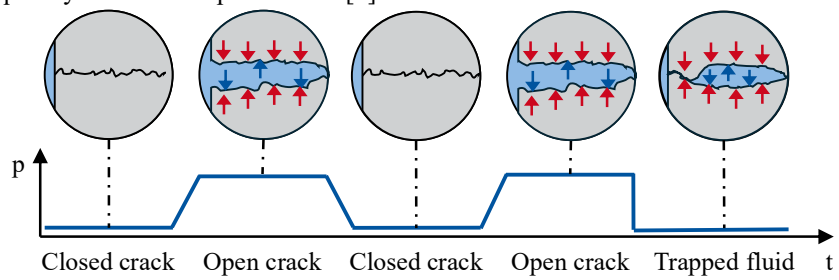

Figure 1-1: Oil-induced crack-closure caused by steep pressure drop rate.

Traditionally, hydraulic components are tested to failure under cyclic loading on pressure-impulse rigs, where cycle frequency significantly affects test duration and thus operating cost. Raising cycle frequency can substantially shorten operating time, in turn, steepen the load gradients, favouring oil-induced crack closure. Consequently, current testing relies on the incorrect assumption that component life is independent of cycle frequency, resulting in discrepancies between theoretical and experimental lifetime predictions [4].

To assess crack propagation during pressure-impulse testing, crack length must be evaluated at distinct intervals. Due to the large scope of the planned measurement series, manual measurement of the forcefully opened crack faces is not feasible. Therefore, this work develops a non-destructive, online monitoring method for hydraulic components to fundamentally investigate the influence of load frequency and pressure drop rates on crack propagation. For this purpose, samples are tested that are designed to initiate a well-defined crack quickly and sustain a steady propagation rate. The detection method involves using acoustic emission (AE) sensors, which are placed at suitable locations on the surface of the samples.

2. THEORY / STATE OF THE ART

The following sections provide the theoretical background and current state of research relevant to this work. They cover the fundamentals of fatigue crack growth, the influence of viscous fluids, and non-destructive testing techniques with a focus on acoustic emission methods.

2.1. Fatigue crack growth

Fatigue cracks are a critical failure mechanism in mechanical components, because they often develop unnoticed and do not cause a significant reduction in mechanical properties until critical failure. [5]

The process leading to final failure in metals, steels, and engineering alloys typically progresses through three distinct stages: nucleation, propagation, and breakthrough. Crack nucleation is the initial phase where microscopic damage begins to accumulate within the

material. This usually occurs under cyclic loading, even when the applied stress is below the material's yield strength. Localized plastic deformation occurs at microstructural imperfections due to dislocation activity, as the material seeks a lower energy configuration. In metals and alloys, persistent slip bands often form within grains and interact with grain boundaries, resulting in surface intrusions and extrusions that serve as early crack precursors. These imperfections can be intrinsic, such as inclusions, grain boundaries, or phase interfaces, or extrinsic, including surface defects like machining marks or scratches. Both types act as stress concentrators, accelerating local damage accumulation and promoting crack nucleation. Once nucleated, cracks begin to grow slowly and stably under continued loading, often referred to as the initiation phase. Initiation typically marks the onset of measurable crack growth from an initial micro-defect. [6]

To describe crack tip propagation, one must first address the mathematical singularity in the stress field at the crack tip [7]. Hence, the stress intensity factor (SIF) K is introduced to characterize this field in a finite and quantifiable manner, enabling calculation of crack growth by means of linear elastic fracture mechanics. It is dependent on the far-field applied stress σ, the current crack length a, and a geometric correction factor f, which accounts for geometry and orientation of the crack, with respect to the stress field. [1]

$$\Delta K = \Delta\sigma\sqrt{\pi a} \cdot f \tag{2-1}$$

Observing the change in SIF ΔK during cyclic loading of stress amplitude $\Delta\sigma$, one can describe the crack growth per cycle da/dN by the Paris-Erdogan equation [8]

$$\frac{\mathrm{da}}{\mathrm{dN}} = \mathrm{C} \cdot \Delta K^{m}, \tag{2-2}$$

with C and m being parameters determined by experimental material tests. The propagation phase can be divided into three phases, as can be seen in **Figure 2-1** in which the crack propagation rate per cycle is plotted against the change in SIF on logarithmic axes. Phase one characterizes the SIF region up to a threshold value ΔK_{th}. Up to this value, no crack propagation is expected. Phase two represents the stable crack growth region, characterized by a linear relationship between $log(da/dN)$ and $log(\Delta K)$, typically described by the Paris Law, extending up to the critical SIF range ΔK_c. Beyond this, in phase three, the crack grows rapidly and becomes unstable, leading to final fracture or breakthrough of the remaining cross-section. Thus, crack growth rate is influenced by the SIF range as well as the stress ratio R, which relates the maximum SIF to the minimum SIF. For a fixed ΔK, da/dN increases with R. Conversely, in the near-threshold regime, the threshold stress intensity factor ΔK_{th} decreases with increasing R [9].

The crack can propagate in relation to the direction of the applied far-field stress, as can be seen in Figure 2-1 on the right side, with three distinct modes identified: Mode I (opening mode), Mode II (sliding mode), and Mode III (tearing mode). In practical applications, a combination of these modes typically occurs. [10] However, this study specifically focuses on the effect of fluid on crack propagation under uniaxial loading of the crack faces subjected to normal stress, which corresponds exclusively to Mode I.

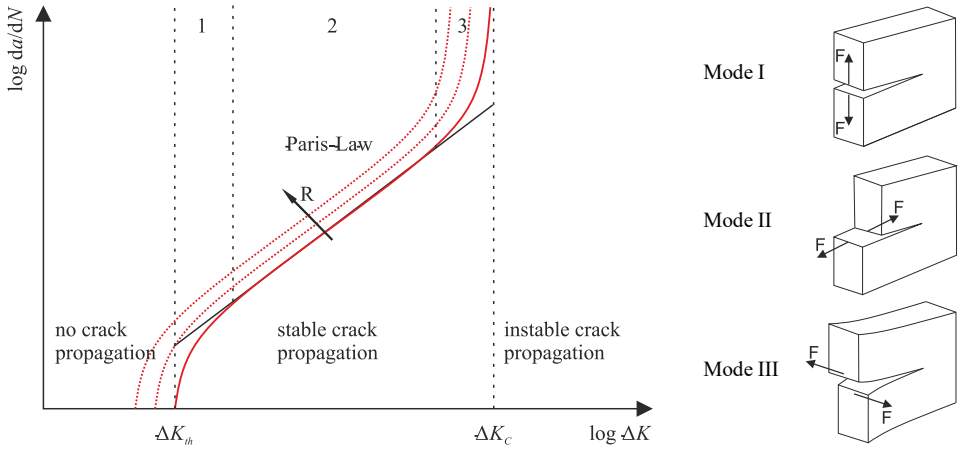

Figure 2-1: Crack growth rate with respect to the stress intensity range (left). Crack modes (right).

Little research has been conducted on the influence of fluid on the crack propagation, since typical metallurgical investigations are standardized and carried out in controlled environments [11]. In most tests, load is applied externally by special test rigs. However, these tests don't represent the real-world loading of cracked hydraulic components. Here, the load is applied directly on the crack faces as hydrostatic pressure. This is why most hydraulic components are subject to pressure impulse testing during development to determine load limits and lifetime.

Early research was conducted by Davis et al., who investigated the effect of oil under hydrostatic pressure on crack propagation in 1989. For this purpose, the specimen was subjected to cyclic mechanical loads in a pressure vessel. Depending on the type of loading, an improvement (tensile loading) or a deterioration (tensile-compressive alternating loading) of fatigue life was observed. [12]

In 2023, Michiels et al. examined both the influence of the pressure gradient [13] during cyclic pressure loading tests on crack growth and the effect of pulse frequency [14]. Additionally, they conducted and validated simulations to evaluate fluid behavior within a crack [3]. It was found that at very high pressure drop rates, oil can be trapped within the crack, as illustrated in Figure 1-1. This leads to a significant change in stress at the crack tip region, especially lowering the effective stress amplitude and thus extending fatigue lifetime. This phenomenon is known as oil-induced crack closure, where the presence of oil within the crack inhibits the crack faces from forming contact. A similar effect can occur due to roughness-induced crack closure, where surface irregularities cause early contact between crack faces, and oxide-induced crack closure, where oxidation products accumulate at the crack tip and impede full closure. [15]

To assess crack propagation rates, the crack length must be measured at defined intervals. In classical fatigue testing, cracks initiate and propagate along the surface and can be monitored using optical or mechanical methods, or through integrated measurement systems within the test rig. In contrast, cracks in hydraulic components, as well as in the specimens investigated in this study, form on the inner surfaces, making direct observation and

measurement significantly more challenging. Moreover, the pressure impulse test rig used in this work does not include built-in capabilities for crack length measurement. Consequently, non-destructive testing (NDT) methods must be employed.

The field of NDT for crack detection is vast, encompassing techniques based on electrical resistivity [16], ultrasonic energy [17], acoustic emission [18]–[21], and electromagnetic impedance [22], as well as digital image correlation [23]. Among these, the present work focuses on the application of AE testing, which enables the online and non-invasive detection of crack initiation and propagation processes during cyclic loading.

2.2. Acoustic emission testing

AE testing is a passive non-destructive testing technique utilized for monitoring the integrity and performance of solid materials, components and structures under stress. This method is based on the detection of high-frequency sound waves generated by the rapid release of energy from localized sources within a material, such as crack propagation, fiber breakage, or other forms of deformation. As these events occur, they emit elastic waves that can be captured by sensitive acoustic sensors such as piezoelectric sensors. In contrast to ultrasonic testing, which requires the active introduction of external acoustic energy, AE testing is considered passive, as it records signals that are naturally emitted by the material itself during loading. The sensors utilize a piezoelectric material that generates an electrical charge in response to mechanical stress. Sensor coupling to the specimen, as well as the setup of the amplification, filtering, and digitalizing devices, is essential for obtaining high quality signals with minimal influence of background noise. The schematics of AE sensor placement on the specimen and the acquired signal are shown in **Figure 2-2**. [24, 25]

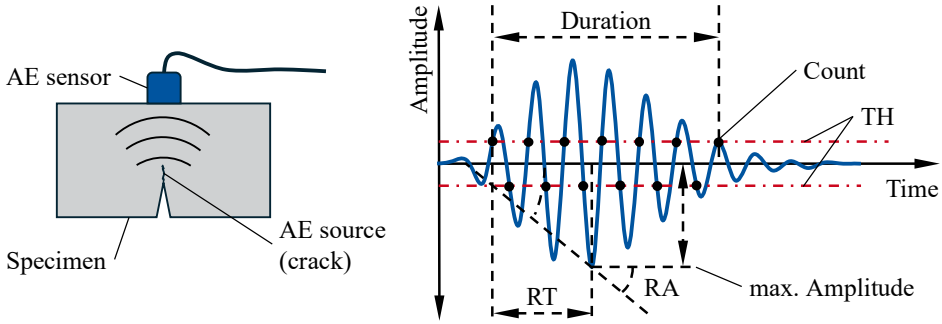

Figure 2-2: Illustration of AE sensor placement on specimen and AE source (left). Schematic AE signal amplitude over time (right) with signal parameters: Risetime (RT), riseangle (RA), duration, maximum amplitude, count of threshold (TH) crossing.

AE signals can be divided into continuous signals (e.g., process-related noise) and transient signals (signals with a recognizable beginning and end), often referred to as bursts [24]. While burst signals can be used to detect specific events such as crack growth, evaluation of continues signals at different time intervals allows for assessing structural changes or degradation over time. In fatigue and material testing burst signals are of primary importance. The raw signal is evaluated in the time and frequency domains to assess the presence of a burst and the corresponding crack propagation event [24]. **Figure 2-3** lists common signal processing approaches in the time domain. The raw signal (top) was created by a pencil lead break on the surface of an aluminium specimen.

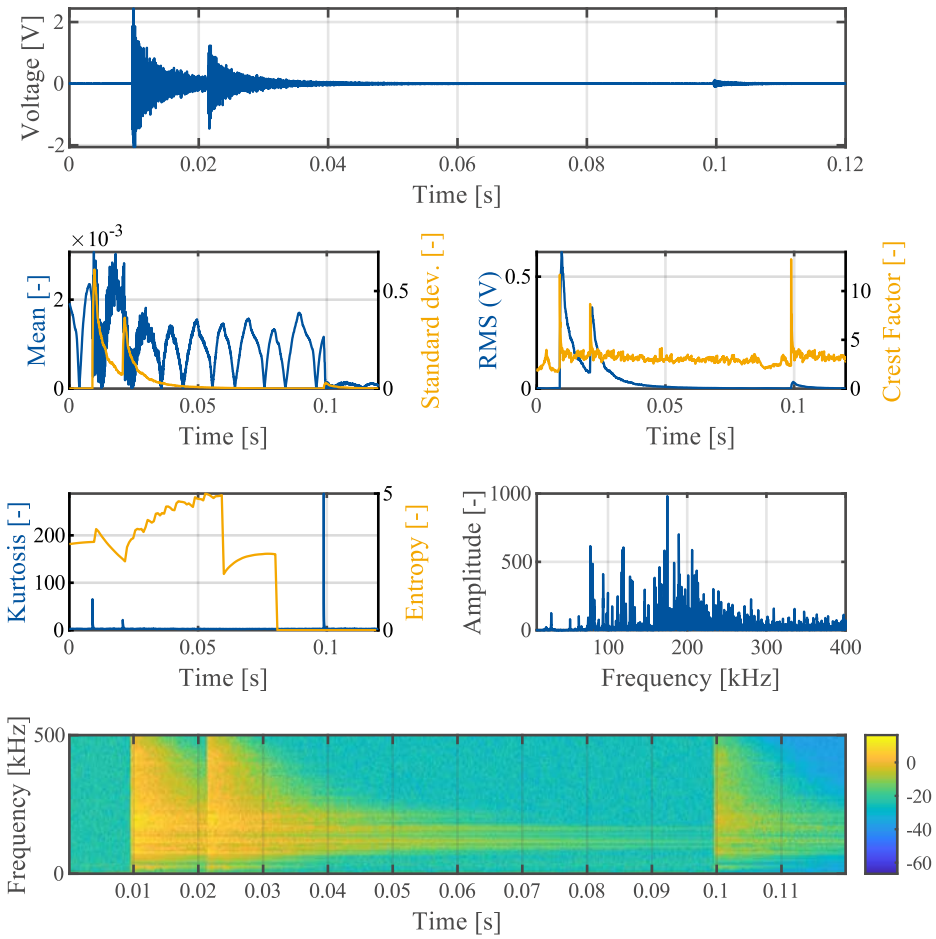

Figure 2-3: Time and frequency domain evaluation of raw signal (top).

Due to the axial symmetry of AE signals, the arithmetic mean often approaches zero, limiting its usefulness for analysis but forming the basis for further calculation. The root mean square (RMS) is the square root of the time-averaged squared measurements, allowing for burst signal evaluation and serving as a measure of signal energy. Variance and standard deviation indicate the dispersion of measurements relative to the mean, providing insights into burst presence: low variance suggests no bursts, while higher variance indicates their occurrence. The crest factor describes the ratio of peak value to RMS, with high values indicating isolated peaks with low energy. Finally, kurtosis measures the deviation from a Gaussian distribution; it equals 3 for normally distributed data and increases in the presence of bursts. In addition to analyzing time-domain parameters, AE signals can also be examined in the frequency domain. Two relevant methods for this study are the Fast Fourier Transform (FFT) and Short-Time Fourier Transform (STFT).

The presented time-domain approaches yield scalar values for a given signal. By applying windowing techniques, it becomes possible to track the temporal evolution of these signal properties, as summarized in Table 1. In the corresponding figures, the response of these

properties to transient signal components, such as bursts, can be clearly observed. Utilizing these processed signals together with appropriately defined threshold values, individual bursts can be detected and characterized. The resulting burst counts and their characteristic parameters can then be employed to evaluate the relationship between AE activity and the propagation of fatigue cracks.

3. METHOD

In the following, the test design, focussing on cyclic hydraulic loading, specimen design, and measurement strategy, is presented.

3.1. Test Design

The experiments are conducted on a pressure impulse test rig from Maximator [26], featuring a hydraulic power of 120 kW and maximum pressures of 1200 bar. This test rig generates a trapezoidal pressure profile with a frequency of 3 Hz, an upper pressure level of 400 bar, and a lower pressure level of 20 bar. The pressure increases at a rate of 20 kbar/s and decreases at 40 kbar/s. HLP46 serves as the pressure medium. **Figure 3-1** illustrates both the specified pressure cycle and the actual pressure during the cycle.

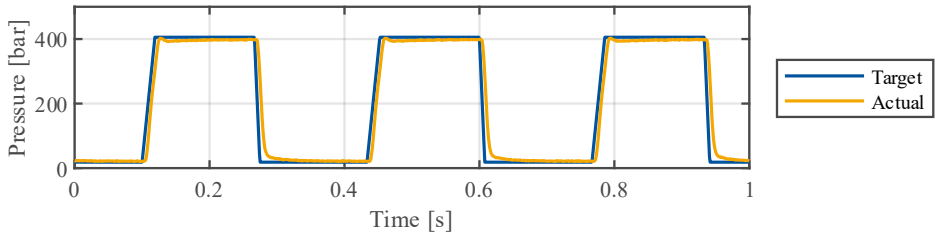

Figure 3-1: Target and actual pressure cycle at 3 Hz.

The geometry of the specimen made from steel S235 JR and the connection to the distribution manifold of the pressure impulse test rig is shown in **Figure 3-2**. The cavity inside the specimen is cyclically subjected to pressure during the experiment. At the base of the cavity, three holes are machined (see detail B) to facilitate fast crack formation due to local stress concentration. These specimens are designed to allow for stable crack growth under uniaxial hydraulic loading of the crack faces. Furthermore, a bleed plug is installed to allow for gas evacuation of the specimen. Bleeding is performed prior to each test run. Sealing the interface between the specimen and adapter is provided by a rubber O-ring.

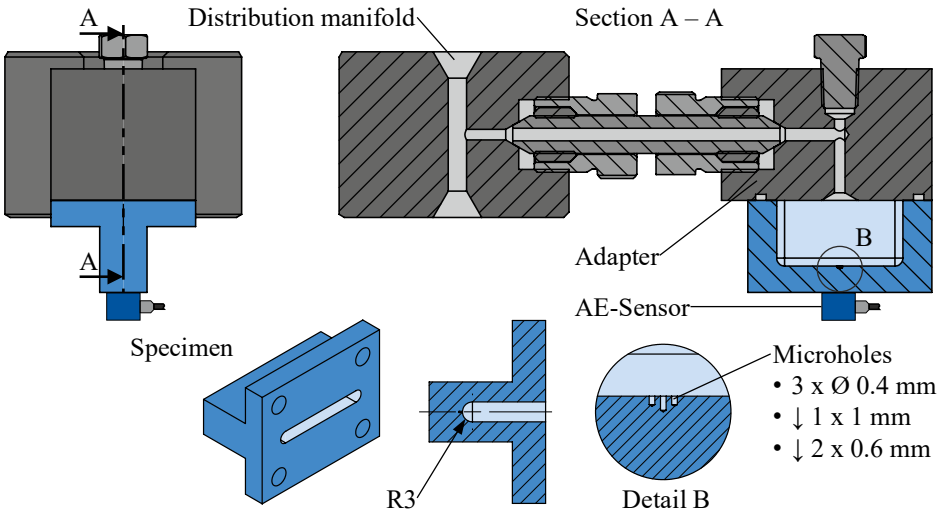

Figure 3-2: Specimen design and connection to pressure impulse test rig. Crack formation and growth is suspected to occur in section A-A of the specimen.

3.2. AE - Measurement setup

The AE sensor is mounted on the end face of the specimen using a magnetic holder, with wax serving as the coupling medium. A second AE sensor is placed at the corresponding position on a specimen without internal holes inside the cavity, hereafter referred to as the dummy specimen. Pressure sensors are installed at the distribution manifold, which are used to monitor and control the pressure profile (see **Figure 3-3).** During the experiment, signals from both AE sensors and a pressure sensor are recorded to evaluate AE activity in relation to the pressure cycle. To ensure temporal synchronization of the results, the signals are digitized using the same A/D converter. Piezotron® AE sensor type 8152C0 from Kistler is utilized. This sensor features an integrated preamplifier and has a sensitivity of 57 dB (ref. 1V) in the frequency range of 50 to 400 kHz. To amplify the AE signals further, Piezotron coupler type 5125C from Kistler is employed, which includes a tenfold amplification along with a 50 kHz high-pass filter and a 1000 kHz low-pass filter. The signals are digitized by the PCIe-6374 analog/digital converter from National Instruments at a maximum sampling rate of 3.5 MHz before being transmitted to the measurement computer. Both data acquisition and analysis are performed using MATLAB R2023b [27].

The high sampling rates required for the reliable detection of AE events result in a significant demand for storage space to capture the measurement data. One AE signal digitized at 3.5 MS/s with a sample size of 16 bits generates approximately 25 GB of measurement data per hour. Depending on the chosen loading frequency, test durations of several hours are expected. These large data volumes pose a challenge for continuous data acquisition, as the memory of the measurement computer will quickly become saturated. A similar issue also affects the evaluation process, as MATLAB requires all necessary variables and data to be present in memory. To address this, the data acquisition concept involves writing data in blocks of fixed sample size from memory to disk. A separate file is created for each block, and these files are numbered in the order of their creation. Specifically, data is acquired every 1000 load cycles over a period of 1 minute. Each acquisition sequence is further

divided into six consecutive blocks of 10 seconds each. This results in a large number of files, each containing a manageable amount of data, and prevents memory overflow during measurements, allowing for gradual evaluation of the measurement data. Figure 3-3 schematically illustrates the implemented data acquisition strategy, showing the periodic measurement intervals and the subdivision into time segments, as well as the sensor and specimen placement in the test chamber.

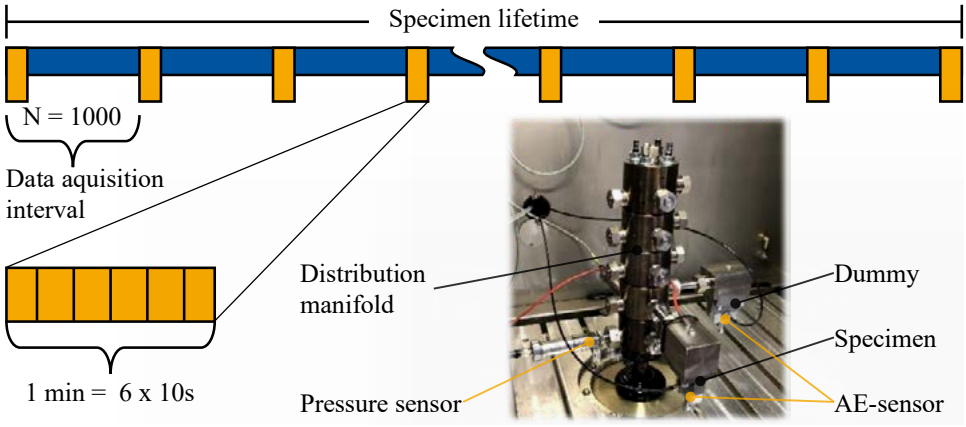

Figure 3-3: Schematic data acquisition strategy showing the periodic measurement intervals and the arrangement of sensors and specimens within the test chamber.

4. RESULTS

Final crack breakthrough of the investigated specimen occurred after 555.427 load cycles. AE and pressure data were acquired at intervals of 1000 cycles for both the test specimen and the dummy specimen, as shown in Figure 3-3. In the following, the raw AE signals of both specimens are presented for selected successive cycle numbers throughout the specimens' lifetime. Subsequently, AE bursts from both specimens are evaluated and characterized according to the methods described above. Finally, the bursts are analyzed in conjunction with the corresponding pressure signals.

Figure 4-1 shows AE signals of both specimens at the beginning of the test (N = 1k) as well as at intermediate cycle numbers in intervals of 100k cycles starting at N = 100k for the duration of 3 s or 10 load cycles, respectively. AE activity can be observed for the dummy specimen from the beginning of the test up to 500k cycles, exhibiting periodic bursts (3 Hz) with amplitudes of approximately ±0.011 V compared to a background noise level of ±0.003 V. This corresponds to a signal-to-noise ratio (SNR) of 3.7, which remains nearly constant throughout the test duration.

In contrast, the AE signal of the investigated specimen shows distinctly different behavior. No notable AE activity is detected during the initial 1000 cycles up to 300k cycles. A slight increase in amplitude is observed at 400k cycles (signal ±0.008 V, noise ±0.003 V, SNR = 2.7). At 500k cycles, the AE bursts become clearly distinguishable from the background noise, reaching amplitudes of around ±0.023 V (SNR = 7.7), indicating the onset of significant crack growth activity.

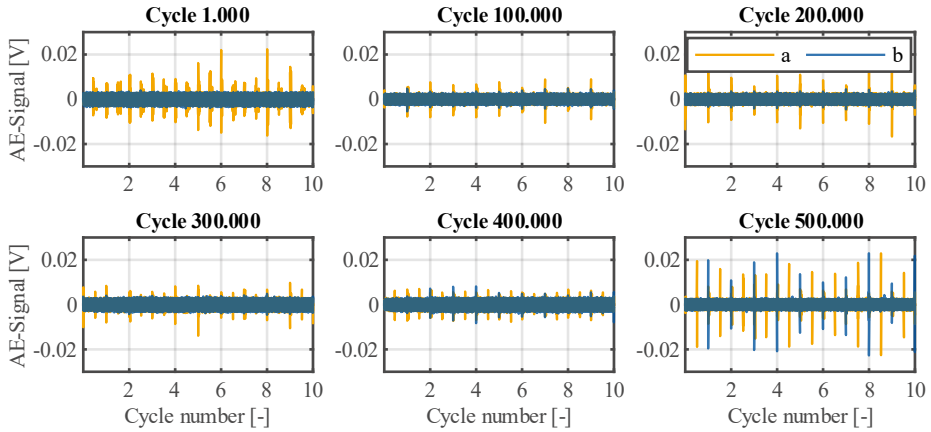

Figure 4-1: Raw AE signals at succeeding cycles for dummy (a) and specimen(b).

The increase in AE activity of the specimen between 400k and 500k cycles necessitates a more detailed examination of the period leading up to the end of the specimen's lifetime. Therefore, **Figure 4-2** focuses on the AE signals for selected cycle numbers closer to the specimen's final failure, shown in comparison with the dummy specimen.

At N = 545k, the specimen exhibits AE burst amplitudes ranging from approximately ±0.015 V to a maximum of ±0.030 V, with a background noise level of ±0.003 V, corresponding to a maximum SNR of 10. In the same interval, the dummy specimen shows a comparable maximum amplitude of ±0.021 V at similar noise levels.

At N = 550k, the specimen signal increases further, with amplitudes between ±0.018 V and ±0.037 V (SNR ≈ 12). The dummy specimen, however, shows only a single pronounced peak of about ±0.040 V, while the remaining signal remains around ±0.011 V with comparable noise (±0.003 V).

Shortly before final failure (N = 555k), the specimen signal exhibits a pronounced increase in AE activity, reaching amplitudes between ±0.050 V and up to ±0.140 V, resulting in a maximum SNR of 47. In contrast to previous intervals, the AE bursts no longer occur strictly at the load-cycle frequency. Instead, alternating high and lower peaks appear, effectively doubling the apparent signal frequency. The lower peaks reach amplitudes of approximately ±0.010 V (SNR ≈ 3). The dummy specimen signal remains largely unchanged during this stage.

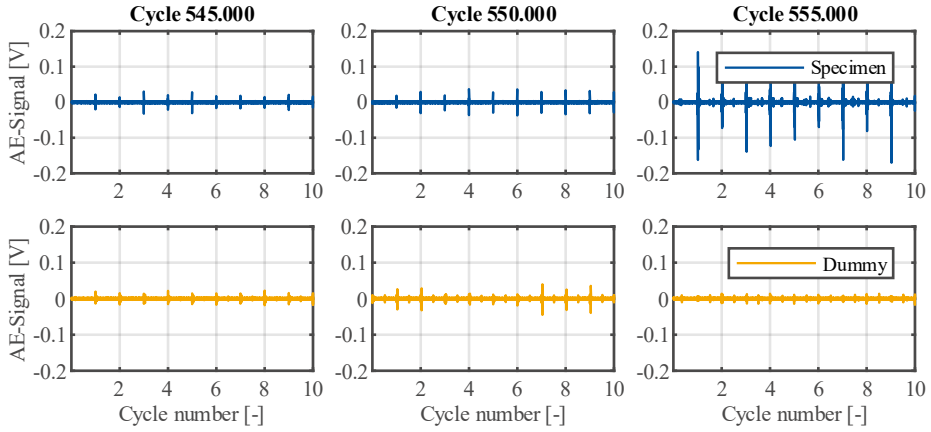

Figure 4-2: Raw AE signals at final succeeding cycles for both specimens.

As those results show distinct cases and a manual evaluation of the bursts of the time signals is not feasible, the method described above is applied to detect and characterize bursts. **Figure 4-3** presents the detected bursts of the specimen over the total test duration, obtained using different detection approaches. The methods include a static threshold applied to the raw signal, burst detection based on calculations in the time and frequency domains, and an entropy-based detection approach. From the bursts detected by those methods, mean values are calculated and compared with those of the dummy specimen, which were determined accordingly. The different detection methods exhibit varying sensitivities. When ranked by their overall sensitivity throughout the test, the methods can be ordered as follows: time-domain analysis (most sensitive), frequency-domain analysis, entropy-based detection, and finally, static thresholding.

The qualitative evolution of the detected burst rate shows no burst activity up to approximately 50k cycles, which aligns with the observations from the raw AE signals. From 50k to 300k, the detection rate remains nearly constant, with an average of around 100 bursts per minute. Between 300k and 400k cycles, a slight increase in detected bursts can be observed, followed by a more pronounced rise between 430k cycles and the end of the test, where all methods yield very similar burst rates of roughly 200 bursts per minute. Shortly before the final fracture, all methods indicate a sharp increase in AE activity. In contrast, the dummy specimen shows almost no detected bursts throughout the entire duration of the test, apart from a few sporadic detections.

It should be noted that data are missing for approximately 5k cycles at 100k, 200k, 300k, 400k, and 500k cycles. During these interruptions, the pressure profile was adjusted by changing the stress ratio from R = 0.05 to 0.6 at a maximum pressure of 400 bar. These steps were necessary to introduce optical beach marks on the fracture surface, allowing the crack growth path to be visually correlated with the corresponding cycle counts. After each change in stress ratio, the test system was restarted. In nearly all cases, a gradual increase in the number of detected bursts was observed immediately following each restart.

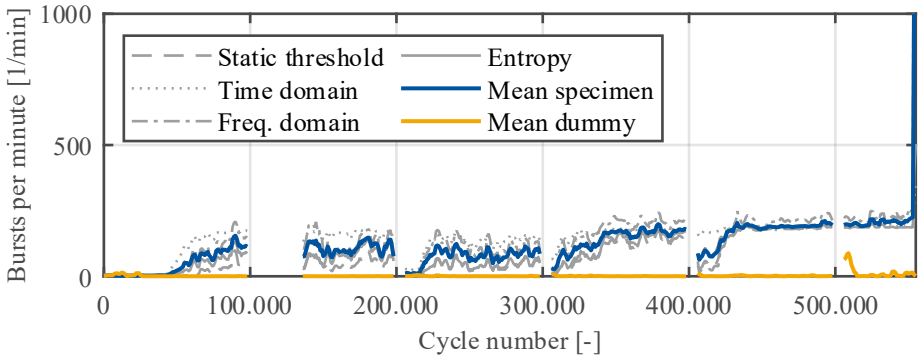

Figure 4-3: Results of burst detection with different approaches for both specimens.

Next, the focus is placed on the characterization of the detected bursts. For each identified burst, its amplitude, duration, and the number of threshold crossings are determined. During each acquisition phase (every 1k cycles for a period of 60 seconds), these parameters are averaged to obtain representative values. The normalized results are presented in **Figure 4-4** for the investigated and the dummy specimen.

The few bursts detected for the dummy specimen do not exhibit any consistent pattern or correlation, and there is almost no variation in their characteristic features from the beginning to the end of the test. In contrast, the burst features of the investigated specimen show a distinct evolution over time. The maximum values for amplitude, duration, and threshold crossings are observed near the end of the test, close to the point of final crack breakthrough. Similar to the trend in the overall burst count, these features remain nearly constant up to approximately 300k cycles, after which a gradual increase is observed, culminating in a pronounced rise shortly before failure.

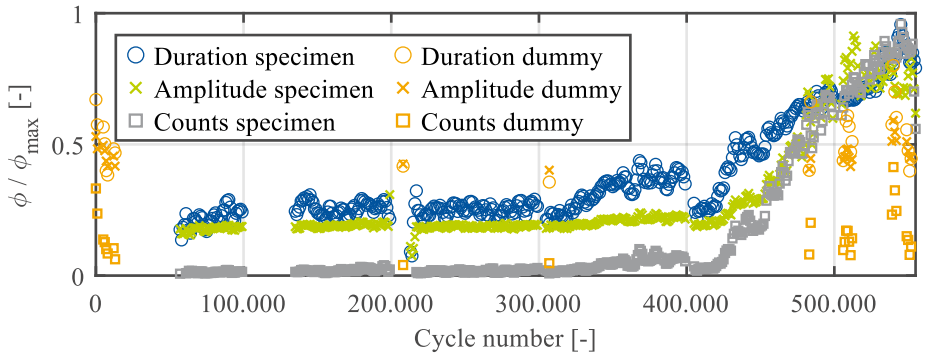

Figure 4-4: Characteristic features of detected bursts for both specimens.

To get a better understanding of the burst activity in relation to the load cycle, **Figure 4-5** illustrates the timing of cumulative burst occurrences within defined cycle intervals over one averaged pressure cycle. During the first 500k cycles, almost all bursts appear right at the onset of pressure increase (approximately 5.5 % of the cycle). As shown for the intervals between 510k to 550k cycles, both the timing of the bursts relative to the pressure rise and their count remain largely unchanged. Only during the last 5k cycles bursts also appear throughout the high-pressure phase.

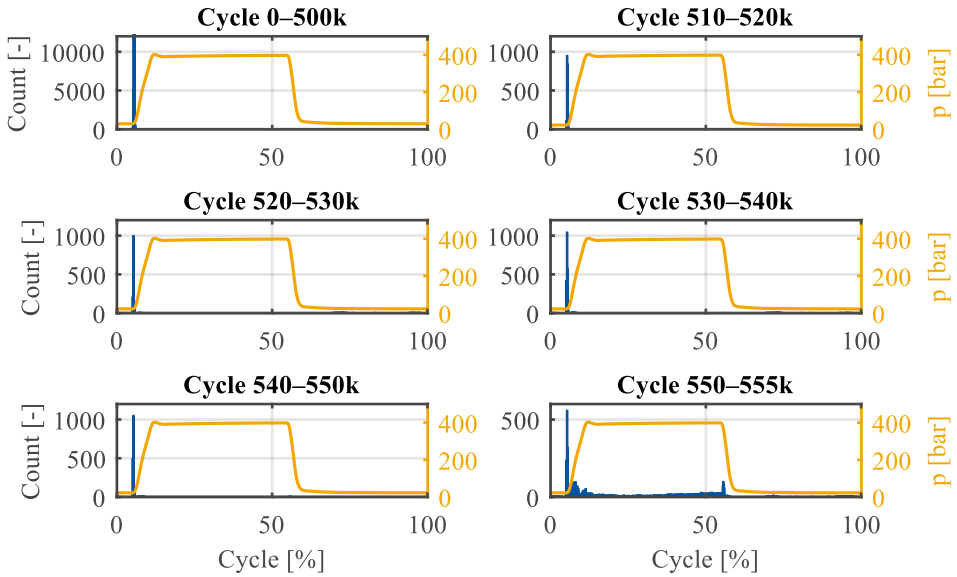

Figure 4-5: Cumulative cycle count for distinct intervals over pressure cycle.

5. DISCUSSION

The observed AE activity correlates strongly with the occurrence of cracking in the investigated specimen. Since the dummy specimen shows no notable change in signal characteristics, the AE sources in the specimen are likely associated with crack propagation. During the crack initiation phase, almost no AE activity is detected. This is followed by a long period of stable crack growth, characterized by nearly constant burst counts and signal features. Toward the end of the test, a phase of unstable crack growth is observed, during which both the number of detected bursts and their characteristic features (amplitude and duration) increase significantly.

However, it is unlikely that all AE activity originates solely from crack propagation. Other potential AE sources include plastic deformation, erosion, corrosion, impacts, and leakage. In addition, the pressure transducer and other hydraulic components in the pressure impulse test rig can generate spurious signals that interfere with AE detection and are audible to the human ear.

Interestingly, the highest AE activity is observed at the beginning of the pressure increase, when the maximum stress intensity at the crack tip has not yet been reached. This suggests that these detections are not only related to crack growth. Instead, they are likely associated with the sealing system of the specimen. The test specimen is sealed using an O-ring, which, due to design, exhibits slight play within its groove. Post-test inspection revealed some abrasion of the O-ring, indicating movement and potential gap extrusion, which could generate AE signals.

To mitigate this effect, a revised sealing concept is proposed, for example, using copper or flat gaskets to achieve a more stable and rigid seal. Additionally, flange deformation was observed during testing, which likely reduced the preload of the sealing assembly and further

contributed to AE noise. Future test setups will employ a stiffer specimen geometry and more uniform clamping with six instead of four bolts. These measures aim to minimize external interferences and enhance the reliability of AE-based crack detection.

To unambiguously attribute AE activity to the source of crack propagation, the implementation of a source localization strategy is suitable. By mounting two AE sensors on the same specimen, the origin of AE events can be determined from the arrival time difference of the signals in combination with the known acoustic wave velocity of the material [24].

To further improve signal quality, a noise-canceling approach can be implemented by using one AE sensor on the specimen and a second on the dummy specimen. The signal from the dummy specimen serves as a reference for background and system noise and can be subtracted from the specimen signal, for example, by applying methods such as continuous wavelet transform (CWT) or cross-correlation. This approach allows for the suppression of noise originating from the test setup, hydraulic system, or other external sources.

For signal evaluation, a manual analysis approach quickly becomes impractical due to the large volume of acquired data. Therefore, machine learning techniques are particularly suitable for the classification and analysis of AE signals. With the existing feature extraction (amplitude, duration, counts, entropy, etc.), the fundamental basis for applying such algorithms is already established. Future work may thus focus on developing automated workflows that use these features for clustering, pattern recognition, or predictive modeling of crack propagation behavior.

6. SUMMARY

This work demonstrates the application of AE techniques for the detection of fatigue cracks in hydraulic components during cyclic pressure impulse testing to investigate the influence of viscous fluids on crack propagation. The study introduces the experimental setup for both pressure impulse and AE measurements and addresses common challenges associated with AE measurements, such as the influence of background noise and the handling of large data volumes.

A dedicated data acquisition and evaluation framework was developed to capture and subsequently analyze AE signals during pressure impulse testing. The result shows crack propagation until final fracture. By comparing AE signals from the test specimen with those from a dummy specimen, which did not form cracks, AE activity related to crack growth could be identified.

Nevertheless, some uncertainty remains regarding the unambiguous attribution of AE activity to the crack propagation source, as AE signals are strongly affected by operational conditions, environmental influences, and especially sealing system behavior. Future work will focus on minimizing these uncertainties through optimized specimen and sealing design, as well as by advancing data analysis techniques using machine learning for automated signal classification and source localization.

Biographies

Lukas Boden obtained his master's degree in mechanical engineering at RWTH Aachen University in 2023. Since then, he is working as a research assistant at the Institute for Fluid Power Drives and Systems (ifas), focussing on identifying the influence of viscous fluid on fatigue crack propagation in fluid power components.

Fabian Blatter studied mechanical engineering at the Karlsruhe Institute of Technology. He is currently working as a Research Associate at the Department of Mobile Machines at the Karlsruhe Institute of Technology. His research areas include simulation of fluid-structure-interaction and hydraulic applications.

Prof. Dr.-Ing. Marcus Geimer received the Diploma degree in mechanical engineering from the RWTH Aachen University, Germany, in 1990, and the Ph.D. degree from the Institute of Hydraulics and Pneumatics, today named the Institute for Fluid Power Drives and Systems, RWTH Aachen University. Since 2005, he has been a Full Professor and the Director of the Institute of Mobile Machines (Mobima), Karlsruhe Institute of Technology

(KIT), Germany. He started his industrial career in 1995 in the field of construction at the company Krupp Berco Bautechnik GmbH, Germany, where he was the Leader of the research group for hydraulic breakers. In 2000, he was with Bucher Hydraulics GmbH, Germany, where he led the construction and customer development for mobile hydraulics.

Prof. Katharina Schmitz studied mechanical and chemical engineering at RWTH Aachen University and Carnegie Mellon University, Pittsburgh (USA) and graduated 2015 as Dr.-Ing. at RWTH Aachen University. Since 2018, she is full professor at RWTH Aachen University and director of the Institute for Fluid Power Drives and Systems (ifas). In addition, she is Vice Dean of the Faculty for Mechanical Engineering at RWTH Aachen, a position she holds since 2020. Prof. Schmitz's awards and honors include several best paper awards and 2023 IMechE Joseph Bramah Medal award.

Investigation of Fatigue Crack Growth under high Pressure Gradients with a Fluid-Structure-Interaction Model

Abstract.

Hydraulic components in mobile machinery are increasingly exposed to dynamic high-pressure gradients, which can accelerate fatigue crack growth and affect component reliability. This study investigates fluid-induced fatigue crack propagation by implementing a newly developed test specimen within an existing fluid–structure interaction (FSI) simulation framework. The specimen was designed to enable reproducible crack initiation, measurable crack propagation, and efficient manufacturability for experimental validation. FSI simulations were conducted across multiple crack lengths and pressure loading configurations to examine the influence of pressure drop and build-up rates. The results indicate that fluid effects, such as hydrostatic pressure and fluid-induced crack closure, modify the effective stress intensity factor (effective SIF) and the corresponding crack growth rates. While the observed trends are generally consistent with Paris' law, the influence of pressure gradients appears limited within the investigated range. Overall, the study highlights existing gaps in understanding fluid-induced crack propagation in hydraulic components and underscores the need for further experimental and numerical investigations, particularly given contradictory findings in previous work.

Keywords. Fluid-structure interaction, fatigue crack propagation, fluid-induced crack closure, pressure gradients

1. INTRODUCTION

Hydraulic systems are frequently exposed to highly dynamic load changes during operation that result in significant and constant changes of pressure. High pressure gradients can occur in different components of a hydraulic system such as axial piston pumps or throttle and orifice geometries of valves. Pressure gradients of up to 1.000 kbar/s have been reported for some of these components [1]. Previous studies have shown that drop rates of pressure in particular have an influence on the propagation rate of fatigue cracks [2, 3]. Under such

All Open Access articles are peer-reviewed, distributed under the Creative Commons Attribution-Non Commercial 4.0 International

conditions, fatigue strength becomes a more decisive criterion. Although design strategies exist that successfully increase the service life of critical regions, they cannot fully eliminate fatigue-related failures. As a result, material fatigue remains a fundamental challenge.

The challenge intensifies in the context of mobile hydraulic applications and increasing power densities, where lightweight components offer clear advantages. However, the reduced and targeted material use required for lighter constructions also increases the likelihood of crack failure. Therefore, a strong need exists to better understand and predict crack growth mechanisms in hydraulic components.

The present work investigates fluid-induced fatigue crack growth using a FSI approach. A new test specimen is developed and implemented within an existing FSI simulation framework originally proposed by Michiels [4]. The paper focuses on the design of this test specimen and on the presentation of simulation results obtained with the updated test specimen. The simulation framework has so far been tested with only one specimen and has shown limitations. These limitations motivate further investigations, particularly with regard to the influence of pressure gradients on fatigue crack growth. The simulation results presented in this paper serve as reference data for future comparisons, including pressure distributions within the crack, calculated SIFs, and resulting crack propagation rates. The updated specimen will be used for the development and validation of a new FSI approach that addresses the limitations of the current framework. The overarching goal of this research is to enable a reliable estimation of crack growth rates of fluid-induced fatigue cracks, which could be used to define inspection intervals for hydraulic components or to replace critical parts prior to failure.

2. Effects on Crack Propagation of Fluid-filled Cracks

This research focuses on fatigue crack propagation in hydraulic components under cyclic loading. Specifically, it investigates fluid-filled cracks, where crack growth is driven by pressurized fluid both inside and outside the crack. In fracture mechanics, several parameters are essential to describe crack behaviour under cyclic loading. The most fundamental loading case mode I (opening mode) is shown in Figure 2.1, where the load acts perpendicular to the x-z-plane and drives the crack faces apart [5].

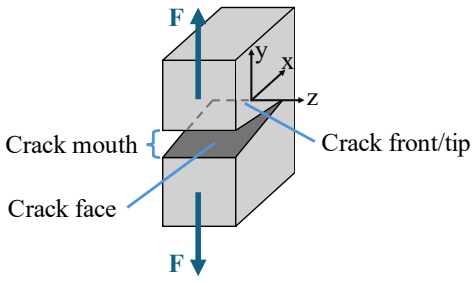

Figure 2.1. Description of the crack mode I (opening mode) and components of the crack

The governing parameter for characterizing the stress field at the crack tip is the stress intensity factor (SIF) K. It is described by the far-field applied stress σ, the current crack length a in x-direction and the geometric correction factor f as [5]:

$$K = \sigma\sqrt{\pi a} \cdot f \qquad (2.1)$$

The R-ratio defines the ratio of minimum to maximum stress σ_{min} and σ_{max} in a load cycle [6]:

$$R = \frac{\sigma_{min}}{\sigma_{max}} \qquad (2.2)$$

The SIF range ΔK is the difference between the minimum and maximum SIF [6]:

$$\Delta K = K_{max} - K_{min} \qquad (2.3)$$

Paris' law from 1963 shows that a decreasing SIF range ΔK reduces the crack propagation. It expresses the relationship between the crack propagation rate da/dN (N is the number of applied cycles) and the SIF range ΔK together with the constants C_p and m_p that depend on the material, temperature, environmental medium and load as [7]:

$$\frac{da}{dN} = C_p \cdot \Delta K^{m_p} \qquad (2.4)$$

Typically, no load is applied to the crack faces [5]. If hydrostatic fluid pressure acts on the crack faces it increases the crack propagation rate [3]. The penetration of fluid also influences the contact behaviour of the crack surfaces. When a pressure drop occurs rapidly in a fluid-filled crack, the fluid cannot completely escape and remains trapped inside the crack. The fluid remaining in the crack indirectly connects the crack faces and prevents a complete return to the original state. When the load is increased again, the crack remains closed to a certain load level. As a result, the crack is not open during the entire loading cycle. Crack closure was first discovered by Elber [8]. Figure 2.2 shows the curve of the SIF over time with and without crack closure effect. In the following, the SIFs are denoted with the subscript I, since the loading discussed in this paper is predominantly mode I.

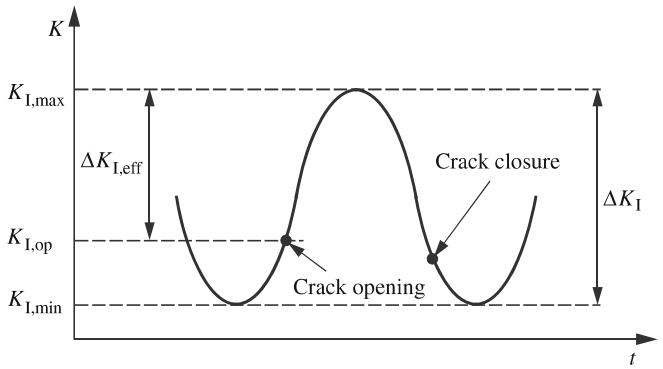

Figure 2.2. Comparison of the SIF with and without crack closure effect [9]

With crack closure effects the effective SIF range $\Delta K_{I,eff}$ is reduced. According to Paris' law it can extend a component's lifetime compared to a crack without entrapped fluid [9, 10]. The classical computation of the SIF ΔK_I doesn't cover shielding effects like crack closure

[11]. Therefore, the effective SIF range $\Delta K_{I,eff}$ covering crack closure is calculated with the maximum applied SIF $K_{I,max}$ and the crack opening SIF $K_{I,op}$ [9, 10]:

$$\Delta K_{I,eff} = K_{I,max} - K_{I,op} \qquad (2.5)$$

Other known crack closure phenomena are plasticity induced, roughness induced, and oxide induced crack closure. Plasticity-induced closure originates from residual deformation in the crack wake, roughness-induced closure from mismatch of the fracture surfaces, and oxide-induced closure from the buildup of corrosion products [5].

Investigations of fluid-induced crack closure are primarily found in related research fields, for example on railway wheel–rail systems and submerged fatigue specimens. For submerged specimens, it has been demonstrated that fluid-filled fatigue cracks exhibit a reduced crack propagation rate compared to air-filled cracks. This is due to fluid-induced crack closure and the reduced effective SIF ΔK_{eff}. [12]

Similar mechanisms have been identified in railway tracks, where fatigue cracks propagate mainly due to entrapped fluid. Under rolling contact, surface cracks open due to traction forces, allowing fluid to penetrate the crack. As the wheel passes and forces the crack mouth to close, the trapped fluid becomes pressurized, generating tensile and shear stresses on the crack faces that accelerate crack growth in the direction of wheel motion. [13, 14, 15] In the absence of fluid, such crack growth is largely suppressed [15].

Numerical and experimental investigations of pressurized cracks have shown partially contradictory results. In [4], simulations of fully fluid-filled cracks indicated that neither the pressure build-up rate nor the pressure drop rate significantly affect the stress amplitude at the crack tip and therefore the crack propagation rate. In contrast, corresponding experiments showed a significant influence of the pressure drop rate on the crack propagation rate.

Despite these studies, the mechanisms behind fluid penetration into fatigue cracks in hydraulic components are not fully understood. There is a lack of systematic investigation into how externally pressurized fluids penetrate and interact with fatigue cracks under cyclic loading. Furthermore, how the interaction of the fluid with the mechanical structure affects the effective SIF of fatigue cracks in hydraulic components has not been fully quantified. Addressing these questions constitutes a critical research gap, especially for the reliable lifetime prediction of hydraulically loaded components under cyclic loading.

3. INTRODUCTION TO FSI APPROACH OF MICHIELS

The interaction between solids and fluids is a multi-physics problem, which is addressed in this study through a two-way fluid–structure coupling. The FSI framework is proposed by Michiels [4] and is summarized in this chapter with a focus on its most relevant characteristics. For a detailed description, the reader is referred to the original publication. The FSI approach avoids fully fluid and structural simulations (e.g. through the finite element method) and instead employs reduced-order models for both the structural and fluid domain. Input parameters for the FSI model include the applied load, weight functions, and flow factors. Weight functions correlate the load to the structural deformation, while flow factors account for roughness effects in narrow crack flows. Both were determined prior in pre-processing steps. The simulation is conducted for a fixed crack length. The resulting outputs of the coupled FSI are the pressure field and fluid flow inside the crack and its crack

opening displacement (COD). The crack is discretized into N stripes with a constant length Δx, shown in Figure 3.1. This model is referred to as strip model and uses the same discretization for the fluid inside the crack.

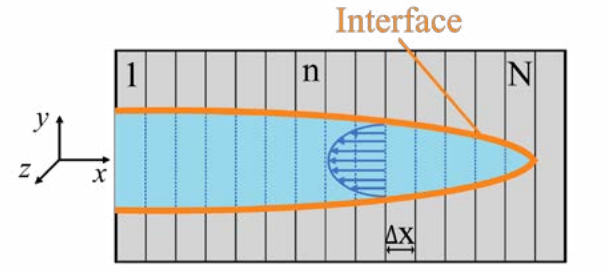

Figure 3.1. Discretization of the crack and the fluid into N stripes. The structural domain is shown in grey, the fluid domain in blue and the interface between both in orange.

Fluid pressure acting on the crack faces is transferred to the structural domain, while the resulting structural displacements are transferred back into the fluid domain, shown in the following Figure 3.2.

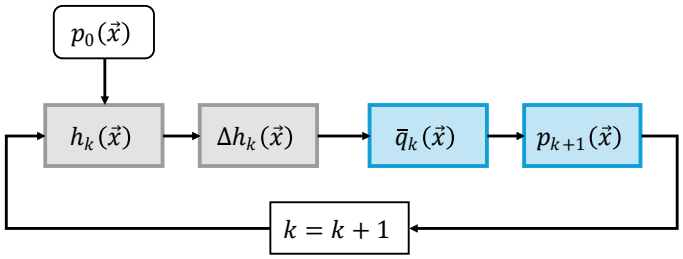

Figure 3.2. Iteration through the two-way coupled FSI with the structural domain in grey and the fluid domain in blue during a timestep k.

At the first timestep k = 0, the initial pressure p_0 is given as 0 bar and transferred to the mechanical domain. The crack height h is calculated with the given arbitrary pressure p and the weight functions, in the following given in matrix notation as W, while ξ describes the centre of a stripe.

$$h(\vec{x} = \vec{\xi}) = \mathbf{W}p(\vec{x}) \qquad (3.1)$$

The used weight functions depend only on the geometry including the crack and are independent from the applied load. They are calculated for the examined specimen with discrete crack lengths via finite element method in a pre-processing step. The detailed calculation procedure of the weight functions can also be found in [4]. Assuming linear elastic material behaviour, the total deformation is obtained by superposition of the deformations induced by individual load contributions. The pressure force acting from the fluid on the crack surface is decomposed into N+1 subparts. One associated with the displacement caused by external forces, like a pressure chamber, and N corresponding to the individual crack sections called stripes.

The resulting structural displacement Δh calculated from equation 3.1 is transferred to the fluid domain. The fluid domain describes the fluid flow inside the crack as a planar flow, neglecting the crack width, and is modelled using an adapted thin-film flow formulation, which is appropriate due to the small crack opening relative to its length. The governing equations are derived from the Navier–Stokes equations under laminar flow assumptions and discretized along the crack using the same spatial resolution as the structural strip model. In addition, the fluid flow is assumed to be fully developed, which is consistent with the neglect of fluid inertia effects. To account for the influence of surface roughness on flow resistance, flow factors are introduced. They represent the reduction in flow capacity caused by rough crack surfaces. The use of flow factors $\theta \in [0,1]$ enables the model to capture roughness-induced flow restriction without explicitly resolving surface topography. They compare the average pressure flow through rough gaps relative to that through smooth gaps. The average Reynolds equation using flow factors was introduced by Patir and Cheng in 1978 [16, 17]. The averaged volume flow per unit length $\bar{q}$ along the crack in x-direction is given by

$$\bar{q} = -\theta \frac{h^3}{12\eta} \frac{\partial p}{\partial x} \qquad (3.2)$$

where h denotes the crack opening and η the dynamic viscosity. For a perfectly smooth surface θ equals 1. The pressure p of the following time step k = k + 1 is calculated by the following equation with the density ρ, reference density ρ_0 and the bulk modulus K:

$$\frac{\partial p}{\partial t} = -\left(\frac{\partial(\rho \bar{q})}{\partial x} + \rho \frac{\partial h}{\partial t}\right) \frac{K}{\rho_0 h} \qquad (3.3)$$

4. TEST SPECIMEN GEOMETRY

A test specimen geometry was proposed by Michiels in [4], which is shown in Figure 4.1. It contains an internal pressure chamber with a notch. Under pressurization, mechanical deformation and stress are induced. Due to the increased stress concentration at the notch root, a crack initiates from this location and subsequently propagates. Since the crack originates from the interior pressure chamber, it remains in contact with the pressurized fluid, that can flow into and out of the crack. The fracture process is predominantly Mode I.

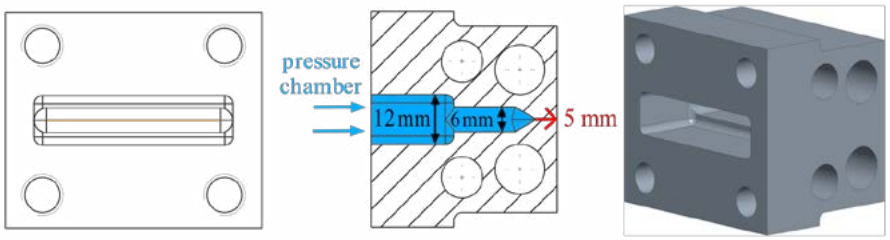

Figure 4.1. Proposed test specimen in [4]. Test specimen contains four threaded holes, a pressure chamber (blue), a notch (orange) and four relief holes. The ligament of the uncracked specimen with a length of 5 mm is shown in red.

According to [4], the experimental configuration enables a stable crack growth regime without causing catastrophic rupture of the structure, allowing the influence of fluid-induced crack closure and fluid flow within the crack to be investigated. Furthermore, it provides a basis for assessing the transferability between planar two-dimensional simulations and three-dimensional test specimens. However, several limitations are associated with this specimen design for experiments on a hydraulic test rig:

- The specimen geometry is complex (threads, geometry of pressure chamber, relief holes) and therefore requires considerable time to manufacture. For future investigations a broader validation campaign is planned with a larger number of specimens to investigate several load configurations (see chapter 4).
- Manufacturing constraints, as a sharp notch cannot be produced with conventional machining like milling. A residual radius remains and varies due to tool wear, resulting in geometric inconsistencies.
- Crack initiation can occur at any location along the notch shown in Figure 4.1, which reduces reproducibility. Also, several cracks can be initiated along the notch during testing.
- The remaining ligament is short, allowing a maximum crack extension of only 5 mm. A longer ligament provides more opportunities to monitor relevant crack growth effects and allows observations over a larger crack length.
- The internal volume is comparatively large. Since the objective is not to measure compression-induced volumetric flow, a minimal dead volume is required.
- Crack breakthrough was observed only after averaged 812k load cycles, representing an excessively high cycle count.

Therefore, a new test specimen is proposed. The following additional requirements are defined for its geometry:

- Less complex test specimen geometry to ensure efficient and reproducible production as well as economical manufacturability.
- Sufficient remaining ligament to allow measurable crack growth and data acquisition over a range of crack lengths.
- Reproducible crack initiation at a defined location within the specimen with only one crack developing per test specimen.
- Rapid crack initiation to minimize the number of load cycles required in total.
- Consistent crack length through minimal geometric variation between specimens in the region from the notch to the opposite side.
- Minimal plastic deformation, as excessive plastic strain may alter the material properties within the plastic zone and distort the fracture behaviour.
- Reduced internal volume to minimize the influence of compression-induced flow.
- Surfaces parallel and perpendicular to crack growth for sensor installation (strain gauge, temperature sensor, acoustic emission sensor).

According to those defined by Michiels and the additional requirements, a new specimen was developed (see Figure 4.2). A parameter study was conducted for the final geometric dimensions, varying the geometric properties of the specimen to achieve a favourable stress distribution for an assumed pressure of 400 bar.

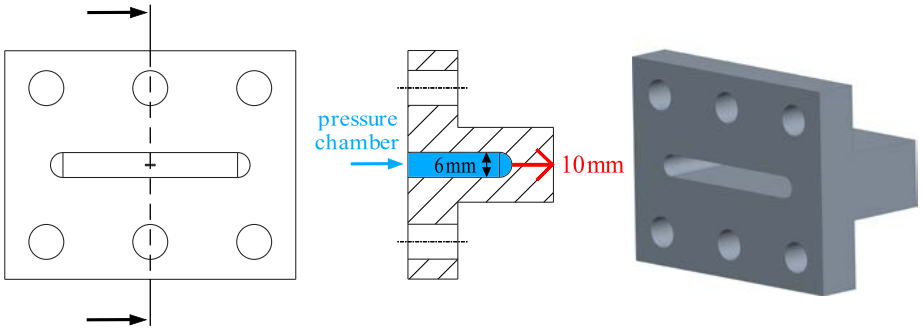

Figure 4.2. Updated test specimen according to the defined requirements. It contains a pressure chamber (blue) and six through holes for connecting the specimen to an adapter of the test stand. The ligament of the uncracked specimen with a length of 10 mm is shown in red.

In the revised specimen design, through holes were implemented instead of threaded holes, eliminating one manufacturing step. The threaded holes were relocated to the adapter, and due to the more slender geometry no relief holes were required. The pressure chamber was designed with a simplified geometry and its dead volume was reduced from 16221.3 mm^3 to 6816.35 mm^3, corresponding to a reduction of 58 %. Furthermore, the ligament thickness was increased from 5 to 10 mm in order to extend the achievable crack length. To ensure consistency across all manufactured test bodies, a more precise tolerance was introduced, resulting in a ligament length with a total deviation of 0.25 mm.

A considerable amount of lifetime is spent in crack initiation [9, 18, 19]. To shorten this phase and define a starting point for crack growth as defined above, micro-notches are introduced in the form of five micro-drilled holes. Cracks usually propagate from discontinuities in geometry like holes, notches or shoulders, where stress concentrations occur. The use of micro-drilled holes for this purpose is a common practice in fracture mechanics testing, as shown in [20, 21]. In the section view of the test specimen in Figure 4.3 the micro-notches are implemented at the center of the inner cavity. This study also focuses on crack propagation rather than initiation, as effects such as crack closure mainly occur during the propagation phase.

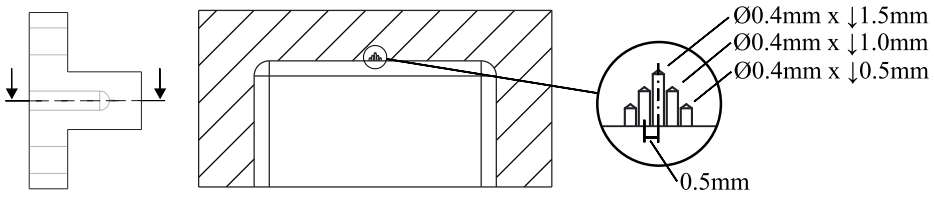

Figure 4.3. Sectional view of the test specimen showing the five micro-drilled holes inserted as micro-notches for a defined crack initiation.

To evaluate the stability of crack growth, a fatigue crack simulation was carried out using the SMART simulation tool within the FEM software Ansys [22]. The initial crack geometry was derived by the outer contour of the five micro-notches. For the crack propagation

simulation Paris' law and the material parameters $C_p = 1.25 \cdot 10^{-9}$ and m_p = 3.38 were used [9]. A maximum pressure of 400 bar and an R-ratio of 0.1 were applied. Also, no FSI inside the crack was considered for this step. Figure 4.4 shows the simulated crack front geometries for different crack lengths.

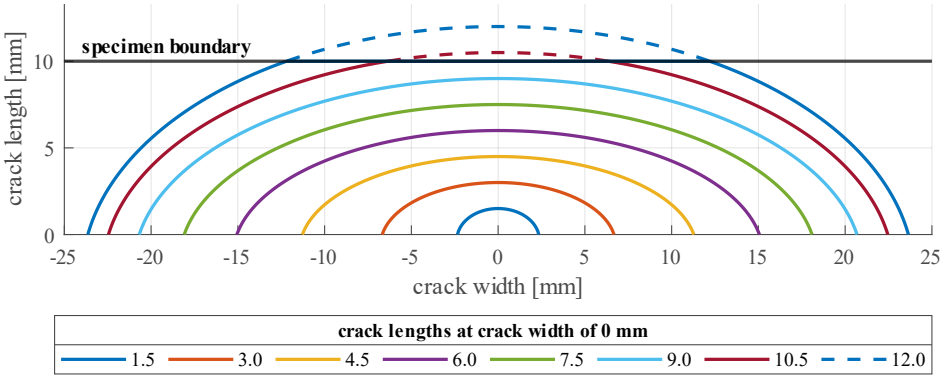

Figure 4.4. Approximated crack front geometries for several crack lengths

The calculated ΔK_I values for crack lengths between 1.5 and 10 mm are presented in Figure 4.5, starting at 1.5 mm due to the micro-notches. The values of ΔK_I remain above the threshold for fatigue crack growth of S235 for R=0.1, $\Delta K_{I,th}$ = 10.2 MPa√m [9]. For structural steels in general, ΔK_{IC}-values between 50 and 150 MPa√m are common [23]. Consequently, the results indicate that stable fatigue crack growth is expected under the investigated loading conditions. The final steep increase in ΔK_I is caused by the reduction in remaining ligament length.

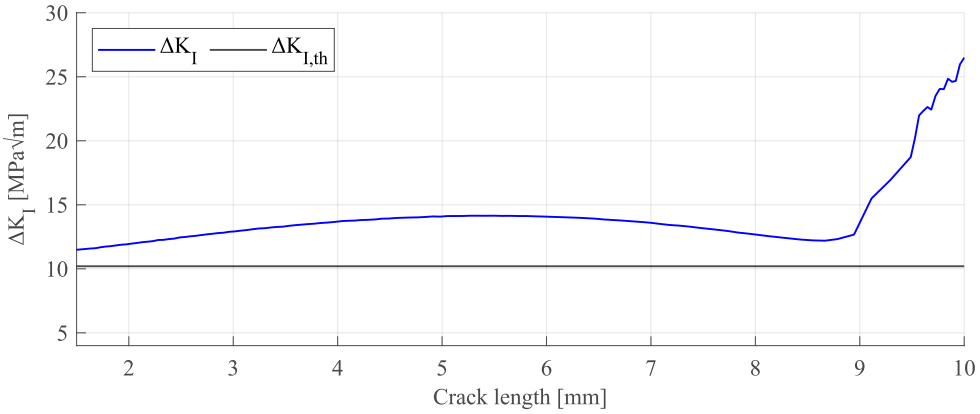

Figure 4.5. Simulated ΔK_I without considering FSI inside the crack shown for crack lengths of 1.5 to 10 mm.

5. RESULTS OF THE FSI APPROACH

The load profile under investigation (Figure 5.1) consists of the low-pressure level p_{min}, the pressure build-up dp_{bu}/dt , the high-pressure level p_{max} and the pressure drop dp_{dr}/dt.

The partitioning of the load cycle ensures that the individual load components are clearly separated and can therefore be investigated in a targeted manner. Furthermore, the interactions of pressure levels, holding times and pressure gradients can be examined. The low-pressure duration t_{LP} includes the period at low pressure and the pressure build-up, while the high-pressure duration t_{HP} includes the period at high pressure and the pressure drop. From these durations, a frequency f can be derived to further describe the cyclic load:

$$f = \frac{1}{t_{LP} + t_{HP}} \qquad (5.1)$$

Additionally, a high-to-low-pressure-duration ratio R_t is introduced:

$$R_t = \frac{t_{HP}}{t_{LP}} \qquad (5.2)$$

The load profile was also used in Michiels [4] and is inspired by pressure impulse tests, e.g. described in EN ISO 6803:2017.

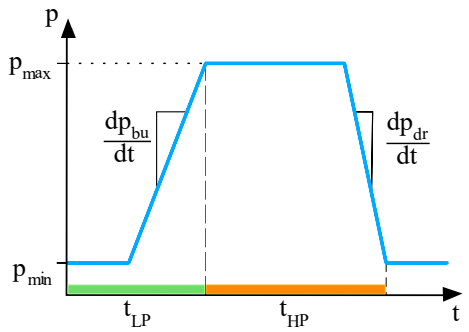

Figure 5.1. Schematic pressure load profile of the test specimen with the duration

The pressure build-up gradient was varied at three levels: 5, 12.5 and 20 kbar/s. The pressure drop gradient was varied at 5, 25 and 45 kbar/s. As this study focuses on pressure gradients, the maximum and minimum pressures were kept constant at p_{max} = 400 bar and p_{min} = 40 bar, respectively. The high-to-low pressure duration ratio was set to R_t = 1 and the excitation frequency to 6 Hz. The FSI simulations were performed for six discrete crack lengths a ∈ {1.5, 3, 4.5, 6, 7.5, 9} mm. Figure 5.2 shows the pressure profile over two load pulses within a crack of length a = 4.5 mm at different positions, for a pressure drop gradient of dp_{dr}/dt = 45 kbar/s and a pressure build-up gradient of dp_{bu}/dt = 12.5 kbar/s.

During pressure build-up, the pressure inside the crack increases with a noticeable delay compared to the system pressure in the pressure chamber. This delay is greater at positions deeper inside the crack. The duration of the investigated high-pressure phase is sufficient to approach the system pressure in the entire crack volume. After the system pressure drops, pressure peaks occur at various positions along the crack. This behaviour suggests that fluid is being entrapped during crack closure, leading to localized pressure increases. The highest pressure of 1440 bar is observed at the crack tip. In contrast, close to the crack mouth at x = 0.25 mm, the pressure decreased without returning to the initial low-pressure level p_{min}. The pressure at the crack mouth equals the system pressure during the whole load cycle due to the set boundary condition.

As the system pressure remains at a low-pressure level following the pressure drop, fluid can gradually escape the crack, resulting in decreasing pressure. A renewed pressure increase in the pressure chamber initially causes a pressure release at the observed positions. Close to the crack mouth (at x = 0.25 mm), the pressure drops shortly before increasing to the system pressure again. Deeper inside the crack the pressure drops to 0 bar and remains at this pressure level for a short period. While a low pressure inside the crack can be explained by the rapid opening of the crack in response to the pressure increase in the pressure chamber, the recorded value of 0 bar is still unrealistically low. This discrepancy is likely caused by insufficient volume flow in the model. Pressure close to the crack mouth does not drop to 0 bar, because of the resupply from the pressure chamber. The 0 bar pressure level is again followed by a subsequent increase to the system pressure that is delayed the deeper inside the crack. The high pressure duration is long enough to allow pressure equalization to p_{max} throughout the crack. In comparison to the former specimen with a shorter ligament of 5 mm, [4], the current simulated pressure profiles follow an equal pattern for a similar crack length.

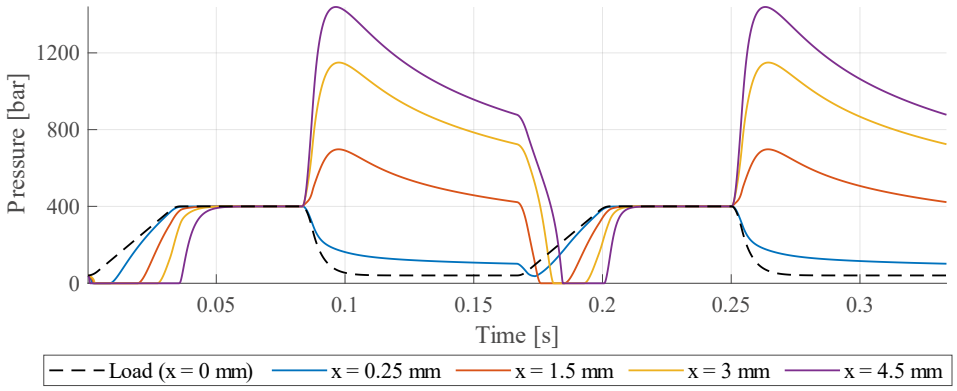

Figure 5.2. Pressure profile along the crack length a = 4.5 mm at various positions over time. The coordinate x = 0 mm corresponds to the crack mouth connected to the pressure chamber, while x = 4.5 mm represents the crack tip. The pressure distribution results from a load applied in two successive pulses.

Figure 5.2 displays the Mode I SIFs together with the corresponding system pressure over time for a crack length of 4.5 mm and the described load configuration. To evaluate the influence of the FSI, the SIF was calculated both with and without considering the fluid in the crack. The FSI accounts for hydrostatic pressure acting on the crack faces as well as fluid-induced crack closure effects. Without FSI, the SIF shows a strong correlation with the system pressure and the SIF range ΔK_I spans a wide interval. When fluid effects are considered $\Delta K_{I,eff}$ is reduced, indicating a lower crack propagation rate according to Paris' law (equation 2.4). Although higher peak values of the SIF are observed, the SIF does not drop significantly, presumably due to crack closure mechanisms. Overall, the comparison of SIF with and without FSI is in good agreement with the theoretical predictions of chapter 2, confirming that the influence of fluid on crack propagation is captured by the model.

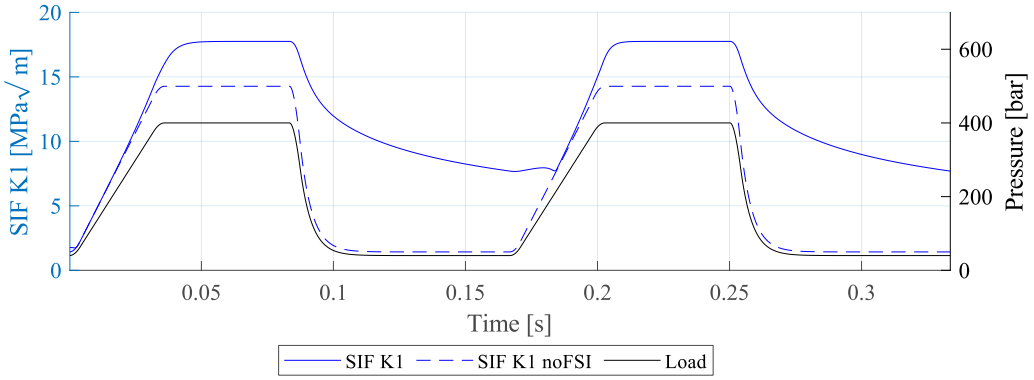

Figure 5.3. Comparison of the SIFs with and without considering the FSI (hydrostatic pressure on crack faces and fluid-induced crack closure). Left axis displays the mode I SIF, the right axis the corresponding system pressure.

According to Paris' law and the above-mentioned material parameters, this load case leads to a crack propagation rate of 0.729 µm per 1000 cycles for the evaluated crack length and load configuration, considering the FSI. Without the hydrostatic pressure and crack closure effects a crack growth rate of 1.5 µm per 1000 cycles was calculated, indicating a faster crack propagation due to a higher effective SIF range $\Delta K_{I,eff}$ at the crack tip for cracks without FSI. Figure 5.4 compares the mean crack propagation rate as a function of pressure drop rate and pressure build-up rate for cases with and without FSI effects averaged over the crack lengths. Crack propagation increases slightly as the pressure drop rate rises, with even higher growth rates predicted when FSI is neglected. In contrast, the influence of pressure build-up rate is comparatively weak, with only minor variations in crack propagation observed.

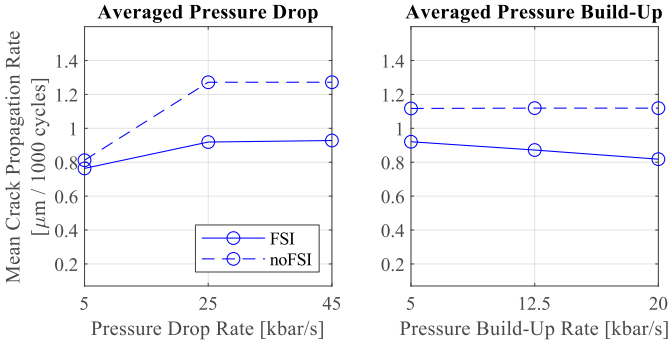

Figure 5.4. Comparison of the average crack propagation rate with and without FSI as a function of pressure drop rate and pressure rise rate. The values shown are averaged over the crack lengths (main effects).

Figure 5.5 shows the crack propagation rates of the discretely simulated crack lengths as a function of the pressure drop and build-up rates. These values primarily serve as a reference for comparison in future investigations. A clear trend can be observed indicating that the

crack propagation rate increases with increasing crack length, corresponding with the introduced crack propagation law by Paris (equation 2.4).

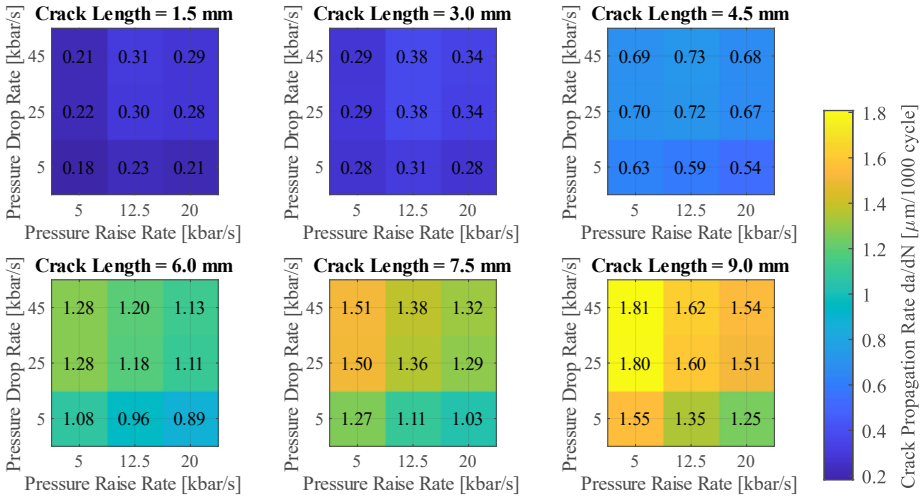

Figure 5.5. Crack propagation rates of discretely simulated crack lengths as a function of pressure drop and build-up rates and considering FSI effects.

6. Discussion and Outlook

In this work, a new version of the test specimen was developed according to extended and refined requirements to enable reproducible crack initiation, longer measurable crack propagation, and efficient manufacturability for a larger test campaign. Simulations showed that the test specimen experiences stable crack propagation without FSI under cyclic loading. The new specimen was implemented into the existing FSI framework. A plausible pressure profile for the first pressurization is achieved. However, during the second pressurization an unexpected depressurization down to 0 bar is observed, motivating a refinement of the simulation in the future. Furthermore, crack propagation rates for all configurations of pressure build-up and drop rate have been simulated. Within the considered interval, an increase in pressure drop rate shows a small influence on fatigue, resulting in a slightly shorter lifetime, while the build-up rate does not have a significant effect. The calculated values serve primarily as a reference point for future improvements.

In future work, the fluid domain should be extended to account for the crack width in a two-dimensional formulation. Fluid flow within the crack is expected to occur not only in the primary x-direction, but also in multiple directions within the crack plane. Introducing an additional spatial dimension would require the definition of an associated flow factor for this direction. As flow factors are defined along main roughness directions [17], this introduces a strong directional dependence of the surface roughness representation and consequently, of the volume flow. For non-isotropic roughness, this assumption is only valid if defined main roughness directions exist and agree with the directions for which the flow factors are defined. Otherwise, the resulting flow description becomes inaccurate. Alternatively, a different approach for modelling surface roughness should be employed. In [24], Rom et al.

compared the average flow model proposed by Patir and Cheng with a homogenization-based approach using a journal and slider bearing. They showed that the homogenization approach provides higher accuracy in predicting averaged pressure distributions while maintaining a comparable computational cost. Furthermore, the homogenization method can account for surface roughness of arbitrary anisotropy. In contrast to the flow factor approach, it offers greater flexibility when applied to non-isotropic surfaces.

Further limitations arise from the simplified fluid modelling assumptions. In particular, the assumptions of laminar, fully developed flow are insufficient to adequately represent the strongly transient flow conditions occurring within propagating cracks. In addition, possible cavitation effects resulting from the low pressure levels observed inside the crack after the pressure drop should be investigated.

Pulsation experiments will be used to compare and calibrate the current approach and following improvements. Furthermore, while the microholes have been considered in the calculation of the weight functions, their influence on the fluid flow, whose influence on fluid flow has not yet been considered will be addressed.

ACKNOWLEDGEMENTS

Feasibility of Electro-Hydrostatic Actuators in Wheel Loader Application: A Case Study Focusing on Energy Efficiency, Controllability and Thermal Behaviour

Abstract.

Hydraulic actuators are extensively applied in non-road mobile machinery (NRMM) owing to their high power-to-weight ratio, robustness, and compact design. Conventional systems, however, exhibit throttling losses in control valves, which limit efficiency. While drivetrain electrification has been widely studied, the electrification of working hydraulics with electro-hydrostatic actuators (EHAs) remains less explored. EHAs eliminate throttling losses and enable energy regeneration, yet their suitability for wheel loaders has not been thoroughly assessed. This study investigates the feasibility of EHAs in wheel loaders through MATLAB/Simulink simulations using measured load cycle data of a typical short Y-cycle. EHA-based and conventional systems are compared with respect to energy efficiency, while thermal behaviour under simulated power losses is analysed using a lumped-parameter model. The results indicate that EHAs exhibit satisfactory position tracking accuracy and markedly improve energy efficiency, while thermal management remains an aspect that must be considered for reliable operation. Thus, EHAs show considerable promise for NRMM applications, provided that they are implemented properly, including adequate cooling.

Keywords. Electro-hydrostatic actuator, electrification, wheel loader, energy efficiency, thermal management.

1. INTRODUCTION

Hydraulic actuators are widely used in non-road mobile machinery (NRMM), such as wheel loaders and excavators, due to their high power density, robustness, and compact design [1, 2]. However, conventional valve-controlled hydraulics suffer from low overall efficiency because of throttling losses in directional control valves [3]. Meanwhile, stricter emission regulations and the growing demand for energy efficiency highlight the need for alternative hydraulic architectures.

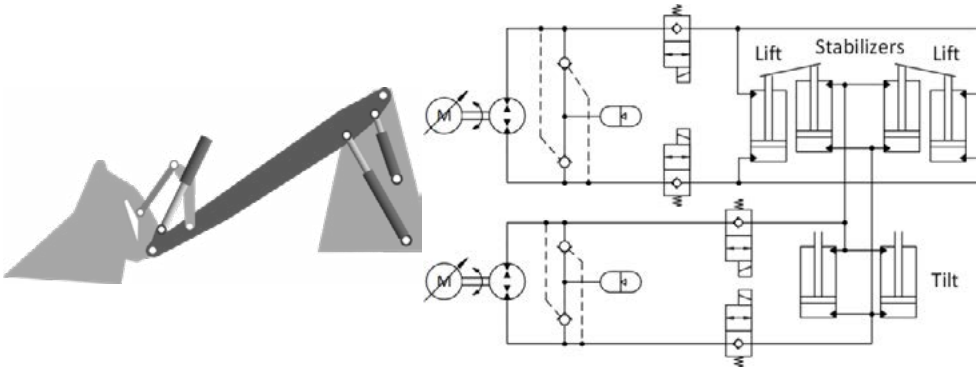
All Open Access articles are peer-reviewed, distributed under the Creative Commons Attribution-Non Commercial 4.0 International

Electrification offers a promising way to meet these requirements. While electric and hybrid drivetrains are already commercially available in NRMM, the electrification of working hydraulics remains less developed [4]. Electro-hydrostatic actuators (EHAs), in which an electric motor drives a hydraulic pump that directly supplies the actuator without control valves, can eliminate throttling losses and enable energy recovery [5, 6]. EHAs have been investigated in several NRMM applications, including mining loaders and excavators, focusing on efficiency improvements and alternative EHA concepts, such as high-speed implementations [7–11]. In wheel loader studies, EHAs have demonstrated significant efficiency gains over load-sensing (LS) systems but also indicated a need for thermal analysis [12].

Thermal behaviour is critical for closed-circuit EHAs, as they lack a reservoir that plays an important role in heat dissipation in conventional hydraulic systems. Elevated oil temperature reduces viscosity, accelerates component wear, and shortens the lifespan of hydraulic oil, thereby making temperature prediction essential during system design. High-fidelity thermal models exist but are computationally demanding for long duty cycles and often unnecessary in early-stage studies [13]. Lumped-parameter models provide a practical compromise, reducing data requirements and computational effort while maintaining sufficient accuracy [14]. Although thermal simulation studies of EHAs have been reported in the literature, for example by Michel et al. [15, 16], these focus on actuator sizes and load cycles that differ substantially from those encountered in wheel loader applications. Consequently, their results cannot be directly extrapolated to the present case, motivating a dedicated thermal simulation tailored to wheel loader operating conditions.

Most prior work addresses efficiency, controllability, or thermal behaviour in isolation and often relies on single-actuator setups, while also overlooking real load cycle data. However, trade-offs may arise between controllability, losses, and temperature rise, while position tracking accuracy may degrade in multi-actuator systems. This paper evaluates EHAs for wheel loader work functions holistically. Using measured duty-cycle and load data [17], a MATLAB/Simulink model with a high-fidelity mechanical boom representation compares an EHA system with an LS baseline. The analysis focuses on energy efficiency, controllability, and thermal behaviour under realistic load cycles to assess the feasibility of EHA integration in wheel loader application.

The remainder of this paper is organized as follows. Section 2 presents the system overview, including the boom structure and EHAs. Section 3 describes the system modelling. Simulation results are given in Section 4, followed by thermal modelling and analysis in Section 5. Section 6 concludes the paper.



2. OVERVIEW OF THE SYSTEM

The system is a 6-tonne wheel loader performing the short Y-cycle of gravel loading. The boom (Fig. 2.1) includes two primary working actuators: lift cylinders and tilt cylinders, and a pair of stabilising (self-levelling) cylinders that are kinematically linked to the lift mechanism. When the lift cylinders extend, the stabilising cylinders move accordingly and drive the tilt cylinders to maintain bucket orientation. In the proposed architecture, the working actuators are implemented as EHAs.

Each EHA employs single-rod (asymmetric) hydraulic cylinders. The unequal chamber volumes are compensated by differential-flow compensation implemented with check valves, which allow flow from a low-pressure accumulator to meet the additional demand on the rod side. Each actuator is isolated by a normally closed 2/2 poppet valve functioning as an on/off load-holding valve (LHV), included for both safety and efficiency. Relief valves protect the system against overload conditions.

The cylinders are supplied by bidirectional pump/motor units capable of four-quadrant operation. The pumps are driven by permanent magnet synchronous motors (PMSMs), enabling high efficiency and precise control. During motion commands, the load-holding valves are energised (open), and otherwise they hold the load.

In the present work, conventional electric motors and hydraulic pumps with a maximum speed of 4000 rpm are employed. However, decentralized EHA architectures generally require more installation space than centralised hydraulic systems, which must be considered during system design. This limitation may be mitigated by using high-speed drives, as demonstrated in [10], which enable higher power density.

3. SYSTEM MODELS

This section presents the system modelling. Section 3.1 develops the EHA model. Section 3.2 derives the electric power of the baseline LS system from measured data. Section 3.3 presents the EHA control architecture with PMSM current and speed control in the inner loops and position control in the outer loop.

3.1. EHA Model

The electro-hydrostatic actuators are modelled in MATLAB/Simulink, while the multibody dynamics of the wheel loader boom are represented in Simscape Multibody. The model incorporates boom and bucket inertias, gravitational effects, and linkage geometry. External loads such as payloads are not explicitly modelled but applied as an external force term derived from measured data. Actuator displacements are kinematically coupled to the linkage, and end-stop impacts are neglected as duty cycles remain within the stroke range.

The EHAs consist of a PMSM, an axial piston pump, hydraulic cylinders, accumulators, and auxiliary valves. The PMSM is described in the rotating d–q reference frame as

$$u_d = R_s i_d + L_d \frac{di_d}{dt} - P\omega L_q i_q \qquad u_q = R_s i_q + L_q \frac{di_q}{dt} + P\omega\left(L_d i_d + \phi_f\right) \tag{3.1}$$

$$T_e = \frac{3}{2} P\left(\phi_f i_q + \left(L_d - L_q\right) i_d i_q\right) \tag{3.2}$$

where u_d, u_q are stator voltages, i_d, i_q currents, R_s stator resistance, L_d, L_q inductances, P pole pairs, ω rotor speed, ϕ_f flux linkage (constant), and T_e electromagnetic torque. Motor parameters are taken from the Bosch Rexroth MS2N10-F0BHA (22.4 kW) datasheet [18].

The axial piston pump/motor is first expressed ideally as

$$Q_t = D_p \omega_p \qquad T_t = D_p \Delta p \tag{3.3}$$

where ω_p [rad/s] is the shaft speed, D_p [m^3/rad] the displacement, and $\Delta p = p_A - p_B$ the differential pressure over the pump/motor. Volumetric and mechanical losses are modelled using the analytical formulation of Huova et al. [19]. The actual flow rates to the A and B sides, and the shaft torque, are given by

$$\begin{aligned} Q_A &= Q_t - Q_{il} - Q_{el,A} \\ Q_B &= -Q_t + Q_{il} - Q_{el,B} \end{aligned} \qquad T_p = T_t + T_l \tag{3.4}$$

where Q_{il} and Q_{el} denote the internal and external leakages, and T_l the torque loss. The internal leakage Q_{il} is defined positive from the A-side to the B-side and may reverse direction depending on the pressure difference. External leakages depend on the pressure differences between the line and the accumulator.

Hydraulic cylinder chamber pressures are governed by

$$\frac{dp}{dt} = \frac{B_{eff}}{V}\left(\sum Q - \frac{dV}{dt}\right) \tag{3.5}$$

where B_{eff} is the effective bulk modulus, V the chamber volume, and Q the chamber flows. The actuator force is

$$F = A_a p_a - A_b p_b - F_\mu - F_{ext} \tag{3.6}$$

where A_a, A_b are piston areas, p_a, p_b chamber pressures, F_μ friction, and F_{ext} the measured external load. Friction is represented using a Coulomb–viscous–Stribeck model.

The accumulator pressure follows a polytropic gas relation,

$$p_{acc} = \left(\frac{V_0}{V_0 - \int Q_{acc} dt}\right)^n p_0 \qquad Q_{acc} = Q_{el,A} + Q_{el,B} + Q_{RV} - Q_{CV} \tag{3.7}$$

where V_0 is the nominal volume, p_0 the pre-charge pressure, and $n = 1.4$. The accumulators are pre-charged to 4.5 bar, with 6 L for the lift and 10 L for the tilt actuator.

Flow through the three types of orifices is modelled using the same orifice law in (3.8), with component-specific definitions for the opening area A:

- Pilot-operated check valve (POCV): the opening area A depends on the control pressure p_c as defined in (3.9)–(3.10).
- Load-holding valve: the area A is set by the on/off signal u_{LH} according to (3.11).
- Cylinder orifices: the area A is constant.

$$Q = AC_{q,max}\tanh\left(\frac{2\lambda}{\lambda_{crit}}\right)\sqrt{\frac{2|\Delta p|}{\rho}}\,\mathrm{sign}(\Delta p) \qquad \lambda = \frac{D_h}{\nu}\sqrt{\frac{2|\Delta p|}{\rho}} \tag{3.8}$$

where ρ is the fluid density, $\Delta p = p_1 - p_2$ the pressure difference across the orifice, and $\lambda_{crit} = 1000$ [20]. The flow number λ characterises the laminar–turbulent transition and modifies the discharge coefficient via the hyperbolic tangent term.

For the POCV, the control pressure and area–pressure relationships are defined as

$$p_c = (p_x - p_1)k_p + (p_1 - p_2) \tag{3.9}$$

$$A(p_c) = \begin{cases} A_{leak}, & p_c \le p_{cr} \\ A_{leak} + k(p_c - p_{cr}), & p_{cr} < p_c < p_{max} \\ A_{max}, & p_c \ge p_{max} \end{cases} \qquad k = \frac{A_{max} - A_{leak}}{p_{max} - p_{cr}} \tag{3.10}$$

The opening area A of both the POCV and LHV follows a first-order lag with a time constant of 0.1 s. The LHV is normally closed and energised according to

$$u_{LH} = \begin{cases} 1, & |\dot{x}_{ref}| > 0\ \mathrm{m/s} \text{ or } |e_c| > 1\ \mathrm{mm} \\ 0, & \text{otherwise} \end{cases} \tag{3.11}$$

where $\dot{x}_{ref}$ is the commanded actuator velocity and e_c the position error. Simulation parameters are listed in Table 1.

Table 1: Parameters of lift and tilt EHAs

Parameter	Lift	Tilt	Parameter	Lift	Tilt
D_p [cc/rev]	50.7	45	J_{PM} [kg·m^2]	0.0035	0.0025
A_a [cm^2]	100.5	127.2	A_b [cm^2]	68.7	88.0
$C_{q,max}$ [–]	0.7	0.7	s [mm]	640	400
p_{cr} [bar]	0.5	0.5	k_p [–]	3	3
V_0 [L]	6	10	p_0 [bar]	4.5	4.5
f_{sw} [Hz]	2000	2000	ϵ [–]	0.5	0.5

3.2. LS Model

The LS system is used as a reference for comparison with the EHA-based system. Measurement data were obtained from an LS configuration originally driven by a

combustion engine [17], but for consistency, the LS system is assumed to be driven by an electric motor operating at constant speed.

Measured pump flow Q_p and pressure p_p are converted into mechanical shaft power using the pump model defined in (3.3)–(3.4). The mechanical shaft power and the corresponding electrical input power are expressed as

$$P_{shaft} = T_p \omega_p \qquad P_{el} = \frac{P_{shaft}}{\eta_{em}(T_p, \omega_p)} \tag{3.12}$$

where $\eta_{em}(T_p, \omega_p)$ is obtained from the manufacturer's efficiency map [21].

3.3. Controller Design

The PMSM in the EHA is controlled by a cascade structure with dq-axis current loops and outer speed loop, all implemented with PI controllers tuned using the method in [22]. The dq-axis currents are regulated by PI controllers with decoupling terms, according to

$$u_q = K_{pc}(i_{q,ref} - i_q) + K_{ic}\int (i_{q,ref} - i_q)dt + \omega_e(L_d i_d + \phi_f) \tag{3.13}$$

$$u_d = K_{pc}(i_{d,ref} - i_d) + K_{ic}\int (i_{d,ref} - i_d)dt - \omega_e L_q i_q \tag{3.14}$$

where $i_{d,ref} = 0$ and $\omega_e = P\omega$. The controller gains are

$$K_{pc} = L_s \omega_c \qquad K_{ic} = R_s \omega_c \tag{3.15}$$

with the current control bandwidth ω_c set one decade below the inverter switching frequency f_{sw}.

The electromagnetic torque is generated by the q-axis current i_q, which serves as the control variable in the outer speed loop. The PI speed controller generates the current reference as

$$i_{q,ref} = K_{ps}(\omega_{ref} - \omega) + K_{is}\int (\omega_{ref} - \omega)dt \tag{3.16}$$

$$K_{ps} = \frac{J_{tot}\omega_s}{K_t} \qquad K_{is} = K_{ps}\frac{\omega_s}{5} \tag{3.17}$$

where J_{tot} is the total inertia, K_t the torque constant, and $\omega_s = \omega_c/5$.

The motor speed reference combines position feedback, velocity feedforward, and dynamic pressure feedback, conditioned by the LHV logic:

$$\omega_{ref} = \begin{cases} K_\omega(u_{fb} + u_{ff} - u_{pf}), & u_{LH} = 1 \\ 0, & \text{otherwise} \end{cases} \tag{3.18}$$

This ensures that the motor is commanded only when the LHV is energised, preventing line pressurisation when the valves are closed.

The velocity conversion ratio between cylinder and motor is defined as

$$K_\omega = \begin{cases} A_a/D_p, & \Delta p_L > 0 \\ A_b/D_p, & \text{otherwise} \end{cases} \tag{3.19}$$

where D_p is in [m^3/rad]. The position feedback is implemented using proportional control, while the velocity feedforward term directly applies the commanded velocity as

$$u_{fb} = K_p(x_{ref} - x) \qquad u_{ff} = K_{ff} v_{ref} \tag{3.20}$$

Damping is increased using high-pass filtered load-pressure feedback:

$$u_{pf} = \frac{K_{pf} s}{s + \omega_{pf}} \Delta p_L \qquad \Delta p_L = p_a - \frac{A_b}{A_a} p_b \tag{3.21}$$

This control approach follows [23], with the addition of the LHV logic. The overall controller is illustrated in Fig. 3.1, and the controller parameters are listed in Table 2.

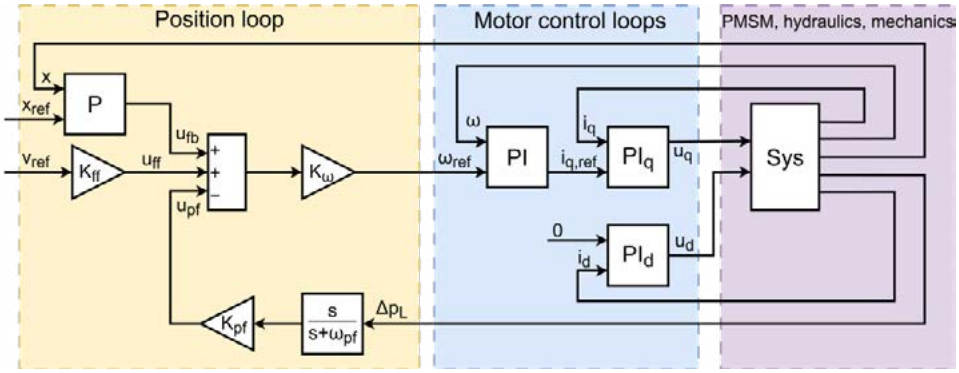

Figure 3.1. Control structure of the EHA showing the position control loop and the motor speed and current control loops. The decoupling terms of the inner PI_q and PI_d current controllers are omitted for clarity.

Table 2: Controller parameters

Parameter	Lift	Tilt	Parameter	Lift	Tilt
K_p [1/s]	2	4	K_{ff} [–]	1	0.5
ω_{pf} [rad/s]	6.60	8.70	K_{pf} [m·s^{-1}·bar^{-1}]	$1.5 \cdot 10^{-4}$	$2 \cdot 10^{-4}$
K_{ps} [A·s/rad]	2.28	2.15	K_{is} [A/rad]	115	108
K_{pc} [V/A]	3.15	3.15	K_{ic} [V·A^{-1}·s^{-1}]	106	106

4. SIMULATION RESULTS

This section presents simulation results of the proposed EHA architecture for wheel loader application. Position references for the lift and tilt cylinders were derived from Y-cycle measurements on a real machine. The analysis focuses on actuator controllability and energy efficiency, while thermal behaviour is discussed separately in Section 5.

4.1. Controllability

Tracking performance is evaluated using the short Y-cycle reference (Fig. 4.1). The actuators follow the position references with satisfactory accuracy. The maximum tracking errors are below 4 mm for the lift actuator and 29 mm for the tilt actuator, with corresponding root mean square (RMS) errors of 1.3 mm and 5.4 mm, respectively. During the load-holding phase, errors remain below 1 mm due to the control rule defined in equation (3.11). The tilt EHA exhibits higher position errors than the lift actuator because of the lift–tilt coupling through the stabilising cylinder. This coupling introduces disturbances in the position loop, requiring the controller to prioritise feedback compensation over faster velocity feedforward action, for which $K_{ff} = 0.5$ is applied in the tilt actuator. Despite these larger deviations, the achieved accuracy can be considered sufficient for typical load-handling tasks.

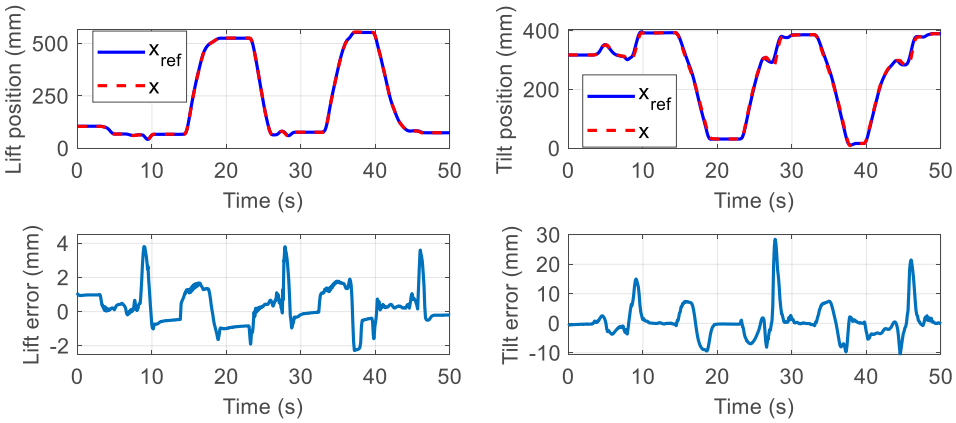

Figure 4.1. Position-tracking performance of lift and tilt actuators during the Y-cycle.

The dynamic behaviour during load-holding valve operation is illustrated in Fig. 4.2. When the LHV is closed, the actuator chamber is isolated from the line, allowing it to hold the load while a pressure difference of approximately 7.6 MPa gradually builds up between the chamber (p_a) and the connected line (p_{la}). When the valve opens, this pressure imbalance induces a brief cylinder motion as the pressures equalise. The resulting position deviation is minor and does not significantly affect overall performance.

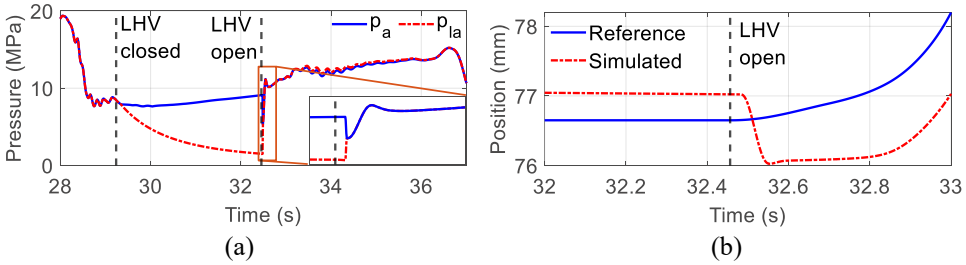

Figure 4.2. (a) Pressure dynamics in the A-chamber and connected line during load-hold valve operation. (b) Position tracking after valve opening.

4.2. *Energy Analysis*

Energy efficiency over the load cycle is evaluated and compared with the LS baseline. The instantaneous mechanical power of the cylinder and the electrical power of the PMSM are

$$P_{cyl} = F_{cyl}\dot{x} \qquad P_{el} = T_e\omega + P_{Cu} + P_{Fe} \tag{4.1}$$

where F_{cyl} is the cylinder force and $\dot{x}$ the piston velocity. Copper and iron losses are

$$P_{Cu} = \frac{3}{2}R_S\left(i_d^2 + i_q^2\right) \qquad P_{Fe} = \frac{K_{Fe}m_{EM}\epsilon}{1000\pi^{3/2}}|P\omega|^{3/2} \tag{4.2}$$

with $K_{Fe} = 4$ W/kg as the core loss per unit mass of sheet metal, m_{EM} the PMSM mass, and ϵ the sheet metal fraction [24]. The iron loss model provides only a simplified approximation. The EHA losses are primarily determined by the component efficiencies, unlike in conventional systems where throttling losses dominate. Therefore, Fig. 4.3 shows the efficiency maps of the main components together with their operation points over the lift actuator load cycle, providing an indication of the achievable overall efficiency. The motor efficiency map in Fig. 4.3a is based on the loss calculations in (4.2), while the pump map in Fig. 4.3b is derived from the model described in (3.3)–(3.4).

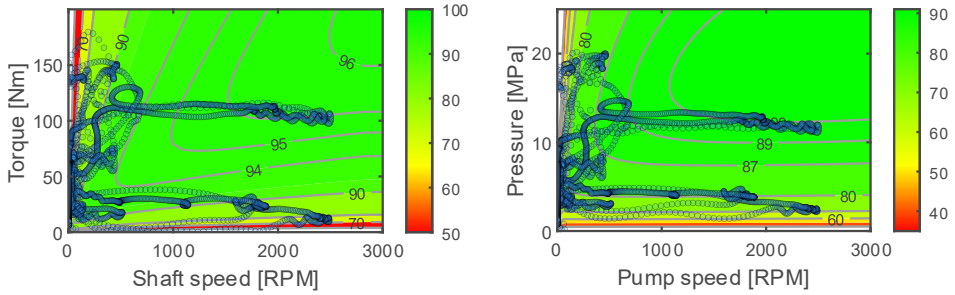

Figure 4.3. (a) Electric motor efficiency map and (b) lift pump efficiency map. Blue circles denote the operation points over the lift actuator load cycle.

Inverter losses are considered under the assumption of a constant inverter efficiency:

$$P_{DC} = \begin{cases} \dfrac{P_{el}}{\eta_{inv}}, & P_{el} \geq 0 \\ \eta_{inv}P_{el}, & P_{el} < 0 \end{cases} \qquad \eta_{inv} = 0.97 \tag{4.3}$$

The cycle energies and efficiency are defined as

$$E_{in} = \int P_{DC}dt \qquad E_{out} = \int P_{cyl}dt \qquad \eta = E_{out}/E_{in} \tag{4.4}$$

Positive P_{cyl} corresponds to load-resistive phases, whereas negative values indicate load-assistive phases. As the boom motion is periodic, the net work on the structure's own mass over a cycle is zero, and only the useful payload work is considered as output.

Figure 4.4 illustrates motor and cylinder powers for lift and tilt EHAs during the short Y-cycle. In load-resistive phases the motor receives electrical input ($P_{el} > 0$) and the cylinder

outputs mechanical power ($P_{cyl} > 0$). In load-assistive phases the load drives the actuator ($P_{cyl} < 0$) and the motor operates regeneratively ($P_{el} < 0$). For the tilt actuator, brief resistive segments with $P_{out} > P_{in}$ occur because the lift actuator momentarily drives the tilt cylinders through the stabilising cylinders.

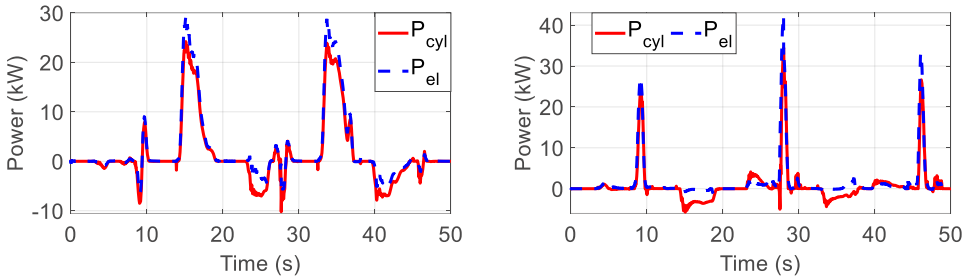

Figure 4.4. Motor electrical power P_{el} and cylinder mechanical power P_{cyl} for lift (a) and tilt (b) EHAs during the Y-cycle.

Figure 4.5 compares lift–tilt powers for LS and EHA systems, and Fig. 4.6 presents the corresponding cumulative energies. For the Y-cycle, the EHA requires 31.9 % of the electrical input of the LS system, yielding efficiencies of $\eta_{LS} = 0.17$ and $\eta_{EHA} = 0.55$. These results demonstrate that the EHA is substantially more efficient than the LS system.

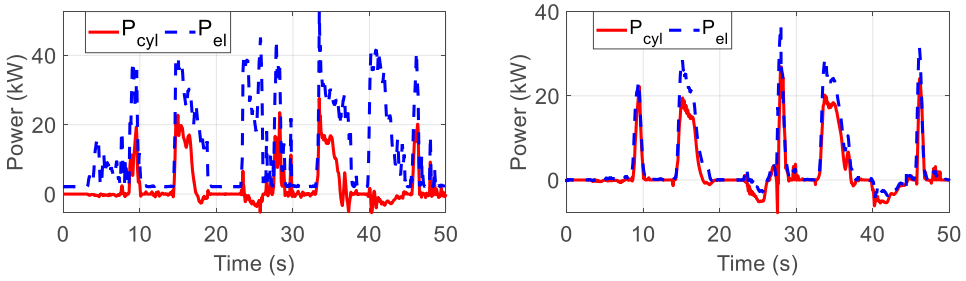

Figure 4.5. Motor electrical power P_{el} and cylinder mechanical power P_{cyl} for LS (a) and EHA (b). Powers are sums over lift and tilt actuators.

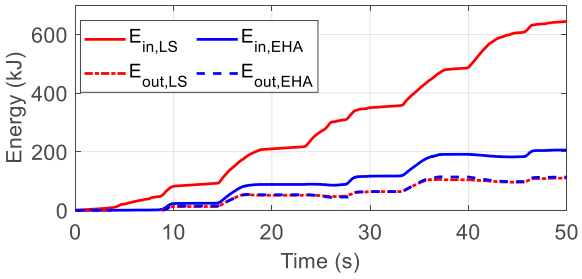

Figure 4.6. Cumulative electrical input energies E_{in} and useful cylinder outputs E_{out} for LS and EHA systems. Energies are sums over lift and tilt actuators.

Component-level losses are obtained by separating resistive and assistive intervals (Fig. 4.7). From the PMSM electrical input of 2.89 kW, 77.0 % is converted into useful mechanical output at the cylinder (2.22 kW). The remainder is dissipated in the motor (6.0%), pump/motor (10.9%), throttling (1.9%), and cylinder friction (5.6%). During assistive phases, the boom's potential energy provides 1.13 kW of mechanical input, of which 47.7 % (538 W) is transferred back to the inverter, while the rest is lost due to electrical, hydraulic, and mechanical losses as well as accumulator charging.

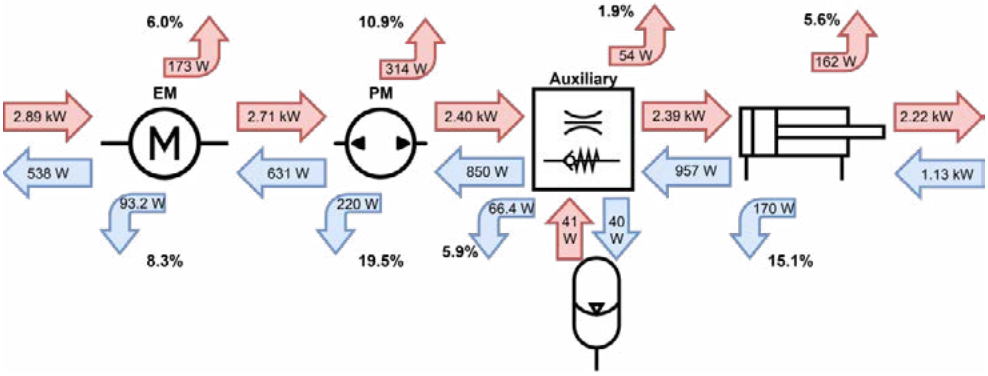

Figure 4.7. Component-level power flows of the lift actuator (EHA). Red = load-resistive (lifting), blue = load-assistive (lowering, regeneration).

Over a full Y-cycle, the mean loss powers are

$$P_{cyl,loss} = 162\ \text{W} + 170\ \text{W} = 332\ \text{W}$$
$$P_{aux,loss} = 54\ \text{W} + 66.4\ \text{W} = 120.4\ \text{W} \quad (4.5)$$
$$P_{PM,loss} = 314\ \text{W} + 220\ \text{W} = 534\ \text{W}$$

These losses are modelled as heat sources in the hydraulic system, while the electric motor losses are excluded from the thermal model (Section 5) since the PMSM is not in direct thermal contact with the hydraulic oil.

Overall, the results demonstrate that the EHA achieves more than three times the efficiency of the LS system under the Y-cycle, primarily due to reduced throttling losses and its capability for regenerative operation. In the present study, the LS system's variable displacement pump is operated at constant speed, which leads to increased losses under partial-load conditions, as the efficiency of the LS pump decreases at lower displacement settings. Since a PMSM is employed, a variable-speed LS implementation is technically feasible and could mitigate these losses, as demonstrated in [12]. Nevertheless, the constant-speed LS configuration represents the traditional load-sensing system architecture and is therefore an appropriate baseline for the present comparison.

The energy breakdown identifies the pump/motor unit as the dominant source of losses, while the auxiliary components contribute only marginally. These findings confirm the superior energy efficiency of the EHA, and the simulated power losses serve as an input in the subsequent thermal analysis.

5. THERMAL ANALYSIS

Thermal management is critical for EHAs, as their closed hydraulic circuit restricts heat dissipation. Unlike centralised hydraulic systems, where oil continuously returns to a reservoir providing effective cooling, the closed-circuit design of an EHA limits heat rejection and leads to higher temperatures. Elevated temperature lowers viscosity, weakens lubrication, and accelerates component wear. This analysis predicts system temperature over the continuous Y-cycle and evaluates the need for additional cooling.

A lumped-parameter model with a single combined control volume, representing the thermal capacities of the fluid and surrounding solids, is used. It defines a single system temperature T and an ambient temperature $T_{sur} = 20$ °C. The model combines convective cooling described by Newton's law of cooling and radiative heat exchange based on the Stefan–Boltzmann law. The oil is assumed to be well mixed, and all losses identified in Section 4.2 are represented as a constant cycle-averaged total heat input P_{loss}.

The system's thermal dynamics are

$$C\frac{dT}{dt} = P_{loss} - Q \qquad Q = \sum_i \frac{T - T_{sur}}{R_{th,i}} \tag{5.1}$$

The lumped heat capacity of the oil and the components is

$$C = c_{p,oil}m_{oil} + \sum_i c_{p,i}m_i \tag{5.2}$$

where c_p denotes specific heat capacity and m mass. Thermal resistances are

$$R_{th,i} = \frac{1}{(h_{conv,i} + h_{rad,i})A_{s,i}} \tag{5.3}$$

where $A_{s,i}$ is the surface area of the component.

The radiative and convective heat transfer coefficients are expressed as

$$h_{rad} = \varepsilon\sigma(T^2 + T_{sur}^2)(T + T_{sur}) \qquad h_{conv} = \frac{Nu \cdot k}{l_c} \tag{5.4}$$

where ε is the surface emissivity, $\sigma = 5.67 \cdot 10^{-8}\ \mathrm{W/(m^2K^4)}$ is the Stefan-Boltzmann constant [25], k is the thermal conductivity of air evaluated at the reference temperature $\bar{T} = (T + T_{sur})/2$, and l_c is the characteristic length of the component. The Nusselt number is geometry-dependent, and simple geometries such as horizontal cylinders and cubes are therefore adopted. The correlations used to calculate the Nusselt numbers for air free convection for the considered geometries are given in Table 3. Heat transfer is assumed to be governed by free convection and radiation, while forced convection resistances associated with internal pipe flow are neglected.

The dimensionless parameters are

$$Nu = \frac{hl_c}{k} \qquad Pr = \frac{\rho\nu c_p}{k} \qquad Gr = \frac{gl_c^3\beta_{air}\Delta T}{\nu^2} \tag{5.5}$$

where Pr is the Prandtl number, Gr the Grashof number, ρ the density, ν the kinematic viscosity, $g = 9.81\ \mathrm{m/s^2}$, and β_{air} the thermal expansion coefficient of air.

The oil heat capacity is updated with temperature following [26]:

$$c_p(T) = c_0 + \alpha_c(T - 273.15) \qquad c_0 = 1807\ \frac{\mathrm{J}}{\mathrm{kg \cdot K}} \qquad \alpha_c = 4.21\ \frac{\mathrm{J}}{\mathrm{kg \cdot K^2}} \tag{5.6}$$

Air is modelled as an ideal gas for evaluating density and thermal expansion:

$$\rho_{air} = p/(R_{air}\bar{T}) \qquad \beta_{air} = 1/\bar{T} \tag{5.7}$$

All other air properties are interpolated from tabulated data from [27]. Thermophysical properties are updated continuously using these relations.

Table 3: Nusselt correlations for free convection geometries [27, 28]. Air properties evaluated at the reference temperature.

Geometry	Nusselt number
Horizontal cylinder	$Nu = \left[0.6 + 0.387(Gr\ Pr)^{1/6}\left(1 + (0.559/Pr)^{9/16}\right)^{-8/27}\right]^2$ $Gr = Gr(T - T_{sur}),\ l_c = d$
Cube	$Nu = 5.748 + 0.752(Pr\ Gr)^{0.252}\left[1 - (0.492/Pr)^{9/16}\right]^{-0.448}$ $Gr = Gr(T - T_{sur}),\ l_c = A/D,\ D = \sqrt{4A_{proj}/\pi}$

Figure 5.1 shows the simulated temperature rise under continuous load-cycle operation. The system temperature approaches 82 °C after 350 min. The hydraulic system temperature exceeds the typical operating range of hydraulic systems (50–60 °C) [29] after about 85 min, indicating that additional cooling is required for long-term reliability. Internal forced convection resistances are omitted, which overestimates heat rejection. The actual cooling capacity may therefore be lower in practice. Furthermore, component power losses depend on the temperature in the real system, so the heat generation in the model may be slightly underestimated.

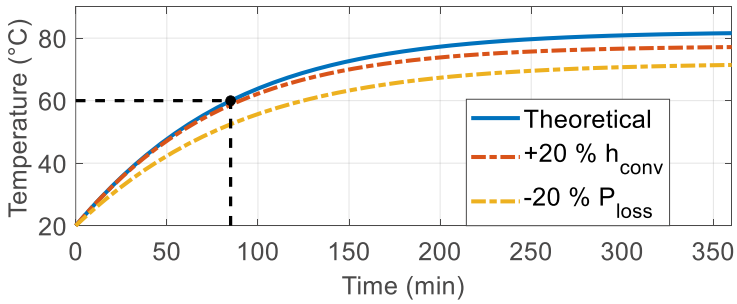

Figure 5.1. Simulated system temperature rise under continuous operation.

Jungnickel (2010, as cited in [14]) reported that natural convection coefficients may exceed theoretical estimates by up to 20 %. Moreover, Ketelsen et al. [14] showed that the results can be highly sensitive to power loss modelling errors. The present sensitivity analysis indicates that increasing the natural convection heat transfer coefficient by 20 % lowers the steady-state temperature by roughly 5 °C, whereas a 20 % reduction in input heat lowers it by about 10 °C. Even in the most favourable case, the temperature remains above the recommended range, indicating that active cooling is required for reliable long-term operation.

Thermal resistances of the components at the steady state temperature are listed in Table 4. These values are updated during the simulation, as they vary with temperature.

Table 4: Heat transfer coefficients and thermal resistances of system components at the steady-state temperature.

Component	Geometry	A_s [cm^2]	l_c [mm]	ε	h_{conv} [W/m^{2}K^{-1}]	h_{rad} [W/m^{2}K^{-1}]	R_{th} [K/W]
Pump	Cube	1350	798	0.90	12.7	7.00	0.376
Hoses	Cylinder	3970	16.2	0.93	8.59	7.24	0.159
Cylinder	Cylinder	4182	104	0.90	6.01	7.00	0.184
Accumulator	Cylinder	1297	200	0.90	5.59	7.00	0.612

6. CONCLUSION

This study evaluated the performance of electro-hydrostatic actuators for wheel loader work functions through simulations based on measured load cycle and external load data. The analysis covered controllability through position tracking precision, energy efficiency in comparison with an LS system, and thermal behaviour using a lumped-parameter model suitable for early-stage evaluation.

The main findings are:

- EHAs achieved satisfactory tracking accuracy, although the load-holding valve caused transient errors. The maximum tracking errors were below 4 mm for the lift actuator and 29 mm for the tilt actuator, with RMS errors of 1.3 mm and 5.4 mm, respectively.
- EHAs required only 31.9 % of the LS system's electrical input for the same work cycle, corresponding to efficiencies of 55.1 % and 17.0 % for the EHA and LS systems, respectively.
- Thermal simulations showed that the EHA exceeded typical hydraulic operating temperatures, indicating the need for additional cooling. The steady-state temperature reached 82 °C with theoretically calculated heat transfer coefficients, and ±20 % variations in these coefficients or heat inputs did not change this conclusion.

These results demonstrate that EHAs provide significant efficiency improvements compared with the LS system, but thermal management must be addressed to ensure reliable operation in such applications. In the present study, active cooling of the EHAs would have been required, which may compromise the efficiency benefits.

Abstract.

This study presents an integrated automation framework that unifies constrained optimal trajectory planning and adaptive robust motion control for electrohydraulic mobile machines. The proposed multi-layer architecture consists of command, planning, control, and actuation levels, ensuring seamless coordination between task execution and dynamic motion adaptation. A nonlinear filter-based time-optimal trajectory planner is developed to generate real-time feasible trajectories under kinematic and dynamic constraints, while an adaptive robust backstepping controller is designed to compensate for nonlinearities, parameter uncertainties, and external disturbances in hydraulic actuation. Additionally, a simplified control strategy is introduced for pressure-compensated systems to enhance industrial applicability. Comparative validation on an unmanned wheel loader demonstrates the proposed framework's effectiveness, achieving high tracking accuracy, strong robustness, and real-time constraint satisfaction. This work contributes to advancing autonomous and intelligent operation of electrohydraulic mobile machines by bridging planning and control in a cohesive system framework.

Keywords. Electrohydraulic systems, Constrained trajectory planning, Adaptive Robust Control, Mobile working machines, Automation control framework

1. INTRODUCTION

1.1 Motivation

The autonomy of mobile working machines [1], such as wheel loaders and excavators, has become a key research direction in both academia and industry. It aims to reduce dependency on skilled operators, improve operational safety, and enable continuous, autonomous operation in complex environments. Reliable automation of such machines fundamentally depends on two capabilities—trajectory planning that respects system constraints, and motion control that ensures precise and robust execution.

Electrohydraulic systems, though offering high power density, present major challenges due to nonlinearities, parameter uncertainties, and high-order hydraulic dynamics, which degrade tracking accuracy and robustness under varying loads and disturbances. Conventional linear controllers struggle to maintain performance in such conditions. Moreover, unlike electric drives, hydraulic systems are limited by flow saturation and slow responses due to fluid dynamics. Achieving time-optimal and constraint-satisfied trajectories while ensuring precise and robust execution remains a key challenge. These factors motivate the development of a unified control framework that integrates constrained trajectory planning with adaptive robust control for safe and effective autonomous operation of electrohydraulic mobile machines.

1.2 Related works

1) Trajectory planning strategies of hydraulic machines

Constraints pose a major challenge to achieving reliable motion control in mobile working machines, particularly in systems with multiple hydraulic actuators interacting with their environment. These constraints encompass both kinematic and dynamic aspects, such as input and hydraulic force limitations [2], and are influenced by factors including hydraulic configuration, safety requirements, and payload conditions specific to each machine [3]. Moreover, constraint boundaries may vary over time due to changes in operating conditions. Violating these constraints can cause actuator damage (e.g., cavitation), safety risks, and motion instability. Therefore, a robust and real-time constrained control strategy is crucial for enabling autonomous operation.

Various constrained control strategies have been proposed to address the limitations of electro-hydraulic systems. In [4], a motion tracking controller with full-state constraints was developed using a barrier Lyapunov function to ensure constraint satisfaction. The study [5] introduced an input-constrained control scheme that incorporates a bounded smooth hyperbolic tangent function to achieve asymptotic tracking. Furthermore, [6] presented a robust nonlinear control method for electro-hydraulic force systems considering output constraints. Although these works have advanced the understanding of constrained control in electro-hydraulic systems, most approaches focus on a single type of constraint and neglect the time-varying characteristics and interdependence among multiple constraints. Consequently, existing research still faces several open challenges: (1) Low-pass filters are often applied to handle aggressive reference inputs, but they introduce steady-state deviations, and the resulting trajectories are typically suboptimal—failing to reach the desired reference in minimum time while respecting the constraints. (2) The tracking accuracy of synthesized constrained trajectories is not guaranteed due to the nonlinearities and uncertainties inherent in electro-hydraulic systems, limiting the realization of optimal constrained motion control.

Integrating a precise motion tracking controller with real-time constrained trajectory planning provides a promising pathway to achieving both robust control performance and constraint satisfaction [3]. In [2] and [7], constrained adaptive robust motion tracking controllers were developed for linear motors and hydraulic actuators by combining a model-based motion controller with a nonlinear filter-type trajectory planner, yielding satisfactory results. The nonlinear filter planner, first proposed in [8], enables real-time generation of time-optimal trajectories that respect motion constraints. While [2] and [7] successfully

demonstrated this approach in simple mechatronic systems, its application to complex electrohydraulic systems of mobile working machines remains largely unexplored. The trajectory planning of such machines introduces greater challenges due to multiple interacting constraints and strong coupling effects, motivating further development of advanced constrained trajectory planning strategies.

2) Precise motion control strategies of electrohydraulic actuators

While trajectory planners can generate optimal constrained trajectories for operations, tracking the desired trajectory may not be executed accurately. This is due to the nonlinear and uncertain nature of electro-hydraulic actuators [9], as well as external disturbances during mobile machine operation [10]. Therefore, a precise and robust motion control is essential for autonomous operation of mobile machines.

To achieve high-precision and robust control of electro-hydraulic systems, adaptive and nonlinear model-based strategies have been extensively explored [11]. Several methods have been proposed to handle uncertain disturbances and nonlinear effects. For instance, [10] developed an active disturbance rejection adaptive control scheme for hydraulic servo systems, while [12] proposed an H_∞-based control method with feedforward compensation to improve terrain disturbance rejection in mobile manipulators. To mitigate nonlinear friction, a modified LuGre model was introduced in [13], and a virtual decomposition control approach based on subsystem dynamics was presented in [14].

Among these approaches, Adaptive Robust Control (ARC) has shown outstanding potential in compensating uncertain loads, enhancing both accuracy and robustness [15]. As illustrated in Fig. 3, ARC integrates parameter adaptation with nonlinear feedback. Considering the high-order dynamics of hydraulic systems, an ARC backstepping scheme has been developed to ensure precise motion tracking under nonlinearities and uncertainties.ARC theory has been successfully extended to various electro-hydraulic configurations, such as electro-hydraulic actuators [9] and electro-variable pumps [16], and shows strong promise for multi-actuator mobile machines, where coupling dynamics remain an open challenge.

Furthermore, the integration and communication of these methodologies are essential for the robust and autonomous operation of mobile machines. However, such integrated approaches remain relatively underexplored, and further research is required to establish cohesive frameworks that seamlessly bridge planning and control for electro-hydraulic mobile machines [17].

1.3 Contributions

This study proposes a unified framework that integrates constrained trajectory planning and robust nonlinear motion control for autonomous operation of electrohydraulic mobile machines. An unmanned wheel loader is used as a representative case study, which is a highly automated unmanned system. The main contributions of this study are:

- A multi-level integrated control architecture is introduced, consisting of command-level: task command, mid-level: constrained trajectory generation, and lower-level: precise motion tracking. This structure ensures seamless coordination between planning and execution, contributing to robust control performance and flexible application.

- A time-optimal constrained trajectory planning algorithm is developed, utilizing a nonlinear filter-based planner with high-order of integrators, which explicitly considers both the kinematic structure and dynamic limitations of the wheel loader's electrohydraulic actuating system. This ensures feasibility and safety in real-world machines' automated operations.
- An Adaptive Robust Control (ARC) is designed for motion control of proportional valve-control hydraulic system, as the underlying controller. It effectively mitigates the impact of system nonlinearities and uncertainties by robust feedback and uncertain parameter online adaptation, ensuring accurate tracking of planned trajectories and overcoming limitations of traditional linear control methods.
- In addition to the advanced ARC method, a simplified controller was also designed, combining linear feedback with dynamic feedforward compensation. This lightweighted controller is specially designed for pressure-compensated hydraulic systems, offering a practical and easily implementable solution for industrial applications (e.g., wheel loads or excavators).
- The above proposed framework was validated on an unmanned wheel loader, a representative mobile machine with a standard electrohydraulic system and multiple actuators. Results demonstrate high trajectory-tracking accuracy and strong robustness against system uncertainties.

By bridging trajectory planning and adaptive robust control within a cohesive framework, the study offers a scalable and effective solution for future autonomous mobile machines.

2. CONTROL FRAMEWORK

The complete architecture integrates the above components into a hierarchical structure, as shown in Figure 2.1, explained as below:

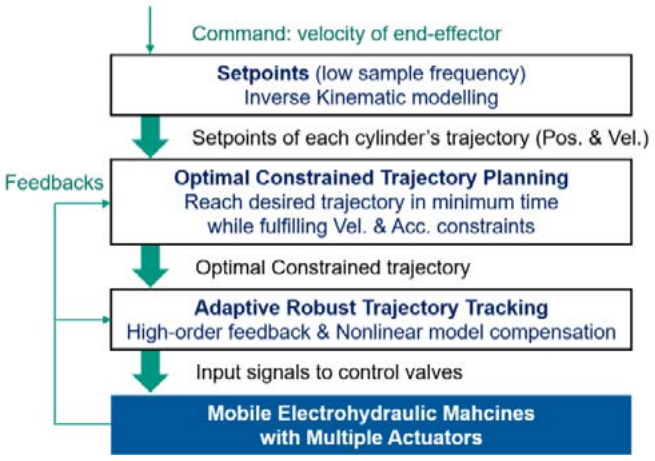

Figure 2.1. Control framework

1) **Command Layer:** The operator or task planner provides the desired end-effector motion (e.g., velocity), as command to the control system. The position & velocity of each actuator can be obtained in the form of discrete setpoints via inverse

kinematic model. This layer can be performed by autonomously or by operator remotely.

2) **Trajectory Planning Layer:** The trajectory planner generates an optimal constrained trajectory based on the setpoints. The planned trajectory reaches the desired setpoints in minimum time with high sampling frequency while simultaneously satisfying velocity and acceleration constraints.

3) **Motion Control Layer:** The motion tracking controller executes the planned trajectories with real time feedback and feedforward compensation. This controller design ensures robustness and precision despite the nonlinearities and uncertainties of the electrohydraulic system.

4) **Actuation Layer:** Control signals are transmitted to the hydraulic valves of the load arm actuators. The feedback from sensors of the electrohydraulic system is given to Trajectory Planning and Motion Control Layer in real-time.

This multi-layered structure ensures high adaptability. Feedback loops across multiple levels allow the system to dynamically compensate for disturbances and operational variations.

3. OPTIMAL CONSTRAINED TRAJECTORY PLANNING

Constraints of the motion control of the hydraulic actuator include the constraints of velocity (i.e., $\dot{x}^+$ and $\dot{x}^-$) and acceleration (i.e., $\ddot{x}^+$ and $\ddot{x}^-$), which are described in (3.1), while the stroke (position) bounds are static constraints that should be addressed at the task-planning level (i.e., setpoints in Figure 2.1) and not the focus of this section.

$$\begin{aligned} \dot{x}^- \le \dot{x} \le \dot{x}^+ \\ \ddot{x}^- \le \ddot{x} \le \ddot{x}^+ \end{aligned} \tag{3.1}$$

The assignments of the preset constraints for trajectory planning depend on the parameters and working conditions of the electro-hydraulic systems.

In this section, a two-integrator based nonlinear filter [8] is detailed to realize the online time-optimal trajectory planning to reach the desired reference while fulfilling the constraints on the velocity and acceleration (6). The two integrators chain is given by

$$\begin{bmatrix} x_p(i+1) \\ \dot{x}_p(i+1) \end{bmatrix} = \begin{bmatrix} 1 & T \\ 0 & 1 \end{bmatrix} \begin{bmatrix} x_p(i) \\ \dot{x}_p(i) \end{bmatrix} + \begin{bmatrix} \frac{T^2}{2} \\ T \end{bmatrix} \ddot{x}_p(i) \tag{3.2}$$

where T demotes the sampling time; i demotes the number of sampling periods. When $i = 0$, $\left[x_p(0), \dot{x}_p(0), \ddot{x}_p(0)\right]^T = [x_d(0), \dot{x}_d(0), \ddot{x}_d(0)]^T$. The state equation of the two integrators chain

$$\boldsymbol{x_p}(i+1) = \boldsymbol{A_c} x_p(\mathrm{i}) + \boldsymbol{B_c} \ddot{x}_p(i) \tag{3.3}$$

where $\boldsymbol{x_p}(\mathrm{i}) = \left[x_p(\mathrm{i}), \dot{x}_p(\mathrm{i})\right]^T$ is the system state when the time $t = i \times T$; $\ddot{x}_p$ here serves as the system input.

The error between the planned trajectory x_p and the originally expected command trajectory x_d is defined by $\boldsymbol{y}$, which is given as

$$\begin{aligned} y(i) &= x_p(i) - x_d(i) \\ \dot{y}(i) &= \dot{x}_p(i) - \dot{x}_d(i) \end{aligned} \tag{3.4}$$

where $\boldsymbol{x_d}$ is the given reference, indicating that when $y(i)$ tends to zero, $x_p(i)$ converges to $x_d(i)$. The error dynamics of the transformed system (10) is given by

$$\boldsymbol{y}(i+1) = \boldsymbol{A_c}\boldsymbol{y}(i) + \boldsymbol{B_c}v(i) \tag{3.5}$$

where $v(i) = \ddot{x}_p - \ddot{x}_d$.

In the error dynamics (3.4), the matrix $\boldsymbol{A_c}$ and $\boldsymbol{B_c}$ are both directly related to the sampling time T. To avoid the system error dynamics explicitly relying on the sampling time T, the following transformation is applied [11].

$$\boldsymbol{y}(i) = \boldsymbol{W}\boldsymbol{\eta}(i) \tag{3.6}$$

where

$$\boldsymbol{W} = \begin{bmatrix} T^2 & -\dfrac{T^2}{2} \\ 0 & T \end{bmatrix} \tag{3.7}$$

and $\boldsymbol{\eta}(i) = [\eta_1(i), \eta_2(i)]^T$. Matrix $\mathbf{W}$ is nonsingular, it implies that inverse transformation

$$\boldsymbol{\eta}(i) = \boldsymbol{W}^{-1}\boldsymbol{y}(i). \tag{3.8}$$

Combining the transformed formulation (3.8) and the error dynamics (3.5), it can be obtained that

$$\boldsymbol{\eta}(i+1) = \boldsymbol{A_d}\boldsymbol{\eta}(i) + \boldsymbol{B_d}v(i) \tag{3.9}$$

where

$$\boldsymbol{A_d} = \begin{bmatrix} 1 & 1 \\ 0 & 1 \end{bmatrix}, \quad \boldsymbol{B_d} = \begin{bmatrix} 1 \\ 1 \end{bmatrix}. \tag{3.10}$$

In the above formulation (3.9), the system state $\mathbf{x_r}$ is transformed into an equivalent state $\boldsymbol{\eta}$. Since $\boldsymbol{W}$ is nonsingular, the eventual convergence to the origin of $\boldsymbol{\eta}$ implies the convergence of $\boldsymbol{y}$ to zero and the tracking of $\mathbf{x}_d$ is achieved.

To fulfil the requirements of the time-optimal trajectory planning objective and the given constraints (3.1), the control input of (3.9) is given by

$$v = \begin{cases} -\ddot{x}^{-}\mathrm{sat}\left(\dfrac{\delta}{\ddot{x}^{-}}\right), & \text{if } \delta \geq 0 \\ -\ddot{x}^{+}\mathrm{sat}\left(\dfrac{\delta}{\ddot{x}^{+}}\right), & \text{if } \delta < 0 \end{cases} \tag{3.11}$$

where $\mathrm{sat}(\bullet)$ is a saturation function; δ is obtained by,

$$\delta \coloneqq \eta_2 + \frac{\gamma}{m} + \frac{m-1}{\alpha}. \tag{3.12}$$

The detailed design of γ, α, m, and further variables for constraints transformation are given in [7, 8], in which theoretical proof has been rigorously performed that the state point is

forced to the origin of the sliding surface σ in minimum time, meanwhile, it also consequences on the fulfillment of the constraints on the velocity and acceleration.

As defined in (3.5) , the optimized acceleration of the trajectory can be written as

$$\ddot{x}_p = v + \ddot{x}_d \tag{3.13}$$

The optimized position x_p and velocity $\dot{x}_p$ can be calculated through differential equation (3.2). This optimized trajectory is given to motion controller in real time, which is detailed in the next chapter.

4. MOTION CONTROL

4.1. Adaptive Robust Controller Design

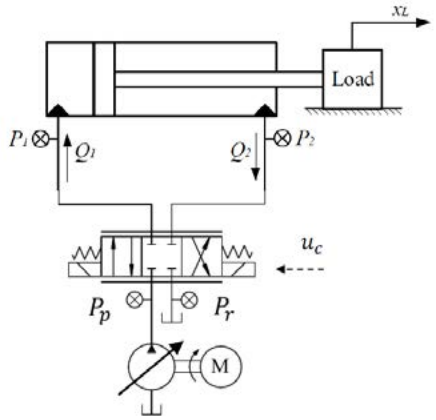

Figure 4.1 A simplified proportional valve-controlled cylinder

1) Dynamics modelling

A simplified general hydraulic system is presented in Figure 4.1, in which the motion of the hydraulic actuator is controlled by a proportional valve. The descriptions of symbols are listed in Table 1 in the Appendix. The dynamics of the cylinder motion can be modelled as

$$m\ddot{x}_L = P_1A_1 - P_2A_2 - b_v\dot{x}_L - b_c \cdot S_f(\dot{x}_L) + F_{\mathrm{d}}(x_L, \dot{x}_L, t) \tag{4.1}$$

where m represents the integrated mass of the inertia load; x_L represents the inertia load displacement; P_1 and P_2 represent the pressures of the head chamber and rod chamber; A_1 and A_2 represent areas of the two sides of the piston; b_v and b_c represent a viscous friction coefficient and a coulomb friction coefficient, respectively; $S_f(\bullet)$ represents a continuous function approximating the $\mathrm{sign}(\bullet)$. In addition, F_{d} represents a lumped uncertain nonlinearity, described as

$$F_{\mathrm{d}}(x_L, \dot{x}_L, t) = F_{\mathrm{dn}} + \tilde{F}_{\mathrm{d}} \tag{4.2}$$

where F_{dn} represents the nominal value of F_{d}.

The pressure dynamics of two chambers of the cylinder actuator can be modelled as

$$\begin{cases} \dfrac{V_1(x_L)}{\beta_e}\dot{P}_1 = -A_1\dot{x}_L - C_i(P_1 - P_2) + Q_1 \\ \dfrac{V_2(x_L)}{\beta_e}\dot{P}_2 = A_2\dot{x}_L + C_i(P_1 - P_2) - Q_2 \end{cases} \tag{4.3}$$

where C_i is the inner leakage coefficient. The flow rate linked to each chamber of the cylinder, controller by the proportional valve, can be modeled as

$$\begin{cases} Q_1 = k_{\mathrm{q1}}\sqrt{|\Delta P_1|}\,u_c \\ Q_2 = k_{\mathrm{q2}}\sqrt{|\Delta P_2|}\,u_c \end{cases} \tag{4.4}$$

where k_{q1} and k_{q2} are the throttling coefficients, $|\Delta P_i|$ (i=1,2) is the pressure drop due to throttling, and u_c denotes the effective valve control, which is proportional to the opening of valve spool.

The state-space variables of the pump control electro-hydraulic actuator are defined as $[x_1, x_2, x_3, x_4]^T = [x_L, \dot{x}_L, P_1, P_2]^T$. The uncertain parameters include m, b_v, b_c, β_e, C_i, and d_n. The uncertain parameter set is defined as $\theta = [\theta_1, \theta_2, \theta_3, \theta_4, \theta_5, \theta_6]^T$ in which $\theta_1 = 1/m,\ \theta_2 = b_v/m,\ \theta_3 = b_c/m,\ \theta_4 = F_{dn}/m,\ \theta_5 = \beta_e,\ \theta_6 = \beta_e C_i$.

The dynamics of the actuator motion control system can be parameterized as

$$\begin{aligned} \dot{x}_1 &= x_2 \\ \dot{x}_2 &= \theta_1(A_1x_3 - A_2x_4) - \theta_2x_2 - \theta_3S_f(x_2) + \theta_4 + \Delta \\ \dot{x}_3 &= \frac{1}{V_1(x_1)}(-\theta_5A_1x_2 - \theta_6(x_3 - x_4) + \theta_5g_1u_c) \\ \dot{x}_4 &= \frac{1}{V_2(x_1)}(\theta_5A_2x_2 + \theta_6(x_3 - x_4) + \theta_5g_2u_c) \end{aligned} \tag{4.5}$$

where $g_i = k_{qi}\sqrt{|\Delta P_i|},\ \Delta = \tilde{F}_{\mathrm{d}}/m$.

2) Controller design

This motion controller is a nonlinear model-based controller, based on an adaptive robust backstepping control structure, to accurately track the planned trajectory x_{p}. As shown in Figure 4.2, the controller includes two steps: motion tracking step and hydraulic force tracking step. Define $\hat{\theta}$ as the estimate of θ with $\hat{\theta}_{\min} < \hat{\theta} < \hat{\theta}_{\max}$ and $\tilde{\theta}$ as the estimation error, (i.e., $\tilde{\theta} = \hat{\theta} - \theta$).

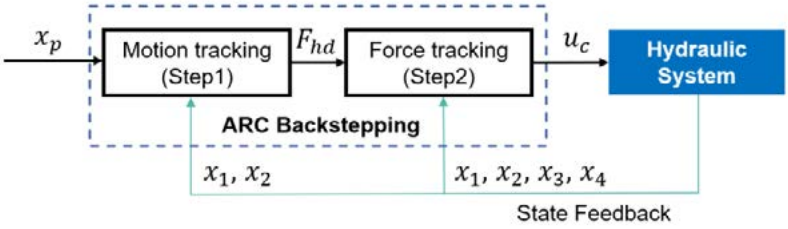

Figure 4.2 ARC Backstepping control strategy

The adaptation law is given by

$$\dot{\hat{\theta}} = \mathrm{Proj}_{\hat{\theta}}(\Gamma\tau) \tag{4.6}$$

where τ is an adaptation function introduced by Eq. (4.10) and (4.13); Γ is an adaptation rate matrix; $\mathrm{Proj}(\bullet)$ is a discontinuous projection [9].

Step 1: Motion tracking

The virtual control input F_h (i.e., hydraulic force) is designed to make the actuator position track the planned trajectory x_r. The output tracking error of the planned trajectory is defined as $z_1 = x_1 - x_r$. A switch function is then defined by

$$z_2 = \dot{z}_1 + k_1 z_1 = x_2 - x_{2eq}, \;\; x_{2eq} = \dot{x}_r - k_1 z_1 \tag{4.7}$$

where $x_r(t)$ represents the planned trajectory to be tracked by output x_1 and k_1 is a positive feedback gain. It is straightforward to see that making z_1 converging to zero implies making z_2 converging to zero [31].

Considering the hydraulic force $F_h = P_1 A_1 - P_2 A_2$, the error dynamics is given by

$$\dot{z}_2 = \dot{x}_2 - \dot{x}_{2eq} = \theta_1 F_h - \theta_2 x_2 - \theta_3 S_f(x_2) + \theta_4 + \Delta - \dot{x}_{2eq}. \tag{4.8}$$

The desired hydraulic force F_{Ld} is defined as the control input of Step 1. Then, the ARC control input law is designed to minimize z_2, which is given by

$$\begin{aligned} &F_{hd}\left(x, \hat{\theta}, t\right) = F_{hda} + F_{hds} \\ &F_{hda} = \frac{1}{\hat{\theta}_1}\left(\hat{\theta}_2 x_2 + \hat{\theta}_3 S_f(x_2) - \hat{\theta}_4 + \dot{x}_{2eq}\right) \\ &F_{hds} = F_{Lds1} + F_{Lds2}, \;\; F_{hds1} = -\frac{1}{\theta_{1min}} k_2 z_2 \end{aligned} \tag{4.9}$$

where F_{hda} demotes an adaptive model compensation; F_{hds} demotes the robust feedback term; k_2 demotes a positive stabilizing feedback gain. Details on how to choose the nonlinear feedback (for F_{hds2}) are proposed in the literatures [15]. The adaptation function of Step 1 is given by

$$\tau_2 = \phi_2 z_2, \; \phi_2 = \left[F_{Lda}, -x_2, -S_f(x_2), 1, 0, 0\right]^T. \tag{4.10}$$

Step 2: Hydraulic force tracking

Control input u_c is synthesized to make the actual hydraulic force track the desired hydraulic force F_{Ld} (i.e., the input of Step 1). The input discrepancy of Step 1 is defined as $z_3 = F_h - F_{hd}$. The error dynamics is modelled as

$$\begin{aligned} \dot{z}_3 = \;& \dot{F}_h - \dot{F}_{hd} \\ = \;& u_c \theta_5 \left(\frac{g_1 A_1}{V_1} + \frac{g_2 A_2}{V_2}\right) - \theta_5 x_2 \left(-\frac{A_1^2}{V_1} - \frac{A_2^2}{V_2}\right) - \theta_6 (x_3 - x_4)\left(-\frac{A_1}{V_1} - \frac{A_2}{V_2}\right) \\ & -\left(\dot{F}_{hdc} + \dot{F}_{hdu}\right) \end{aligned} \tag{4.11}$$

in which $\dot{F}_{hdc}$ and $\dot{F}_{hdu}$ represent the calculable part and uncalculable part of $\dot{F}_{Ld}$, respectively.

The ARC control law u_c, the valve control input, is given by

$$u_{\mathrm{c}}\left(x,\hat{\theta},t\right)=u_{\mathrm{ca}}+u_{\mathrm{cs}}$$
$$u_{\mathrm{ca}}=\frac{1}{\hat{\theta}_5\left(\frac{g_1A_1}{V_1}+\frac{g_2A_2}{V_2}\right)}\left(\theta_5x_2\left(-\frac{A_1^2}{V_1}-\frac{A_2^2}{V_2}\right)+\theta_6(x_3-x_4)\left(-\frac{A_1}{V_1}-\frac{A_2}{V_2}\right)+\dot{F}_{hdc}-\hat{\theta}_1z_2\right)$$
$$u_{\mathrm{cs}}=u_{\mathrm{cs1}}+u_{\mathrm{cs2}},\ \ u_{\mathrm{cs2}}=-\frac{1}{\hat{\theta}_{5\min}\left(\frac{g_1A_1}{V_1}+\frac{g_2A_2}{V_2}\right)}k_3z_3 \tag{4.12}$$

in which u_{ca} functions is an adaptive model compensation term; u_{cs} is the robust feedback term; k_3 is a positive stabilizing feedback gain; u_{cs2} is a nonlinear feedback term.

The adaptation function is given by

$$\tau=\tau_2+\phi_3z_3 \tag{4.13}$$

where ϕ_3 is defined as

$$\begin{aligned}\phi_3 \ &=[z_2-\frac{\partial F_{Ld}}{\partial x_2}F_h,-\frac{\partial F_{hd}}{\partial x_2}x_2,-\frac{\partial F_{hd}}{\partial x_2}S_f(x_2),\frac{\partial F_{hd}}{\partial x_2},\\ &\quad u_{\mathrm{ca}}\left(\frac{g_1A_1}{V_1}+\frac{g_2A_2}{V_2}\right)-x_2\left(-\frac{A_1^2}{V_1}-\frac{A_2^2}{V_2}\right),-(x_3-x_4)\left(-\frac{A_1}{V_1}-\frac{A_2}{V_2}\right)]^T.\end{aligned} \tag{4.14}$$

The theoretical proof of the two-step ARC backstepping controller has been rigorously performed in the literatures [9, 15] and it is omitted in this section. It is proved that the proposed controller guarantees the transient performance and asymptotical tracking in the presence of uncertainties only.

4.2. Lightweighted Controller Design for Pressure-Compensated Systems

In pressure-compensated hydraulic systems, the valve input can be represented as either the desired flow rate (for upstream compensation) or the desired actuator velocity (for downstream compensation). The pressure compensation mechanism effectively decouples the valve flow from load pressure variations, thereby simplifying the control design. As a result, a lightweight linear controller can achieve stable and accurate motion tracking in applications with moderate dynamic requirements.

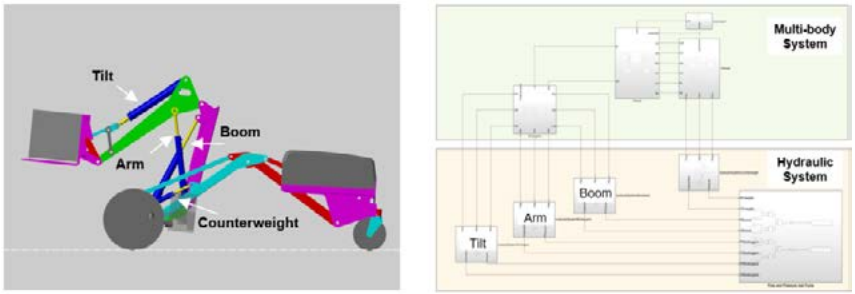
$$v_{\mathrm{input}}=\dot{x}_p+k_{\mathrm{p}}(x_{\mathrm{d}}-x_1)+k_{\mathrm{v}}(\dot{x}_{\mathrm{d}}-x_2) \tag{4.15}$$

where k_{p} and k_{v} are positive feedback gains for position and velocity; the planed velocity $\dot{x}_p$ servers as the feedforward term for dynamic compensation. Thereby, the flow rate input can be calculated by

$$Q_{\mathrm{input}}=v_{\mathrm{input}}\boldsymbol{A} \tag{4.16}$$

where $\boldsymbol{A}$ denotes the effective piston area of the corresponding chamber (rod or head side), depending on the actuator's moving direction.

5. VERIFICATION ON UNMANNED WHELL LOADER



5.1. System Formulation

Figure 5.1. Two-wheel wheel loader by Quimo (picture from [18])

The machine used for a case study in this paper is an unmanned wheel loader, named two-wheel wheel loader, designed by Quimo as shown in Figure 5.1. The working arm of the wheel loader comprises three hydraulic cylinders, each named according to its function: the boom cylinder, arm cylinder, and tilt cylinder, as shown in Figure 5.2 (a). In addition, a counterweight cylinder is used to adjust the counterweight and ensure stability of the machine. All cylinders are equipped with linear position sensors, enabling the measurement of position and velocity. The hydraulic system adopts a load-sensing system with upstream pressure compensators. The valve block used in this study is an M4-12 load-sensing valve block coupled with an A10VO variable-displacement pump (both from Bosch Rexroth).

A co-simulation platform was developed in MATLAB/Simulink using the Simscape "Multibody" and "isothermal Fluid" library, integrating the multi-body dynamics of the wheel loader, the simplified upstream pressure-compensated hydraulic circuit, and their coupled dynamic interactions, as illustrated in Figure 5.2 (b). The density of the steel used for the working arm is set to 7800 kg/m³ in the simulation program.

5.2. Single Cylinder Control Result

Before machine-level verification, the proposed controller was first applied to a proportional valve–controlled single-cylinder system. Case 1 was conducted to validate the optimal constrained control performance of the planning strategy integrated with the proposed Adaptive Robust Controller (ARC) described in Section 4.1, referred to as C1. The maximum velocity limit $\dot{x}^+$ in Eq. (3.1) was set to 0.20 m/s for the planner, while the

desired trajectory x_d had a maximum velocity of 0.23 m/s. As shown in Figure 5.3, controller C1 accurately tracked the planned constrained trajectory x_p that reached x_d at steady state while maintaining a smooth transient response. The velocity of the planned trajectory remained strictly within the prescribed constraint boundary throughout the motion, and the actual actuator velocity x_2 demonstrate the accurate tracking of the planned actuator velocity $\dot{x}_p$.

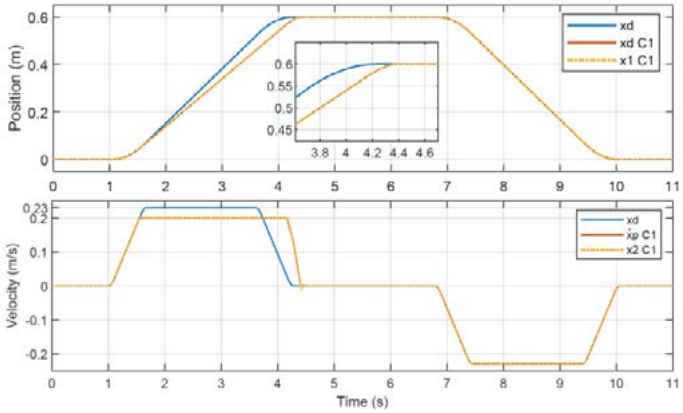

Figure 5.3. Positions and velocities in Case 1

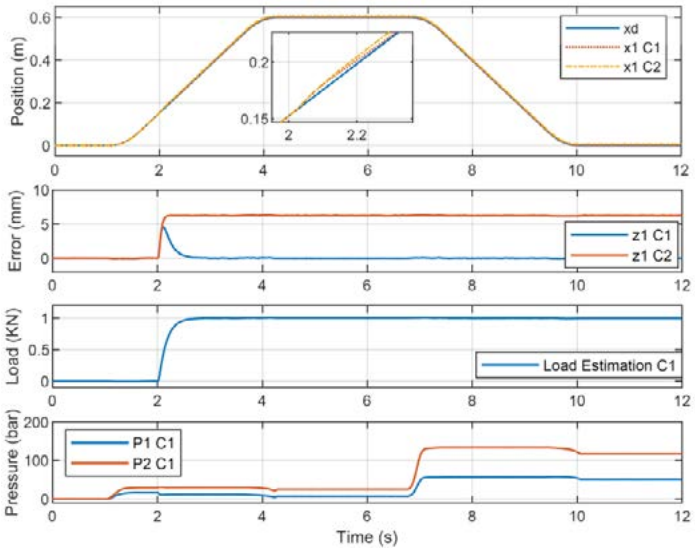

Figure 5.4. Position, tracking errors, load estimation in Case 2

Case 2 was performed to evaluate the anti-disturbance capability of the proposed controller. For comparison, another model-based controller with the same structure but without parameter adaptation was implemented as a baseline, denoted as C2. An external disturbance force of 1 kN was applied to the actuator at t = 2 s. As shown in Figure 5.4, both controllers experienced an immediate rise in tracking error following the disturbance. However, C1 rapidly suppressed the error and restored accurate tracking, demonstrating its superior

disturbance rejection. This improvement is attributed to the effective online parameter adaptation in C1, which also provided accurate load estimation results, as shown in Figure 5.4. The pressure signals of both chambers of the hydraulic cylinder are also presented to provide additional insight into the internal force states of the actuator.

5.3. Working Arm Control Result

In this section, the proposed control framework (as illustrated in Figure 2.1) is fully applied to the working arm of the unmanned wheel loader, with an external mass load of 50 kg.

In this case, since the upstream pressure compensator defines the control input as the desired flow rate, the lightweight controller introduced in Section 4.2 is employed for the motion control layer. For comparison, a baseline controller (C3) is implemented—an open-loop controller with feedforward compensation but without feedback—to demonstrate the significance of closed-loop control in multi-actuator hydraulic systems.

Figure 5.5 shows the control results of the working arm, where the trajectories of all three cylinders are presented. The desired trajectories x_d are discrete setpoints generated at a low sampling frequency of 20 Hz. The proposed controller C1 generates real-time constrained trajectories x_p at 100 Hz, guiding the system smoothly toward x_d while optimally satisfying all constraints. The measured position signals x_1 demonstrate that all cylinders accurately track the planned trajectories under C1. In contrast, C3 exhibits poor tracking accuracy, with cumulative position deviations over time due to the absence of feedback control.

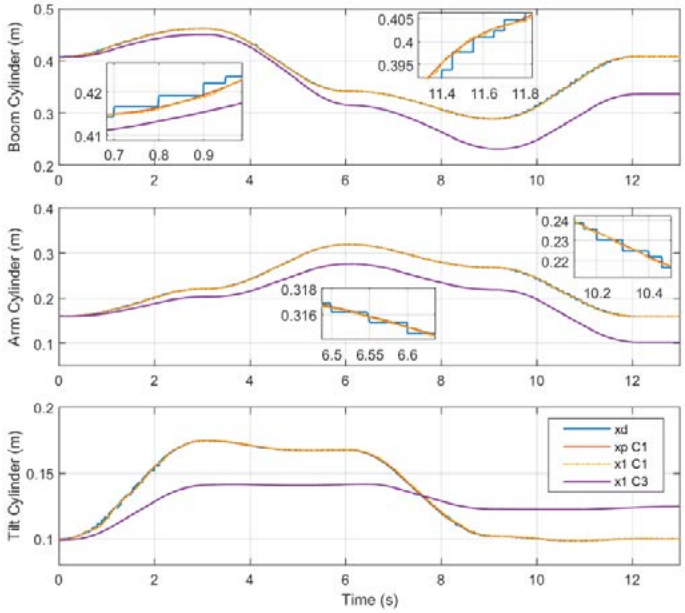

Figure 5.5. Results of working arm control

A comparison of C1 and C3 on the machine level is shown in Figure 5.6. The full operation cycle was designed to drive the end effector along a square trajectory in 12 seconds. Controller C1 maintained high tracking accuracy throughout both transient and steady-state phases, successfully accomplishing the desired motion. In contrast, C3 resulted in significant

deviations at both the cylinder and end-effector levels. Demonstration videos corresponding to Figure 5.6 are provided in the **Appendix**.

6. CONCLUSION AND FUTURE WORK

This paper presented a unified framework integrating constrained optimal trajectory planning and adaptive robust motion control for electrohydraulic mobile machines. The multi-layer architecture enables coordinated, constraint-satisfied, and robust motion execution. A nonlinear filter-based planner and an adaptive robust controller were combined to achieve precise, time-optimal tracking under nonlinearities and uncertainties. Experimental verification on an unmanned wheel loader demonstrated that the proposed approach outperformed baseline linear and open-loop controllers in tracking accuracy, robustness under uncertainty, and constraint compliance. A lightweight controller for pressure-compensated hydraulic systems was also introduced for practical industrial use. The proposed framework provides an effective and scalable basis for the autonomous operation of future electrohydraulic mobile machines.

In the future work, the integration of higher-level perception and task planning modules, such as environment sensing and adaptive task sequencing, will be explored to enable fully autonomous operation of mobile machines. Furthermore, future work will emphasize experimental validation across various types of machines under varying payloads and external disturbances. These extensions will further enhance the robustness, scalability, and industrial applicability of the proposed automation framework.

ACKNOWLEDGEMENT

This work was carried out as part of a research project funded by the Ministry of Economics, Labour and Tourism of Baden-Württemberg, Germany. Furthermore, we would like to thank the project partner QuiMo for designing the mechanical system of the unmanned wheel loader and providing its desired movement (i.e., Setpoints x_d in Section 5.3).

Exploratory Analysis of Optimisation Results for the Multi-Pump System Using Data-Driven Methods

Artur Tozzi de Cantuaria Gama, Samuel Kärnell, Liselott Ericson

Linköping University, Department of Management and Engineering, Division of Fluid and Mechatronic Systems, Linköping, Sweden, artur.tozzi@liu.se

Abstract.

Reduced climate impact is a major topic in the mobile machinery industry, and electrification is one of the ways to achieve that. Electrified vehicles provide new opportunities to improve the hydraulic system design to achieve higher efficiency. A Multi-Pump System (MPS) approach has been proposed, that provides connection paths between any hydraulic machine port to any actuator chamber through a manifold of on/off valves. This flexibility provides multiple alternative ways to control the system that are challenging to describe intuitively, specially when multiple actuators are considered. This paper presents an exploration of different machine learning algorithms for data analyses applied to the output of control optimisation of the MPS. The results show that dimensionality reduction might not be enough to provide a visualisation approach with clear borders between operating modes for the design of control rules. A supervised classification approach called k-nearest neighbours (kNN) is then trained on the optimisation results to predict the hydraulic machines operating modes based on the actuators' states. Using part of the data for training and testing allows a measurement of the accuracy of this approach. The accuracy of the algorithm varies between 53 % and 96 %, depending on the parameters set for the kNN, greatly reducing the number of options to consider for the design of a control system.

Keywords. Multi-pump system, data-driven analysis, machine learning, dimensionality reduction, classification.

1. INTRODUCTION

The global trend of electrification and digitalisation of hydraulic systems brings opportunities for novel subsystems architectures. Electric vehicles provide new degrees of freedom for the design and control of these systems and also require more efficient solutions to minimise the effects of the overall lower energy density compared to fossil fuel alternatives.

Mobile machinery hydraulic systems have traditionally relied on centralised pump architectures, where multiple actuators share flow through proportional valves. When several actuators operate simultaneously, significant energy losses occur due to throttling and flow sharing [1]. Consequently, conventional valve-controlled systems exhibit low overall efficiency. In contrast, a comparative study between a conventional system and a self-contained electro-hydraulic cylinder demonstrated an improvement in efficiency from 22 % to 57 % [2].

All Open Access articles are peer-reviewed, distributed under the Creative Commons Attribution-Non Commercial 4.0 International

An electrified vehicle can adopt similar solutions to those applied to combustion engines, such as displacement control [3, 4]. The disadvantage is that the hydraulic machines share a single shaft, limiting their operation to the same angular speed, thus variable displacement is needed. Electro-hydraulic actuators (EHAs) aim to decentralise the hydraulic system and eliminating flow sharing between actuators can improve efficiency [2, 5, 6]. The downside is the increase in total installed power, as each EHA must be sized to provide the maximum corresponding actuator power.

Common- or multi-pressure rail solutions can also be employed [7–9], but they typically still required some level of throttling for finer control, although a more recent proposal aims to achieve varying pressure levels [10]. Finally, a novel solution proposes a network of variable-speed drives to control the hydraulic machines for multi-actuator operation and to remove the directional valves [11–13], although sizing components and defining the ideal short-circuits between actuators' chambers is non-trivial.

This paper focuses on another proposal called the Multi-Pump System (MPS) [14]. The system aims to minimise throttling losses by using only on/off valves and focuses the control system on the variable-speed, fixed-displacement, 4-quadrant operation pump/motors. Since the hydraulic machines can be shared between actuators and recuperation and regeneration are available, the total installed power can be reduced.

Controlling such a system is challenging, as there are many options to achieve the same behaviour. An optimisation strategy available in [14, 15] determined the operating conditions that minimise power consumption for a system with a single actuator. The results can be used to define the optimal operating conditions for the hydraulic machines based on the actuator's speed and force. Visualising the data and extracting control rules for this system is intuitive [16], but each additional actuator doubles the number of dimensions to consider.

1.1. *High-Dimensional Control Challenges in the Multi-Pump System*

Figure 1.1 shows an example of the MPS, referred to as 3P2A, with three pump/motors (3P), two actuators (2A), and a constant pressure source for the low-pressure line. The valve manifold allows any pump/motor port to connect to any actuator chamber. By sharing the hydraulic machines between the functions, the overall installed power can be reduced compared to alternatives such as individual electro-hydraulic actuators. The system design facilitates expansion, meaning that more actuators or hydraulic machines can be considered, which only requires adding a row or column of valves, respectively, for each new component [14].

One drawback of this solution is that the control strategy is tightly coupled to the operating state of each system component. The number of active hydraulic machines and their operating modes (pump or motor) depend on the combined operating quadrants of the actuators throughout the drive cycle. In theory, flow distribution among the hydraulic machines can be achieved in infinitely many ways, and should account for energy recuperation and regeneration, leading to a large number of possible configurations.

Previous research discussed how an optimisation approach can be used to explore the control variables design space [14, 15]. Based on the actuator(s) operating points, the algorithm can identify what are the optimal ways to distribute the flow throughout the system during steady-state operation to minimise power consumption. The goal is to identify unusual valve connections and define transition boundaries that determine when to activate the hydraulic machines and how to distribute the flow between them.

The design space is reduced, but remains high-dimensional and difficult to interpret. As a result, direct visualisation of the results might not be possible, and more structured analyses are required. This paper presents an exploratory application of established machine learning techniques for high-dimensional data analysis to use the optimisation results.

The characteristics and algorithms of the applied methods are not discussed in detail, as they are will established in the literature. Mathematical descriptions and examples are provided in [17, 18], while practical implementations in *Python* are presented in [19]. The methods used

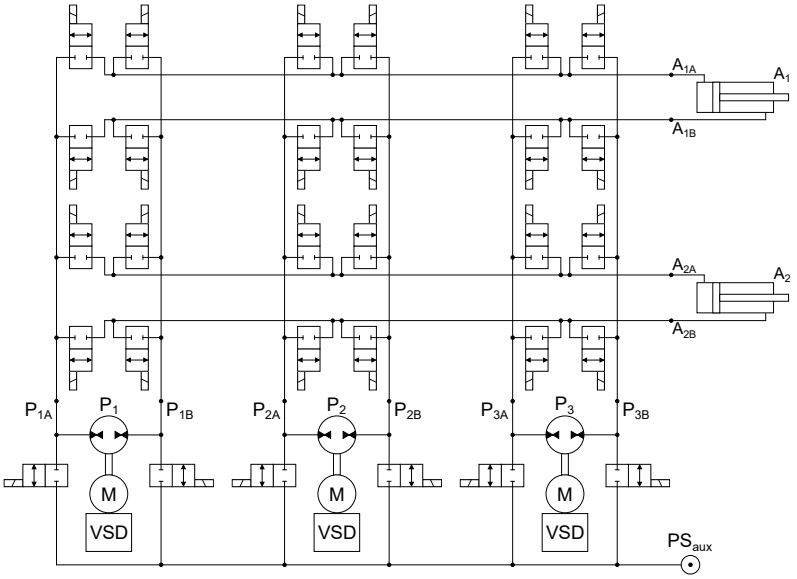

Figure 1.1: A 3P2A Multi-Pump System with three pump/motors, two actuators and a constant auxiliary pressure line.

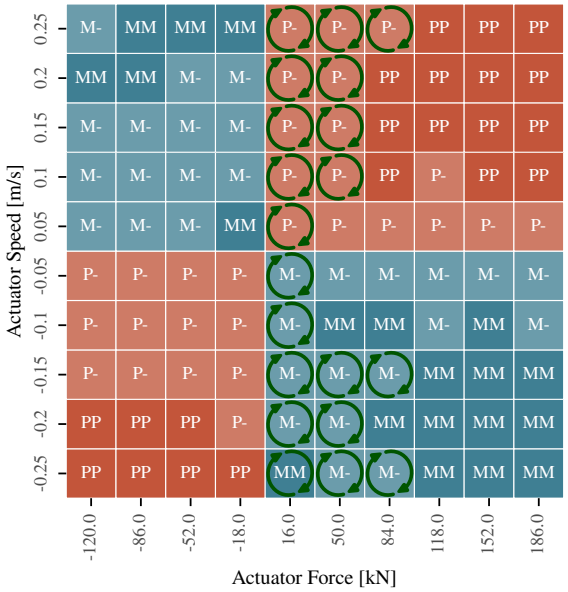
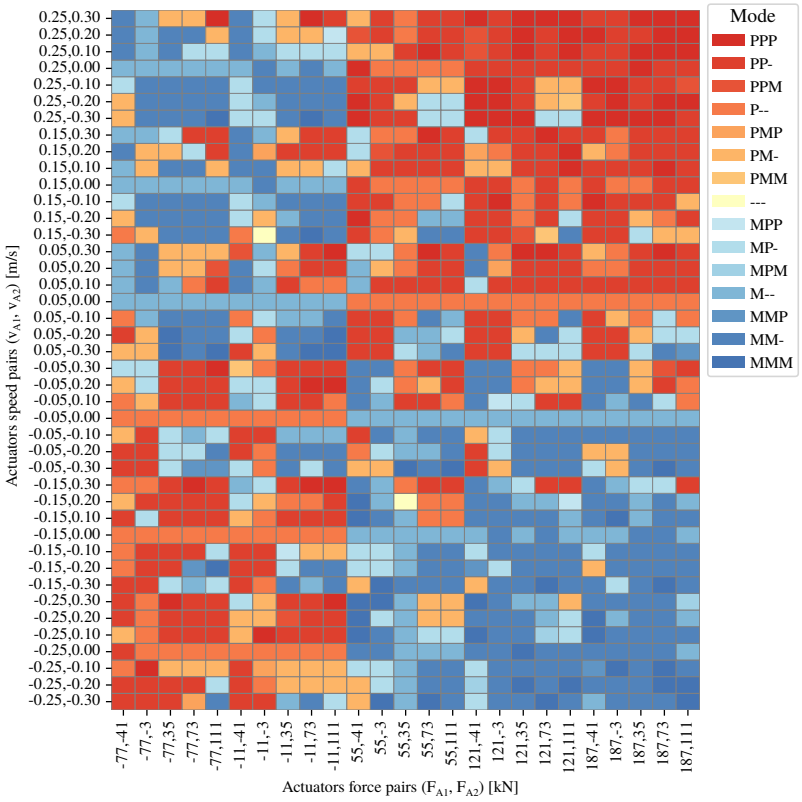
in this work are available in the *Scikit-learn* library [20], and the following descriptions are based on these references unless stated otherwise.



2. Problem Statement and Motivation for a Machine Learning Approach

For a system with a single actuator, the transition boundaries between operating modes are straightforward to define due to the low-dimensional operating space, as illustrated in fig. 2.1a for a 2P1A system. The axes represent the desired actuator speed and force–which can be determined from the chamber pressures and the corresponding actuator areas (piston- and rod-side).



Each speed-force combination corresponds to an optimal operating mode for the two hydraulic machines, found by the optimisation algorithm. The two letters shown in each cell refer to pump/motors P_1 and P_2, respectively: "P" indicates pump mode, "M" is motor mode, and "-" an inactive machine. The green arrows indicate regenerative mode, when the actuator chambers are short-circuited to reduce the required pump/motor flow. The resulting division enables the design of a mode-based control strategy, where control decisions depend on the region in which the operating point lies.

Figure 1.1 illustrates a system with an additional actuator and one more pump/motor, a 3P2A configuration. To maintain a high degree of freedom for control, the pump/motors are sized so that two can provide the maximum combined actuators' flow. The third machine, of identical size, provides redundancy and allows the system to achieve high actuator velocities without requiring all three machines to operate at high angular speeds.

The additional actuator introduces two extra dimensions to the input space. To reduce the visualisation to two dimensions, a representation similar to Fig. 2.1b can be used. In this graph, the x-axis represents pairs of actuator speed values: the first actuator's speed is held constant while the second actuator's speed is varied across its discrete values. Once all values for the second actuator have been covered, the first actuator's speed is incremented to the next grid level, and the process repeats. The same approach is applied to the force values.

(a) 2P1A system [16].

(b) 3P2A system [14].

Figure 2.1: Optimal operating modes for two MPSs architectures: (a) 2P1A and (b) 3P2A systems.

The optimisation can assign any of the pump/motors to operate at each evaluated point, which may result in functionally redundant solutions—for example, the operating modes `P--`, `-P-`, and `--P` all represent the same system behaviour. To address this, the solutions are reorganised such that the first character always corresponds to the pump/motor with the highest absolute angular speed, which can be assumed to be P_1 in Fig. 1.1. For instance, a mode like "-PM" would be reordered as "MP-", indicating that the machine with the highest angular speed operates as a motor, the second as a pump, and the third is inactive.

The previous step reduces the number of combined operating modes to consider, but defining transition criteria from the resulting graph remains challenging. While the corner regions are relatively easy to interpret, the intermediate areas exhibit more complex and irregular boundaries. This lack of clear separation makes it difficult to extract consistent rules solely from the graph. Alternative arrangements of the axes values were tested, but they did not lead to significant improvements in interpretability.

Hydraulic systems for mobile machinery often have three or more actuators, increasing the challenge of defining the transition criteria. It is thus interesting to apply methods that can adapt to a varying number of input variables, or for the purposes of using machine learning terminology, the features or dimensions of the problem.

2.1. *Selected Machine Learning Methods*

Different machine learning algorithms could be employed to undertake this problem, which depends on what the aim is and what information one wants to employ for the analysis. The proposal for this paper can be summarised in the following questions:

- Which machine learning methods should be employed for the MPS problem based on the optimisation results?
- Assuming a system plant with limited sensors and a direct application to a control system using only the measurable variables such as actuator speed and pressure levels:
  - Is it possible to summarise the available information into a bi-dimensional representation that can be used as a guideline for the definition of rules and transition regions for a control system?
  - Can any method produce a model from the optimisation data available that can take the necessary control decisions with satisfactory precision?

The results presented in this paper therefore focus on two complementary approaches. The first considers dimensionality reduction approaches, which can be used for visualisation of patterns in the data in lower dimension or to produce a simplified model of the system. The second approach relies on supervised classification algorithms. As the operating modes are already defined by the optimisation procedure, they can be treated as class labels, enabling the algorithms to categorise the data based on the available input variables.

The following sections present results for the two approaches. The algorithms applied here were selected for their illustrative value and are not necessarily optimal, as the best choice depends on the specific problem context. This paper focuses on the dimensionality reduction techniques Principal Component Analysis (PCA) and Linear Discriminant Analysis (LDA), as well as the supervised classification algorithm *k*-nearest neighbours (kNN).

2.2. *The Optimisation Results*

The Genetic Algorithm (GA) employed to produce the data used in this analysis is described in [15]. A similar process is done for the 3P2A system with varying actuator speeds and force levels. The goal of the optimisation is to minimise power consumption at steady-state, thus transitions between operating modes and valve switching are not accounted for.

The optimisation is performed six times for each combined operating point of the actuators in order to limit the computational cost. The reason is that the GA is used as a stochastic,

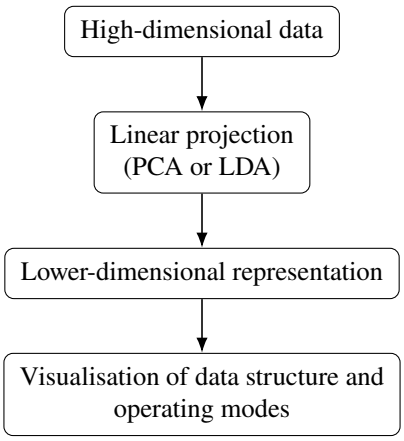
explorative method and does not guarantee global optimality. Instead, this optimisation problem can exhibit multiple local minima with similar performance. From a control perspective, having multiple feasible solutions is advantageous, as it provides flexibility when selecting operating modes and transitioning between configurations. The operating modes presented in fig. 2.1b refer to the best solution of the six runs.

The combined actuators' operating points, as shown in fig. 2.1b produced a total of 1 050 points, thus totalling 6 300 optimisation runs. The values of all system variables are available for analysis. Around 2,6 % of these points are discarded as they converged to undesired operation conditions, e.g. with too large error in the actuators' speeds. Thus, the following methods are applied to a data set with a total of 6 134 points.

The 3P2A has at least four features, corresponding to the force and speed of each actuator, but more could be employed. Assuming that in a real system only pressure levels can be measured, the following results use the actuators' reference speed values and pressures on each chamber as the features for analysis. The aim is to evaluate whether this feature set is sufficient to support control decisions at pump/motors level.

3. Dimensionality Reduction for Visualisation

The main idea with dimensionality reduction is to represent a high-dimensional data set into fewer dimensions. Some methods focus on identifying redundant aspects of the data set that have minimal effect on the distribution and thus could be ignored without high loss of information. Figure 3.1 summarises the process employed in this work.



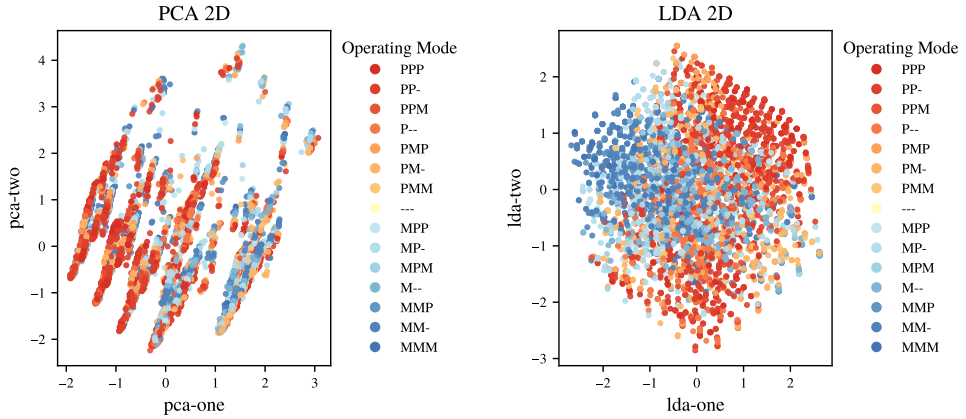


Figure 3.1: Overview of the dimensionality reduction workflow using PCA and LDA.

PCA and LDA are both dimensionality reduction techniques. They create new variables—linear combinations of the original features—that aim to represent the data in fewer dimensions. PCA is an unsupervised method that identifies directions of maximum variance in the data, thereby spreading the data points as widely as possible. LDA, on the other hand, is a supervised technique that uses known class labels to find directions that maximise the separation between classes. Although LDA can also be used for classification, it is often use for dimensionality reduction in a way that preserves the separation.

As these are linear methods, it is also possible to determine the features values from a data point in the lower dimension space. This could be used to determine the operating modes for a point that was not evaluated during the optimisation. Their downside is that the linear approach may not capture the non-linear characteristics of the system, thus underperforming regarding the data separation. Nevertheless, they can provide simple models from a data set with a large number of inputs.

Figure 3.2 shows the two-dimensional projections obtained by using the first two components as the x- and y-axes for both PCA and LDA. In both cases, the first components describe the dominant structure of the data, which results in the most distinct separation. Figures 3.2a and 3.2b show the resulting data clustering for PCA and LDA, respectively.

(a) Principal Component Analysis (PCA).

(b) Linear Discriminant Analysis (LDA).

Figure 3.2: Visualisation of the first two components for the dimensionality reduction algorithms.

From these results, limited information can be extracted from visualisation alone, although some initial clustering can be seen. Table 3.1 shows the explained variance (*PCA Var. Ratio*) and cumulative explained variance (*PCA Cum. Var.*) for each PCA component, as well as the equivalent discriminant ratios (*LDA Discr. Ratio*) and cumulative discriminant ratio (*LDA Cum. Discr.*) for LDA. There are a total of six features, the actuators' speeds and the pressure levels in each chamber. Accordingly, PCA can yield up to six components, while LDA produces at most one fewer discriminant component than the number of classes.

Table 3.1: Explained variance ratios for PCA and discriminant ratios for LDA, including cumulative values.

Component	*PCA Var. Ratio*	*PCA Cum. Var.*	*LDA Discr. Ratio*	*LDA Cum. Discr.*
1	0,22	0,22	0,77	0,77
2	0,19	0,42	0,13	0,90
3	0,19	0,60	0,06	0,96
4	0,17	0,77	0,02	0,98
5	0,17	0,93	0,02	1,00
6	0,07	1,00	-	-

The first two PCA components explain just 42 % of the total variance in the data, indicating that a two-dimensional projection provides a limited representation of the data, as in fig. 3.2a. LDA, on the other hand, captures 90 % of the cumulative discriminant ratio with the first two components; however, this does not translate into clear visual separation due to the large number of operating-mode classes and their possible overlap.

Overall, neither method yields a two-dimensional representation with clear separation between operating modes. This might be expected, as the analysis attempts to determine the pump/motor operating modes based only on actuators information, thus neglecting non-linear behaviour and discontinuous characteristics of the system.

4. Supervised Classification with K-Nearest Neighbours

An alternative approach is to use the operating modes obtained from the optimisation to train supervised classification methods. Once trained, these models can predict the pump/motor operating modes (classes) based only on the input variables provided during training.

The k-nearest neighbours (kNN) algorithm is selected due to its simplicity and intuitive interpretation. For a given input point, the algorithm identifies the k closest points in the training data and assigns a class based on a majority vote. Two weighting strategies are considered: uniform weighting, where all neighbours contribute equally, and distance-based weighting, where closer neighbours have a stronger influence. Distances are computed in the multi-dimensional feature space, allowing the method to incorporate multiple input features simultaneously. Figure 4.1 presents the steps employed in this paper, and section 4.1 expands on these steps.

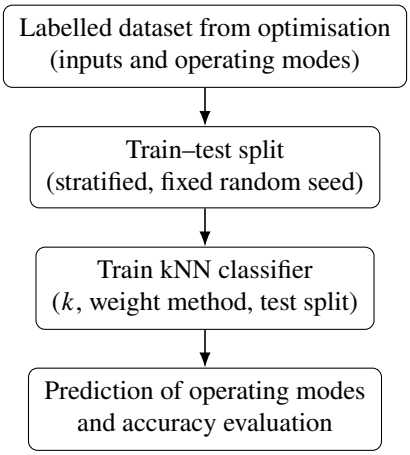

Figure 4.1: Overview of the supervised classification workflow using kNN.

4.1. *Accuracy Evaluation and Hyperparameters*

The classification accuracy is evaluated by dividing the dataset into separate training and test sets. The trained model is applied to the inputs of the test set, and the predicted operating modes are compared with those obtained originally from the optimisation.

To ensure that that all operating modes are accounted for during training, a stratification approach is used to ensure that both training and test sets contain examples of each class. Therefore, the data split is generated through a randomised procedure with stratification, and a fixed random seed is used to provide the same train-test separation when comparing results with different hyperparameters.

The parameters used and varied for the kNN classifier are:

- **Number of neighbours:** $k = 5$.
- **Weighting method:** uniform or distance.
- **Test set fraction:** 10 %, 20 %, 30 %.

The small number of neighbours was chosen to prioritise local information. Since several operating modes occur infrequently in the dataset, using a small k reduces the influence of frequent classes and distant samples, thus mitigating misclassification of rare operating modes.

4.2. *Classification Results*

Table 4.1 shows the accuracy for different evaluations with kNN using the unmodified optimisation data. One characteristic of the MPS is that it might have multiple viable solutions for each combined operating point of the actuators. In the table, the *Exact* column refers to the kNN accuracy in finding the exact operating mode determined by the optimisation runs in the test set.

The results are also presented for the training and test sets. Using the same training set to evaluate the kNN serves as a sanity check on the model memorisation. Generalisation is assessed from the test set.

Table 4.1: Comparison of kNN classification accuracies (%) for different test set sizes and weighting methods. Exact = strict accuracy, Accept. = acceptable accuracy (any valid mode for same operating point), Top-3 = accuracy within three most probable modes.

Split	**Uniform weights**			**Distance weights**		
	Exact	*Accept.*	*Top-3*	*Exact*	*Accept.*	*Top-3*
Training set						
10 %	68,3	95,2	99,8	100,0	100,0	100,0
20 %	67,6	94,3	99,8	100,0	100,0	100,0
30 %	67,5	93,2	99,7	100,0	100,0	100,0
Test set						
10 %	54,2	90,2	98,5	58,3	94,6	98,5
20 %	54,0	89,2	98,7	58,2	95,3	99,0
30 %	53,2	86,6	98,9	57,9	94,9	99,2

In this context, the distance-weighted approach may not be ideal. If two optimisation runs converge to the same mode for a given operating point of the actuators, the features used for training may be identical due to model simplifications. Consequently, the test point for the kNN algorithm may exactly match one of the training points, resulting in nearly zero distance, as the points coincide in the feature space. This explains the 100 % accuracy for the training set in tab. 4.1.

For the *Exact* columns, the accuracy varies between 53,2 %-68,3 %, which could be misleadingly low. Since multiple solutions are viable, a more reasonable approach would be to evaluate if the kNN determines any of the operating modes that the optimisation found for the corresponding operating point of the actuators. These are the values in the *Accept.* columns, increasing the accuracy to 86,6 %-95,3 %. This reflects the case where multiple operating modes are interchangeable from a control perspective.

The kNN output is also not a single value, but rather a probability for each of the possible classes. For a given actuator operating point, the highest probability mode from the kNN may not match the one found by the optimisation, but the second or third most likely class might. This is shown in the *Top-3* column, which verifies whether any of the most probable classes selected by the kNN corresponds to the optimisation result, moving the accuracy to 98,5 %-99,8 %.

5. DISCUSSION

The kNN classifier is a viable approach for predicting the operating modes of hydraulic machines. Using only reference speeds and chamber pressure values—which can be available in real applications—the algorithm can estimate the hydraulic machines' operating modes with acceptable accuracy when appropriate considerations are taken into account.

Using the ranked output of the algorithm, based on neighbour votes, can also be helpful for the control design. It greatly reduces the number of options to consider, making it possible to efficiently evaluate which of the options would lead to fewer transition losses.

A current limitation of this approach is that the hydraulic machines operating modes do not cover short circuiting actuator chambers. In a dynamic system, if the external force changes, the pressures will vary according to the current valve combination. The kNN would then provide the operating mode that best fits the current valve setting.

Future work could therefore perform a similar analysis but focused on the valve signals, define operating modes for the actuators, or determine short-circuited chambers from the optimisation results. A separate kNN, or other algorithm, could then be employed to find the viable system connections.

The dimensionality-reduction methods were also evaluated as potential preprocessing steps. While PCA maximises variance and LDA maximises class separability assuming linear projections, neither method improved the separability of operating modes in lower-dimensional spaces for the kNN. This suggests that non-linear relationships in the system play a significant role in determining the operating modes.

The next step is to apply the proposed classification to a dynamic model to evaluate how well the control system will perform. This includes setting criteria to select the operating mode based on neighbour vote confidence of the kNN and evaluating the model's ability to interpolate operating-mode decisions for actuator conditions not covered during training.

5.1. *Other Machine Learning Methods and Possible Applications*

Other machine learning methods exist but were not considered in this work. Unsupervised clustering and classification are not suitable in this case, as the classes-corresponding to operating modes- are already defined based on the torque and angular speed values obtained from the optimisation.

Neural networks and reinforcement learning are also commonly used approaches but were outside the scope of this study. These methods typically require large datasets for training, and parameter tuning is challenging as they are, in a way, complex optimisation problems. One of the objectives of this work was to identify a compromise between model capability and practical application, favouring methods that are easier to implement while still capable of supporting the control decision process.

Regression methods were also considered but not explored in this paper. No satisfactory compromise was found for the development of a simple yet reliable model based on limited inputs. A possible explanation is that information from the actuators is transmitted to the pump/motors through the valve manifold, and relevant details are lost when valve states are not included. This does not mean that the approaches are not viable, but rather that a more detailed analysis is required.

6. CONCLUSION

A Multi-Pump System poses a combinatorial control problem due to the large number of possible connections between hydraulic machines and actuators. While optimisation can identify power-efficient operating modes, the direct use of optimisation results in a control strategy is impractical.

This work showed that linear dimensionality-reduction techniques such as PCA and LDA are insufficient to achieve a clear separation of operating modes for a 3P2A MPS, due to the non-linear characteristics of the system. This motivated the use of a supervised classification approach. A kNN classifier was therefore applied to map operating conditions to operating modes. The achieved accuracy ranged from 53.2 % to 99.5 %, depending on whether exact operating mode prediction or the identification of a feasible alternative was required.

The results show that, although low-dimensional projections are insufficient for direct interpretation, supervised classification can be used as a tool to analyse and structure optimisation outcomes. Further work is required to assess the robustness of this approach for operating points outside the training data and to evaluate its relevance when applied in a

dynamic or control-oriented context. In addition, the current approach does not address other aspects of the control process, such as valve configurations or the conditions to short-circuit actuator chambers, which might be necessary for a effective design of the control system.

Abstract.

Interstage separation of launch vehicles is essential for reliable payload delivery into orbit. Helium, owing to its chemical inertness and low density, is widely used as the working medium in pneumatic separation systems. While high-pressure helium deviates significantly from ideal-gas behavior, and traditional cubic equations of state (EoS) introduce cumulative errors. To overcome these issues, a new corresponding state EoS is proposed, considering intermolecular interactions and the influence of temperature on molecular forces and volume. Based on the new EoS, a transient thermodynamic model is established, with strategies developed for both open and closed systems, and applied to the analysis of interstage separation. Results indicate that within –30 °C to 120 °C and 1–35 MPa, the proposed EoS achieves a maximum absolute error below 0.82%, significantly improving computational accuracy. The transient model reproduces the thermodynamic behavior of fixed-volume open, variable-volume open, and variable-volume closed systems, with average deviations from experiments below 5.2%, confirming its validity. Under heavy-load conditions of 90 t and 120 t, the minimum supply pressure of the gas tank is determined to be 12.5 MPa to ensure a separation velocity ≥ 5 m/s while keeping the separation duration under 1000 ms. A theoretical basis and key parameters are provided for the design and optimization of interstage separation systems.

Keywords. Real-gas equation of state, Helium, Interstage separation, Launch vehicles, Transient thermodynamic modelling.

1. INTRODUCTION

During the flight of a launch vehicle, multiple separation events are required, among which the interstage separation system plays a crucial role in reducing structural mass and improving payload efficiency, as shown in Figure. 1. The primary task of this system is to achieve non-interfering separation of the expended stage within a millisecond timescale [1]. This process involves precise mechanisms that must be triggered at the exact moment while minimizing disturbances to the attitude and trajectory of vehicle.

All Open Access articles are peer-reviewed, distributed under the Creative Commons Attribution-Non Commercial 4.0 International

Currently, two main technical approaches are employed for interstage separation. Traditional expendable configurations predominantly rely on pyrotechnic devices, in which energetic materials drive the separation mechanism by breaking or releasing structural connections between stages [2]. In contrast, non-pyrotechnic separation technologies significantly reduce the adverse effects of high temperature and explosive shock, offering greater flexibility and enabling safe separation under low-thermal-load conditions [3]. Typical non-pyrotechnic approaches include mechanical separation [4], electromechanical separation [5], electromagnetic separation, smart-material–driven separation [6], and pneumatic separation [7]. Among these, pneumatic separation is the most widely applied owing to its advantages of reusability, versatility, and low cost [8]. This technique relies solely on compressed gas to generate thrust, thereby enabling the relative acceleration between adjacent stages.

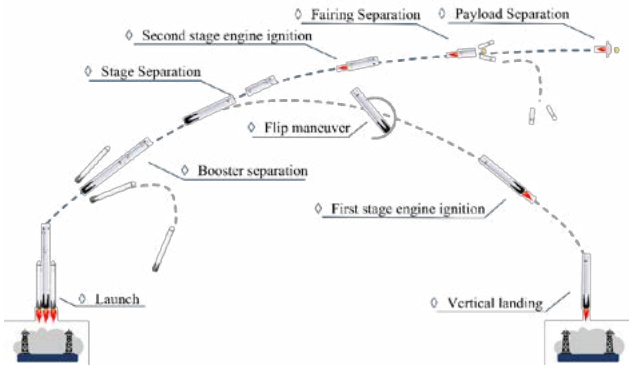

Figure 1.1 Multiple Separation Events of a Launch Vehicle

For safety considerations, helium is commonly selected as the working medium in pneumatic separation systems, primarily due to its chemical inertness and low specific gravity [9]. The molar mass of helium is only one-seventh that of air, which enables a significant reduction in the volume and weight of storage vessels while meeting system performance requirements. Consequently, the structural mass of the launch vehicle can be lowered, and the required amount of pressurant for a given structural configuration can be reduced, thereby further decreasing overall energy consumption. In high-pressure helium systems used for rocket interstage separation, the working fluid often exists under high-pressure or even supercritical conditions. Under such circumstances, the ideal gas law fails to accurately capture the thermodynamic behavior, making the development of an equation of state (EoS) capable of representing real-gas effects particularly essential [10].

Among existing formulations, cubic EoS, typified by the van der Waals (VDW) EoS [11], have attracted considerable attention in both engineering practice and scientific research. To improve accuracy in representing vapor-phase behavior, Redlich and Kwong [12] modified the temperature-dependent term of the VDW EoS. Building on this foundation, Soave [13] and Peng and Robinson [14] introduced further refinements to the temperature and volume functions, resulting in the SRK and PR EoSs, respectively, which significantly enhanced the predictive accuracy of pure substances over a wider temperature range and under vapor–liquid equilibrium conditions. Alternatively, virial-type EoS, expressed as a power series expansion, exhibit reliable predictive performance in the low-pressure region [15].

Extensions to this class of EoS have been achieved by introducing empirical parameters, as demonstrated by Benedict, Webb, and Rubin, and subsequently by Lee et al. [16], thereby broadening their applicability to multicomponent mixtures.

With the advancement of statistical mechanics and computational science, the focus of EoS research has gradually shifted toward theoretical formulations rooted in molecular interaction mechanisms. Based on perturbation theory, Chapman et al. [17] developed the Statistical Associating Fluid Theory (SAFT), which incorporates successive contributions of intermolecular interactions and provides accurate descriptions of complex fluid behavior. Building upon this framework, Alanazi et al. [18] introduced thermodynamic models that account for chain structures and molecular association phenomena, and compared them with cubic EoS for hydrogen-containing mixtures. Their results indicated that cubic EoS retain superior predictive performance for such systems. Despite their sound physical foundation, EoS derived from perturbation theory and virial coefficients are computationally intensive and exhibit limitations in predicting thermophysical properties under high-pressure conditions.

To address these issues, a new real-gas EoS is proposed by combining the advantages of cubic formulations and perturbation theory. Through the introduction of composite molecular correction factors and temperature-dependent coefficients, the accuracy of helium property prediction under high-pressure conditions is significantly improved. On this basis, a transient thermodynamic system model incorporating real-gas effects is established to capture the dynamic variations of pressure and temperature within the interstage separation chamber. Finally, the validity of the proposed model is verified through a case study of a high-pressure helium separation system for rocket interstages, providing critical theoretical insights and technical parameters for the design of aerospace separation systems.

2. Real-Gas Equation of State Applicable to High-Pressure Helium Systems

When analyzing high-pressure helium systems, the choice of an appropriate EoS is essential for accurately predicting the physical properties of the gas. Helium, an inert gas with a stable closed-shell electronic structure, is a monoatomic and nonpolar species characterized by a symmetric electron cloud. Moreover, due to its very low molecular weight, helium exhibits pronounced quantum effects and is regarded as a prototypical quantum gas.

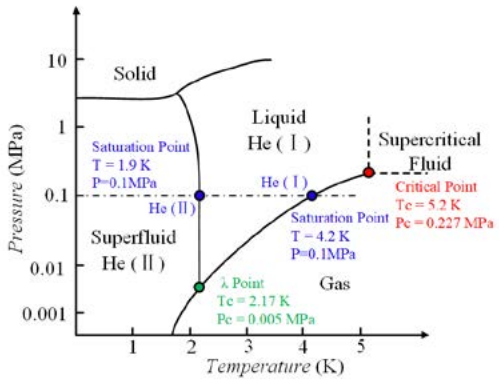

Figure 2.1. Phase Diagram of Helium

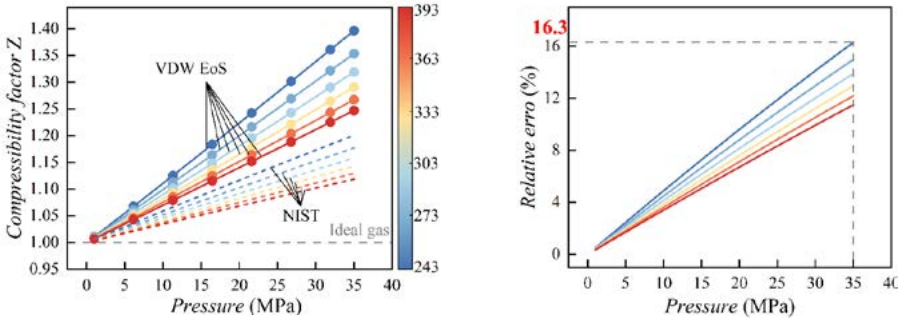
As shown in Figure. 2.1, the phase diagram of helium is unique in that it exhibits two liquid phases: the normal liquid phase (He I) and the superfluid phase (He II). Consequently, helium does not possess a conventional solid–liquid–vapor triple point. Instead, a λ-point appears at the intersection of the vapor, liquid, and superfluid phases.

The ideal-gas EoS assumes that gas molecules are point masses without volume and that no intermolecular forces exist other than elastic collisions. In reality, helium is a quantum system with intermolecular interactions, and its behavior deviates substantially from the classical ideal model of non-interacting point particles. This deviation becomes particularly significant under high-pressure conditions, where the weak but non-negligible dispersion forces arising from its nonpolarity and inertness become increasingly important, and the finite molecular volume is more pronounced. Under such circumstances, the ideal-gas EoS fails to provide accurate predictions, and the adoption of a real-gas EoS is therefore indispensable.

2.1. Real-Gas Equation of State

Common real-gas EoS can be classified from several perspectives, as summarized in Table 2.1. Virial-type EoS involve complicated mathematical expressions, multiparameter EoS are

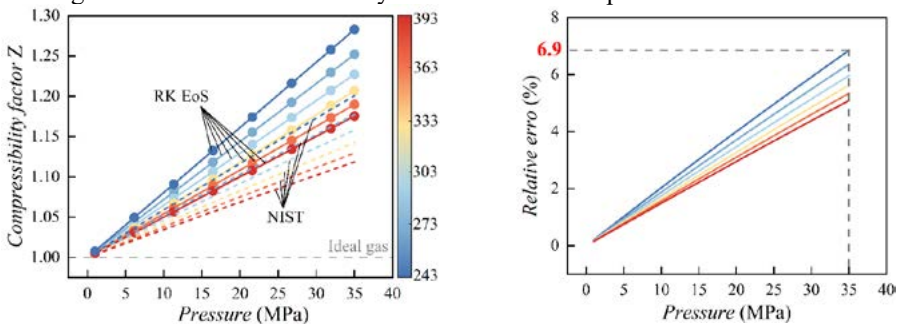
Table 2.1. Types of Commonly Used Real Gas EoS



Type	Theoretical basis	Representative equations
Virial	Statistical mechanics	$p = RT\rho(1 + B\rho + C\rho^2 + D\rho^3 + \cdots)$
Cubic	Van der Waals concept	Van der Waals EoS: $p = \frac{RT}{V_m - b} - \frac{a}{V_m^2}$ Redlich-Kwong EoS: $p = \frac{RT}{V_m - b} - \frac{a}{T^{0.5}V_m(V_m + b)}$ Soave-Redlich-Kwong EoS: $p = \frac{RT}{V_m - b} - \frac{a(T)}{V_m(V_m + b)}$ Peng-Robinson EoS: $p = \frac{RT}{V_m - b} - \frac{a(T)}{V_m(V_m + b) + b(V_m - b)}$
Multiparameter	Empirical fitting	Benedict-Webb-Rubin EoS: $p = RT\rho + (B_0RT - A_0 - C_0/T^2)\rho^2 + (bRT - a)\rho^3 + a\alpha\rho^6 + C\rho^3/T^2\,(1 + \gamma\rho^2)e^{-\gamma\rho^2}$
Perturbed-chain	Statistical mechanics	Statistical associating fluid theory: $A^{total} = A^{idealgas} + A^{monomer} + A^{chain} + A^{association} + A^{other}$
Crossover	Scaling laws	Universal method [19]: $p = -\left(\frac{\partial A}{\partial v}\right)_T = \frac{RT}{v_{0c}}\left[-\frac{v_{0c}}{v_c}\left(\frac{\partial \Delta\bar{A}}{\partial \Delta\eta}\right)_T + \left(\frac{1}{b} - \frac{T_{0c}}{T}\frac{\Omega_a a_0}{Z_{0c} b_2 b_3}\right) + \frac{v_{0c}}{v_c}\left(\frac{\partial K}{\partial \Delta\eta}\right)_T\right]$

strongly dependent on experimental data, and perturbation-chain or crossover-type EoS are suitable for describing complex molecular systems. By contrast, cubic EoS require fewer parameters and involve simpler calculations, making them more applicable for analyzing high-pressure helium systems.

The compressibility factor Z is an important dimensionless parameter that characterizes the deviation of real gases from ideal-gas behavior, defined as



$$Z(p,T) = \frac{pV_m}{RT} \tag{2.1}$$

For an ideal gas, Z is always equal to 1. In the case of real gases, however, Z is a function of both pressure and temperature, reflecting the influence of intermolecular interactions. For helium, the compressibility factor varies with both pressure and temperature.

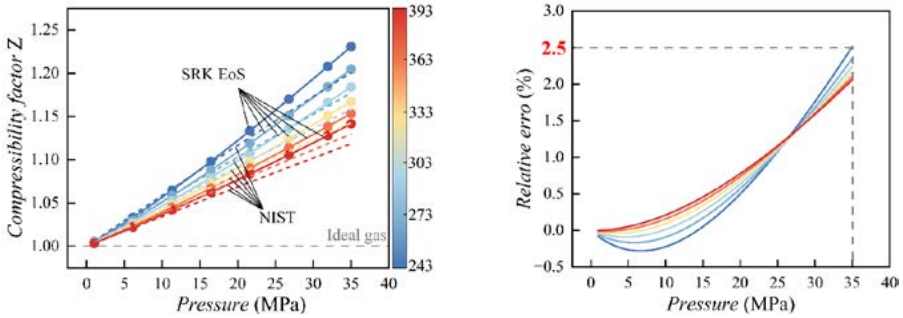
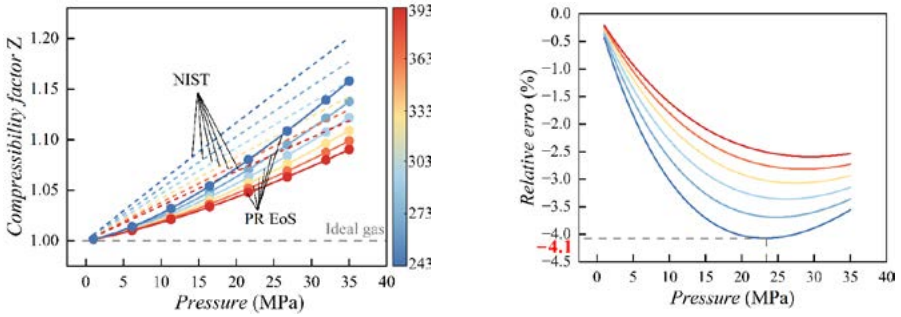
Figure 2.2. Prediction Accuracy of VDW EoS: Comparison with NIST Data



(a) Compressibility factor Z comparison (b) Absolute error in Z

Figure 2.3. Prediction Accuracy of RK EoS: Comparison with NIST Data

The variation of the compressibility factor of helium with pressure and temperature is investigated. To assess the predictive accuracy of classical cubic EoS, four representative EoSs are selected: van der Waals (VDW), Redlich–Kwong (RK), Soave–Redlich–Kwong (SRK), and Peng–Robinson (PR) EoSs. The compressibility factors of helium are calculated using these formulations and compared systematically with the reference data from the REFPROP database developed by the National Institute of Standards and Technology (NIST). The results are presented in Figures 2.2–2.5.



The comparison shows that within the typical operating range of high-pressure helium systems for interstage separation, with temperatures from 243 K to 393 K (−30 °C to 120

°C) and pressures from 1 MPa to 35 MPa, the VDW EoS exhibits the largest absolute error of 16.3%. The errors for the RK and PR EoSs are 6.9% and −4.1%, respectively, whereas the SRK EoS yields the smallest deviation of 2.5%. It should be noted that due to inherent assumptions and simplifications in the EoSs, systematic deviations arise in the prediction of high-pressure helium properties. Such deviations may further accumulate in practical engineering modeling. Therefore, in order to improve the accuracy of high-pressure helium system calculations, it is necessary to employ a real-gas EoS with smaller intrinsic prediction errors.

2.2. A New Real-Gas Corresponding State EoS

By combining the advantages of cubic EoS and perturbation theory, and considering the molecular association phenomena under high-pressure conditions, a new real-gas corresponding state EoS is developed based on statistical thermodynamics. The specific form of the equation is expressed as follows [20]:

$$p_r = \frac{8}{3}\left[\frac{T_r}{V_{mr}/\gamma - \xi/3} - \frac{9/8}{T_r^{\alpha}(V_{mr}/\gamma)^2}\right] \tag{2.2}$$

According to the principles of statistical thermodynamics, a composite molecular correction factor is introduced to represent the ratio between the actual number of molecules N_t contained in 1 kg of gas under arbitrary states and the number of molecules N_c under the critical state:

$$\gamma = \frac{N_t}{N_c} = \left(\frac{3}{8Z_c}\right) \cdot \left[1 - \left(1 - \frac{8}{3}Z_c\right) \cdot T_r^{-\Delta I/2} \cdot e^{(1/T_r - 1)} \cdot V_r^{-1}\right] \tag{2.3}$$

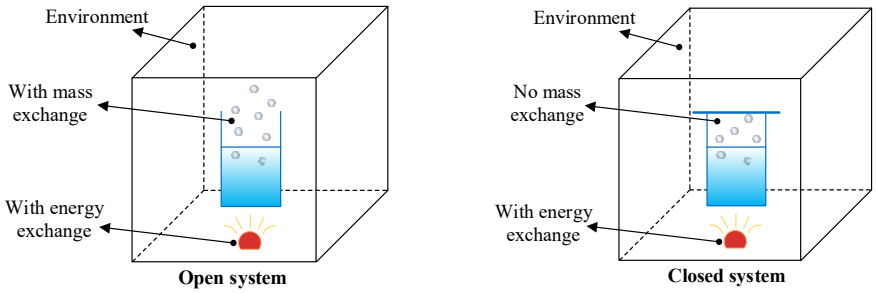
In addition, the effects of temperature on molecular volume and intermolecular forces are taken into account. The resulting molecular volume correction coefficient is given as:

$$\xi = \frac{b}{b_c} = \sqrt{\frac{0.5 + \sqrt{0.25 + 0.375}}{0.5 + \sqrt{0.25 + 0.375T_r}}} \tag{2.4}$$

And the intermolecular force correction coefficient is expressed as:

$$\alpha = \left[\ln\left(\frac{27}{8}\right) - \ln\sqrt{\frac{0.5 + \sqrt{0.25 + 0.375}}{0.5 + \sqrt{0.25 + 0.375\,T_B/T_c}}}\right] \Big/ \ln(T_B/T_c) - 1 \tag{2.5}$$

Within the same ranges of temperature and pressure, calculations are performed using Equation (2.2), and the predicted values are systematically compared with reference data from the NIST database. The absolute error distribution is also plotted, as shown in Figure 2.6. The results indicate that the maximum absolute error of the proposed EoS is only 0.82%, demonstrating high predictive accuracy. Furthermore, the proposed formulation is concise in form and clear in structure, which facilitates its practical application in engineering systems.



3. HIGH-PRESSURE GAS ANALYSIS METHOD BASED ON A REAL-GAS EOS

High-pressure helium thermodynamic systems can generally be categorized into open and closed systems, as illustrated in Figure 3.1. An open system allows both mass and energy exchange with the surroundings, whereas a closed system permits only energy exchange without mass transfer. When formulating the thermodynamic conservation equations for high-pressure helium systems, pressure and temperature are adopted as the primary variables to characterize mass and energy conservation. Based on the first law of thermodynamics and incorporating the real-gas equation of state, time-dependent governing equations are derived with pressure and temperature as state variables. This provides the foundation for transient analysis of the system.

3.1. Thermodynamic Model of Open System

The real-gas equation of state in Equation (2.2) can be expressed as:

$$f(m,p,V,T) = 0 \tag{3.1}$$

(a) Open system (b) Closed system

Figure 3.1. Mass and Energy Exchange in Open and Closed Thermodynamic Systems

Assuming gas pressure, mass, temperature, and volume are taken as variables, the partial differential form is obtained. Accordingly, the time-dependent variations of pressure, mass, temperature, and volume can be written as:

$$\frac{\partial f}{\partial p}\frac{\mathrm{d}p}{\mathrm{d}t} + \frac{\partial f}{\partial m}\frac{\mathrm{d}m}{\mathrm{d}t} + \frac{\partial f}{\partial T}\frac{\mathrm{d}T}{\mathrm{d}t} + \frac{\partial f}{\partial V}\frac{\mathrm{d}V}{\mathrm{d}t} = 0 \tag{3.2}$$

From this relation, the governing equation with pressure as the primary variable is derived as:

$$\frac{\mathrm{d}p}{\mathrm{d}t} = -\frac{\partial f}{\partial m}\frac{\mathrm{d}m}{\mathrm{d}t} - \frac{\partial f}{\partial T}\frac{\mathrm{d}T}{\mathrm{d}t} - \frac{\partial f}{\partial V}\frac{\mathrm{d}V}{\mathrm{d}t} \tag{3.3}$$

(a) Typical fixed-volume open system (b) Typical variable-volume open system

Figure 3.2. Typical Open Systems

Figure 3.3. Typical Closed Systems

The gas inside the high-pressure chamber follows the first law of thermodynamics, where the increment of system energy equals the difference between the input and output energy. This is expressed as:

$$\mathrm{d}U + \delta E_k + \delta E_p = h_{in}\mathrm{d}m_{in} - h_{out}\mathrm{d}m_{out} + \delta Q - \delta W \tag{3.4}$$

Combined with the second law of thermodynamics, the internal energy can be formulated as a function of any two independent variables among T, p, and v. Expressed in terms of T and v., the first internal energy equation is given by:

$$\mathrm{d}u = c_v \mathrm{d}T + \left[T\left(\frac{\partial p}{\partial T}\right) - p\right] dv \tag{3.5}$$

For fixed-volume open systems such as gas cylinders, shown in Figure 3.2(a), the system performs no external work, and only a single inlet or outlet exists for the gas. Neglecting changes in kinetic and potential energy, the first law of thermodynamics for a fixed-volume open system is expressed as:

$$u\mathrm{d}m + m\mathrm{d}u = (u + pv)\mathrm{d}m + \delta Q \tag{3.6}$$

By substituting Equation (3.5) into Equation (3.6), the time-dependent governing equation for temperature in a fixed-volume open system is obtained as:

$$\mathrm{d}T = \frac{1}{mc_v}\left[T\left(\frac{\partial p}{\partial T}\right)\right]\left(\frac{V}{m}\right)\mathrm{d}m + \frac{\delta Q}{mc_v} \tag{3.7}$$

where the partial derivative of pressure with respect to temperature is evaluated based on the real-gas EoS in Equation (2.2).

Due to the constant volume of the open system, the time-dependent pressure governing equation is given by Equation (3.3):

$$\frac{\mathrm{d}p}{\mathrm{d}t} = -\frac{\partial f}{\partial m}\frac{\mathrm{d}m}{\mathrm{d}t} - \frac{\partial f}{\partial T}\frac{\mathrm{d}T}{\mathrm{d}t} \tag{3.8}$$

For variable-volume open systems, such as the rodless chamber of an intake cylinder shown in Figure 3.2(b), and by neglecting changes in gas kinetic and potential energy, the first law of thermodynamics is expressed as:

$$u\mathrm{d}m + m\mathrm{d}u = (u_{in} + pv_{in})\mathrm{d}m + \delta Q - p\mathrm{d}V \tag{3.9}$$

By substituting Equation (3.5) into Equation (3.9), the time-dependent governing equation for temperature in a variable-volume open system is obtained as:

$$\mathrm{d}T = \frac{1}{mc_v}(u_{in} - u)\mathrm{d}m + \frac{1}{mc_v}\left[T\left(\frac{\partial p}{\partial T}\right)\right]\left(\frac{V}{m}\right)\mathrm{d}m - \frac{1}{mc_v}\left[T\left(\frac{\partial p}{\partial T}\right)\right]\mathrm{d}V + \frac{\delta Q}{mc_v} \tag{3.10}$$

where the variation of specific internal energy is derived by integrating Equation (3.5), which yields:

$$u_{in} - u = \int c_v \mathrm{d}T + \int \left[T\left(\frac{\partial p}{\partial T}\right) - p\right] dv \tag{3.11}$$

The time-dependent governing equation for pressure in a variable-volume open system is obtained as Equation (3.3).

3.2. Thermodynamic model of closed systems

For variable-volume closed systems, such as the rod chamber of a cylinder shown in Figure 3.3, the gas volume, temperature, and pressure vary with time, while the mass remains constant. By neglecting changes in gas kinetic and potential energy, the first law of thermodynamics is expressed as:

$$m\mathrm{d}u = -p\mathrm{d}V + \delta Q \tag{3.12}$$

By substituting Equation (3.5) into Equation (3.12), the time-dependent governing equation for temperature in a variable-volume closed system is obtained as:

$$\mathrm{d}T = -\frac{1}{mc_v}\left[T\left(\frac{\partial p}{\partial T}\right)\right]\mathrm{d}V + \frac{\delta Q}{mc_v} \tag{3.13}$$

Since the mass of a variable-volume closed system remains constant, its time-dependent governing equation for pressure is derived from Equation (3.3) as:

$$\frac{\mathrm{d}p}{\mathrm{d}t} = -\frac{\partial f}{\partial T}\frac{\mathrm{d}T}{\mathrm{d}t} - \frac{\partial f}{\partial V}\frac{\mathrm{d}V}{\mathrm{d}t} \tag{3.14}$$

By solving the governing equations of pressure and temperature for the three typical thermodynamic systems, a transient thermodynamic system model that incorporates real-gas effects is established.

4. THEORETICAL ANALYSIS AND EXPERIMENTAL VALIDATION OF THE INTERSTAGE PNEUMATIC SEPARATION SYSTEM

The investigated interstage pneumatic separation system consists of four high-pressure supply gas tanks connected in series, solenoid valve, and a separation cylinder, as shown in Figure 4.1. Before system operation, the gas tanks are pre-charged with high-pressure helium as the energy source. Upon receiving the activation command, allowing the high-pressure gas to pass through the valve and flow into the rodless chamber of the separation cylinder. The piston is then driven to move, generating the thrust required for separation and enabling the rapid unlocking and separation of the first and second stages, as illustrated in Figure 4.2.

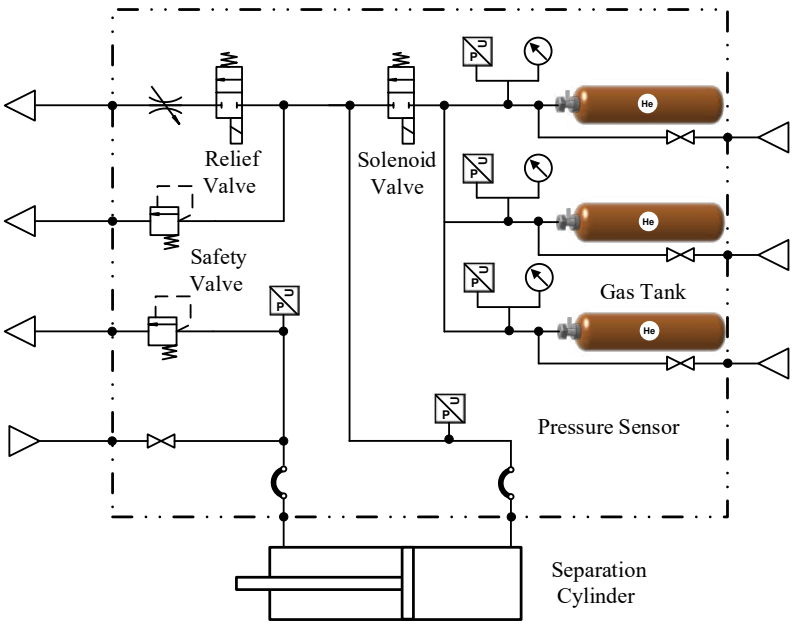


Figure 4.1 Schematic diagram of the interstage high-pressure helium separation system

For the first stage of the rocket, which is connected to the cylinder barrel, the force balance equation is expressed as:

$$p_1 A_1 - p_2 A_2 = m_1 \frac{\mathrm{d}^2 x_1}{\mathrm{d}t^2} + B_1 \frac{\mathrm{d}x_1}{\mathrm{d}t} + K_1 x_1 - \beta m_1 g \tag{4.1}$$

For the second stage, which is connected to the piston rod, the force balance equation is expressed as:

$$p_1 A_1 - p_2 A_2 = m_2 \frac{\mathrm{d}^2 x_2}{\mathrm{d}t^2} + B_2 \frac{\mathrm{d}x_2}{\mathrm{d}t} + K_2 x_2 - \beta m_2 g \tag{4.2}$$

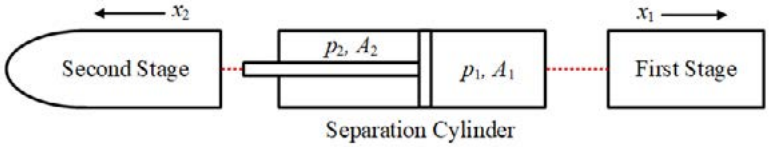

Figure 4.2 Connection relationship between the stages and the separation cylinder [21]

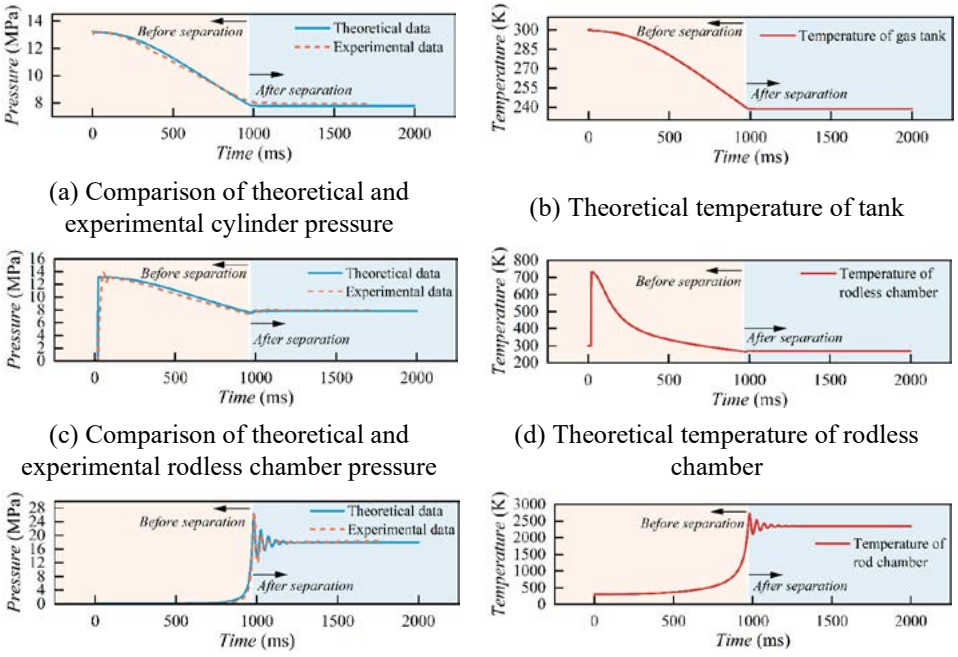

Table 4.1. Calculation Parameters and Values

Parameter	Symbol/Unit	Value
Critical pressure of helium	p_c/MPa	0.227
Critical temperature of helium	T_c/K	5.2
Critical volume of helium	V_{mc}/(m^3/mol)	57.3e-6
Molar mass of helium	M/(kg/mol)	4.003e-3
Gas cylinder volume	V/L	80
First-stage mass	m_1/t	90
Second-stage mass	m_2/t	120
Gravitational acceleration	g/(m/s^2)	9.8

To simulate the dynamic characteristics of the high-pressure chambers in this pneumatic system, a high-pressure gas analysis method based on a real-gas EoS is employed. According to the thermodynamic characteristics of the system components, the high-pressure gas tank is treated as a fixed-volume open system, with its pressure and temperature dynamics governed by Equations (3.7) and (3.8). The rodless chamber of the cylinder is treated as a variable-volume open system, described by Equations (3.10) and (3.3). The rod chamber is modeled as a variable-volume closed system, with pressure and temperature variations governed by Equations (3.13) and (3.14). Together, these equations establish a complete mathematical model for the system's dynamic response. The differential equations are solved using an eighth-order Dormand–Prince algorithm, with relevant constant parameters listed in Table 2, where load conditions are referenced to a representative heavy-lift rocket stage of approximately 100 t as reported by NASA [22]. Since the interstage separation process occurs on a millisecond time scale, which is much shorter than the characteristic timescale of heat transfer, the system is treated as adiabatic.

During the construction of the ground test bench for interstage separation, the first and second stages are simulated by coaxially arranged rail-mounted flat cars. Pressure sensors are installed in the gas supply system to monitor the pressures in the gas tank, the rodless chamber, and the rod chamber of the actuator cylinder. The supply pressure during the test

is 13.2 MPa. The separation instant is defined as the moment when the first and second stages just lose contact, which is measured to occur at 967 ms. A comparison between the theoretical model and the experimental results shows that the average percentage errors of the three chambers are 1.62%, 3.15%, and 5.14%, respectively, thereby validating the accuracy of the theoretical model. The comparison of pressure characteristics between theoretical predictions and experimental results, as well as the theoretical temperature variation curve, is presented in Figure 4.3.

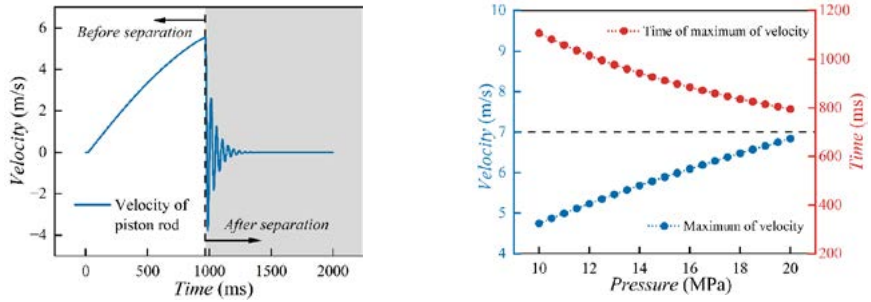
(e) Comparison of theoretical and experimental rod chamber pressure

(f) Theoretical temperature of rod chamber

Figure 4.3. Comparison of Theoretical and Experimental Results for Interstage Separation Pressure Characteristics and Theoretical Temperature Profile

After the separation command is issued, the gas tanks begin supplying the rodless chamber through the solenoid valves. The pressure evolution during separation can be divided into three stages:



(1) Before separation: The pressure in the gas tanks decreases gradually (Figure 4.3(a)), while the rodless chamber pressure rises rapidly until it matches the tank pressure (Figure 4.3(c)). Once the rodless chamber pressure exceeds the piston start-up pressure, the piston rod begins to extend, leading to an increase in chamber volume and a gradual decrease in pressure.

(2) At the separation point: The piston rod reaches its maximum displacement, and the rodless chamber volume stabilizes. At this moment, the gas tanks and rodless chamber are fully connected, maintaining equal pressures. Meanwhile, the volume of the rod chamber reaches its minimum, and its internal pressure rises sharply to a peak value (Figure 4.3(e)).

(3) After separation: The cylinder system can be abstracted as a mass–spring system under inertial effects. Due to gas compressibility, the piston rod undergoes oscillatory motion, which gradually decays to an equilibrium state.

The gas temperature variations in each chamber follow a similar trend to the pressure changes, as shown in Figure 4.3(b), (d), (f), consistent with fundamental thermodynamic principles.

The fundamental task of the interstage separation system is to achieve reliable separation of the two stages within an extremely short time and over a limited stroke. The relative separation velocity serves as the most direct indicator of this function. As shown in Figure 4.4(a), at the moment of separation, the relative velocity reaches a maximum of 5.52 m/s. A higher separation velocity indicates a faster separation action. As illustrated in Figure 4.4(b), with increasing inlet pressure, the separation velocity increases accordingly, and the time required to reach the maximum velocity is shortened. To ensure that the separation velocity is not lower than 5 m/s and that the separation duration is less than 1000 ms, the minimum supply pressure of the gas tank must be no less than 12.5 MPa.

5. CONCLUSIONS

To address the significant deviation of high-pressure helium from ideal gas behavior and the cumulative errors associated with conventional cubic EoS, a new corresponding state EoS is proposed based on the intermolecular interaction mechanism and the temperature dependence of molecular forces and molecular volume. On this basis, a transient thermodynamic model is developed using the proposed real-gas EoS, with dedicated modeling strategies formulated for open systems and closed systems. This model is further applied to the case of the interstage high-pressure helium separation process. The main conclusions are as follows:

(1) Within the typical operating temperature range (−30 °C to 120 °C) and pressure range (1–35 MPa) of the interstage separation high-pressure helium system, the proposed real-gas EoS achieves a maximum absolute error below 0.82%. This effectively reduces systematic deviations and significantly improves computational accuracy.

(2) The transient thermodynamic model constructed with the proposed EoS can accurately capture the thermodynamic behavior of fixed-volume open systems, variable-volume open systems, and variable-volume closed systems in the interstage separation process. The

average percentage error compared with experimental data is below 5.2%, thereby validating the effectiveness of the modeling approach in high-pressure gas analysis.

(3) Under heavy-load conditions, where the first and second stages carry 90 t and 120 t, respectively, to satisfy the technical requirements of a separation velocity not lower than 5 m/s and a separation duration of less than 1000 ms, the supply pressure of the gas tank must be no less than 12.5 MPa.

Abstract.

Hydraulic spool valve (HSV) is a key regulating component in fluid power systems owing to its capability for precise flow and pressure control. Unbalanced radial flow force (RFF) is a major contributor to spool instability and friction-induced failure, particularly in open-neutral configurations where flow field asymmetry is prominent. Although conventional design assumes that radial forces are self-balanced due to geometric symmetry, practical valve structures constrained by standardized port layouts frequently induce asymmetric pressure and velocity distributions. To address this issue, a novel balanced through-hole design is proposed and integrated into the mid-shoulder region of the spool. Computational fluid dynamics (CFD) simulations are employed to investigate the generation mechanism of RFF and to evaluate the effectiveness of the proposed structure. The Realizable k-ε turbulence model is adopted to capture the dominant turbulent features, and the individual contributions of pressure and viscous forces to the RFF are quantified. A parametric study is conducted to examine the influence of through-hole inclination angle on force reduction performance. The study results indicate that RFF is predominantly pressure-driven, accounting for more than 85% of the total force, with pronounced asymmetry concentrated in the mid-shoulder region. By introducing a dual through-hole structure inclined at 15°, the RFF acting on the mid-shoulder is reduced by 45.5%, while the total spool RFF is decreased by 29.9%. The proposed design effectively improves flow symmetry and suppresses local pressure gradients, providing a practical solution for RFF mitigation in compact hydraulic spool valves.

1. INTRODUCTION

Hydraulic systems are extensively applied in critical engineering domains such as construction machinery, marine equipment, and aerospace, where they serve as core components in applications, e. g. electric loader bucket and boom drive control [1]. These

All Open Access articles are peer-reviewed, distributed under the Creative Commons Attribution-Non Commercial 4.0 International

systems are valued for their rapid response, high power density, and precise controllability [2]. As a core regulating component within a hydraulic system, hydraulic valve plays a pivotal role in determining system responsiveness, stability, and energy efficiency. Among them, the hydraulic spool valve (HSV) employing thin-walled orifice structures exhibit reduced sensitivity to oil viscosity and temperature variations, making them widely used in advanced components such as proportional and servo valves [3].

The spool-to-sleeve clearance of HSVs typically ranges between 5 to 20μm, serving functions such as clearance sealing and motion guidance [4]. Ideally, axial movement of the spool should only induce minimal and stable friction. However, in practical applications, hydraulic forces, thermal deformation, and particulate contamination alter the lubrication state [5], leading to spool hysteresis, jamming, or stiction. Such phenomena can significantly deteriorate control performance and, in severe cases, induce valve failure or safety incidents [6]. Consequently, understanding and mitigating spool stagnation has become a critical issue in hydraulic valve research, traditionally attributed to unbalanced flow forces and lubricant viscosity effects.

Among the influencing factors, flow force is widely recognized as one of the primary contributors to control performance degradation [7]. HSVs regulate flow direction and magnitude through axial displacement of the spool. When the orifice formed between the spool shoulder and sleeve is partially opened, fluid acceleration occurs, which alters the flow momentum and generates force on the spool. Flow force is commonly categorized into steady-state and transient components. The transient component is usually considered negligible compared to the steady-state force. When fluid flows through the throttle port, it experiences changes in velocity and direction, resulting in hydraulic forces on the spool surface, both in axial and radial directions [8].

While research on axial flow force has matured, the radial flow force (RFF) has received relatively limited attention. Many studies have assumed that due to geometric symmetry, RFFs are self-balanced and can be neglected [9]. However, in actual engineering designs, the flow chamber geometry is often asymmetric. This asymmetry results from practical constraints related to valve block layout and standardized port configurations, especially for base-mounted HSVs that follow ISO mounting standards. These designs lead to uneven pressure and velocity distributions along the cylindrical surface of the spool and the annular gap between spool and sleeve [10]. The resulting unbalanced RFF may push the spool toward one side, causing increased friction and possible motion failure.

To mitigate RFFs, researchers have developed a variety of structural modifications. One common method involves machining circumferential pressure-equalizing grooves on the spool shoulder to improve pressure distribution. Hong et al. proposed the use of spiral grooves along the spool surface [11]. These grooves enable simultaneous axial and circumferential pressure release, which effectively reduces pressure peaks and lowers total RFF by over 60 percent. Han et al. introduced a guide groove connected to a central pressure-equalizing groove, which distributed pressure more uniformly and enhanced the response frequency of the valve [12]. Additionally, the shape of the spool edge, such as right-angle, conical, or curved forms, influences the throttle jet direction and thereby affects the RFF at the outlet [13]. However, experimental results show that in many cases, the inlet section's RFF remains largely unchanged despite structural modifications.

Most existing studies focus on negative-opening HSVs, whereas open-neutral configurations remain underexplored. Moreover, complex multi-step throttling structures, such as claw-shaped notches [14], limit the applicability of circumferential balancing grooves. Importantly, traditional groove-based methods act as passive compensation mechanisms, redistributing pressure after radial forces have already developed. In contrast, the present study aims to suppress RFF at its point of origin. By introducing pressure-relief through-holes directly within the spool shoulder, where jet impingement and pressure stagnation occur, the proposed design aims to suppress the formation of pressure asymmetry rather than redistributing it downstream.

2. PHYSICAL MODEL DESCRIPTION

The typical multi-way spool valve (MSV) working principle and structure of the loader hydraulic system are shown in Figure 2.1. Positioned within the main hydraulic circuit, the MSV dis-tributes flow from the main pump to the boom/bucket cylinders, enabling efficient operation of the work equipment. The MSV features a series-parallel integrated two-section design, structurally composed of the valve body, bucket spool valve section, boom spool valve section, and check valves, as shown in Figure 2.1(a). The inlet of two sections is arranged in series, granting priority to the bucket section from Figure 2.1(b). When the bucket section active, it prevents simultaneous operation of the boom section. The return oil passages adopt a parallel configuration, allowing both sections to return oil concurrently.

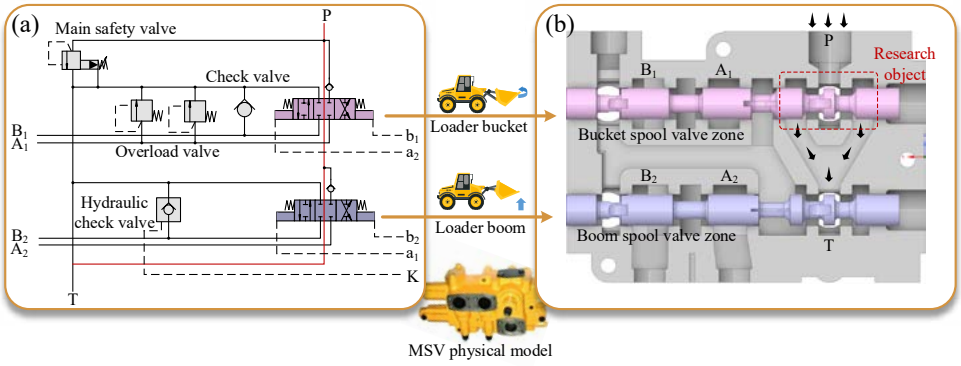

Figure 2.1. MSV working principle and structure of the loader hydraulic system: (a) Working principle; (b) Valve structure.

Due to the asymmetric and discontinuous internal flow passage geometry, the fluid develops an unbalanced turbulent flow. This generates uneven fluid pressure distribution on the spool surface, resulting in unbalanced RFFs. Furthermore, the unbalanced RFF tends to induce spool tilting, leading to asymmetric variation in the clearance between the spool and valve body. In severe cases, this may cause direct contact between the spool and valve body, significantly increasing frictional resistance during spool movement and potentially resulting in sticking or even complete seizure. Specially, when high-pressure fluid enters the valve chamber, it initially impacts the shoulder of the P-T flow path on the spool. Thus, this paper focus on the unbalanced RFF mechanism and reduction approach based on the P-T flow path of the bucket spool valve. The simplified HSV geometry is shown in Figure 2.2.

This study investigates a full circumferential opening spool valve, whose structural characteristics are illustrated in Figure 2.2(a). The HSV is composed of valve body and valve spool. Specially, as shown in Figure 2.2(b), the valve spool mainly consists of five components. Hydraulic fluid enters through the inlet, passes through four throttling orifices, and exits via both left and right outlets (as shown in Figure 2.2c). The valve body and spool exhibit strict bilateral symmetry. When the spool is in its neutral position, x_{01}=x_{04}=0.4 mm and x_{02}=x_{03}=0.35 mm.

3. NUMERICAL SIMULATION

3.1. Computational fluid domain

The main valve structure is simplified and the extracted fluid domain is shown in Figure 3.1(a). It is a symmetric structure and thus the fluid domain can be simplified as a half to decrease simulation time, shown in Figure 3.1(b). The boundary condition status is shown in Figure 3.1(c) to satisfy the realistic working condition and symmetry flow field.

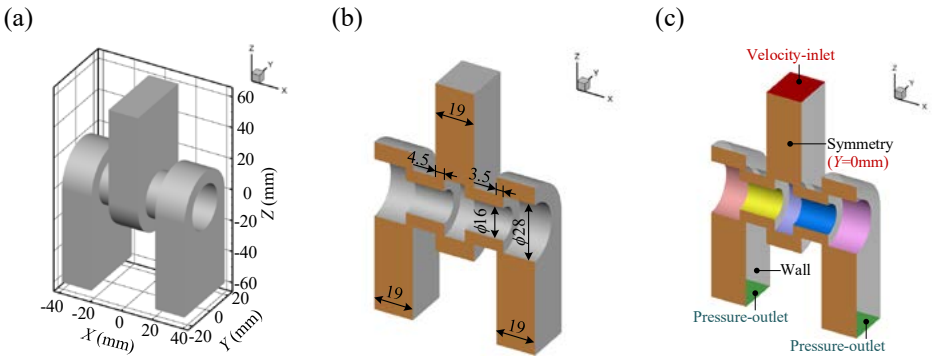

Figure 3.1. Fluid domain model and key structure size: (a) Complete fluid domain; (b) One-half fluid domain from *x*-axis; (c) Fluid domain boundary condition settings.

3.2. Meshing and independence verification

This investigation employs ANSYS Fluent® software to perform numerical simulations associated with HSVs. Compared to structured grids, unstructured grids are more efficient and easier to control in terms of grid numbers. Given the complex configuration of the HSV's orifice and its compact volume, the entire computational domain is divided into a three-dimensional unstructured mesh using Fluent Meshing® software to ensure grid quality and improve computational efficiency. To capture complex turbulence behaviour such as high-speed jet of valve ports and vortex, five 'Body of Influence' (Boi) regions are developed to refine the mesh, which are shown in Figure 3.2(a). Consequently, at least four mesh models of varying densities are produced in one fluid domain.

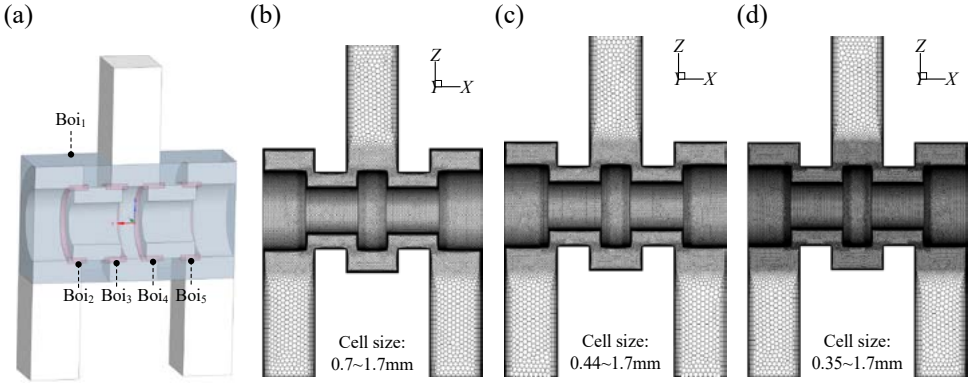

Figure 3.2. Boi regions setting for mesh refinement and mesh quantity comparison: (a) Boi regions setting for mesh refinement; (b) Mesh A with cell size 0.7~1.7mm; (c) Mesh B with cell size 0.44~1.7mm; (d) Mesh C with cell size 0.35~1.7mm.

Table 3.1. Mesh independence verification setting

Region	Mesh A	Mesh B	Mesh C
Overall size (mm)	1.70	1.70	1.70
Boi_1 size (mm)	1.20	0.75	0.60
Boi_2 size (mm)	0.70	0.44	0.35
Boi_3 size (mm)	0.80	0.50	0.40
Boi_4 size (mm)	0.80	0.50	0.40
Boi_5 size (mm)	0.70	0.44	0.35

Mesh division is a pivotal factor in numerical simulations, with the number of meshes directly impacting computational accuracy and determining the convergence and correctness of residual results. Consequently, to guarantee calculation precision and enhance efficiency by reducing computation time, it is imperative to assess the mesh density's relevance prior to the commencement of calculations. The mesh independence test is conducted for a steady simulation. Three mesh models of varying densities are produced, as depicted in Figure 3.2(b)-(d). The detailed mesh setting of different Boi regions is shown in Table 3.1. When the liquid flows at a velocity of 4.8733 m/s, the model with three different mesh numbers is calculated with the outlet pressure set to 0 MPa as the boundary condition. The pressure of inlet (P_{in}) and the radial fluid force (F_r) on the valve core are monitored for the mesh

independence. The final results of the mesh independent verification and the error of mesh independence index are presented in Table 3.2. As observed from Table 3.2, an increase in the number of grids leads to a closer alignment between the monitored P_{in} and F_r. When the mesh quantity is increased to 841 908, the error of P_{in} and F_r are at 0.33% and 0.14%, which has been maintained within 0.5%. For a better radial fluid force mechanism revealing and faster computation speed, Mesh C is chosen for the subsequent simulation.

Table 3.2. Mesh independence verification results

Mesh type	Mesh elements	Inlet pressure (Pa)	% Change	Spool RFF (N)	% Change
Mesh A	219 473	61764.3	--	1.436	--
Mesh B	524 611	61006.4	1.20%	1.405	2.20%
Mesh C	841 908	60803.2	0.33%	1.406	0.14%

The selection of the turbulence model and near-wall mesh strategy is guided by the specific flow characteristics of the HSV rather than an assumption of fully developed turbulence. Although hydraulic oil exhibits relatively high viscosity, the flow inside the valve is dominated by strong acceleration through narrow throttling orifices, high velocity gradients, and jet–wall interactions, which promote locally turbulent and separation-dominated flow structures even at moderate Reynolds numbers

In regards to the near-wall approach for Realizable k-ε, the particular complexity of the valve geometry leads to the separation and reattachment of boundary layer easily. For this reason, the 'enhanced wall treatment' (EWT) is employed in the present work, which solves viscous substrates directly for the large pressure gradient of the valve port [15]. The number of boundary layers is 10, and the growth ratio is 1.2. The critical value of y+ of the fluid domain wall, which signifies the non-dimensional wall distance, is currently maintained below 5. This configuration enables adequate resolution of near-wall pressure gradients and wall shear stresses without excessive mesh refinement. Mesh independence verification further confirms that the selected turbulence model and boundary layer settings yield stable predictions of inlet pressure and radial flow force, with variations below 0.5%, indicating that the numerical results are not unduly sensitive to the chosen near-wall discretization.

3.3. Physical properties and boundary conditions

In this investigation, the calculation is performed under steady-state conditions. The physical properties of liquids used in the simulation are shown in Table 3.3.

Table 3.3. Physical properties and boundary conditions for the CFD simulations

Targets			Values or settings
Physical properties	Hydraulic oil L-HM46	Temperature (°C)	40
		Density (kg/m^3)	870
		Viscosity (Pa·s)	0.04
Boundary conditions	Inlet	Velocity (m/s)	4.8733
	Outlet	Pressure (MPa)	0
	Symmetric face	Symmetry	--
	Valve body Valve spool	Wall	No-slip and adiabatic

Monitoring faces are established at the inlet/outlet positions of the throttle holes to monitor pressure pulsations and flow rate pulsations. These data points are utilized to assess the stability of the calculation results and will be compared and analysed with the experimental findings at a subsequent stage. The boundary condition status is shown in in Figure 3.1(c) to satisfy the realistic working condition and symmetry flow field. Given that the HSV possesses a stable structure and its internal flow dynamics are solely determined by the inlet and outlet boundary conditions, velocity-inlet and pressure-outlet conditions are employed for the calculations while assuming an adiabatic wall surface and no-slip condition.

3.4. Solution strategy

The pressure-based solver is used in the solution. Different discretisation formats are used for the control equation terms to accelerate convergence, 'Least Square Cell Based' discretisation for the gradient term, 'PRESTO!' for the pressure term, 'Second Order Windward' discretisation for the momentum term and each turbulence term. The final discretised control equations are solved by 'Coupled' algorithm. Especially, these parameter settings are verified stable in many HSV simulations. In the simulation process, convergence is deemed to have been achieved when the corresponding parameters within an identical grid cell remain invariant between two successive calculations. Nevertheless, this ideal condition is seldom encountered in practical computations. To affirm the convergence of computational results, the following criteria are typically satisfied: (1) the residual value of the continuous equation should be less than 10^{-5}, with a remaining residual value of less than 10^{-6}; (2) monitor changes such as spool RFF within the fluid domain are less than 0.5%.

4. RESULTS AND DISCUSSION

4.1. Spool radial unbalanced flow force analysis

Before analysing the radial unbalanced force characteristics within the HSV, the flow characteristics of the flow channel should be given. Therefore, the average velocity of the centre cross-section (Y=0 mm) just as Figure 3.1(c) of the valve is first obtained, as shown in Figure 4.1.

Since the hydraulic oil flow inside the valve chamber is restricted by the walls of the spool and the valve body, distinct flow characteristics can be observed. The flow zone division and flow characteristics are shown in Figure 4.1(a) and (b). As the oil enters through the inlet, firstly a part of the oil impinges on the middle shoulder (region A_1), secondly the convergence enters the inlet throttling port (region A_2) and forms a free jet, and then it collides with the wall of the valve neck (region A_3) to form a wall jet region. Next, the wall jet enters the outlet throttling port (region A_4), where the chamber area increases, allowing the jet to fully develop, which is called the outflow jet region. When the outflow jet contacts the wall, another wall jet begins to form, which has a lower velocity magnitude and a wider jet width than the previous wall jet region. At the same time, a portion of the oil is trapped in the narrow region formed by the spool shoulder and the valve body (region A_5), forming a strong vortex.

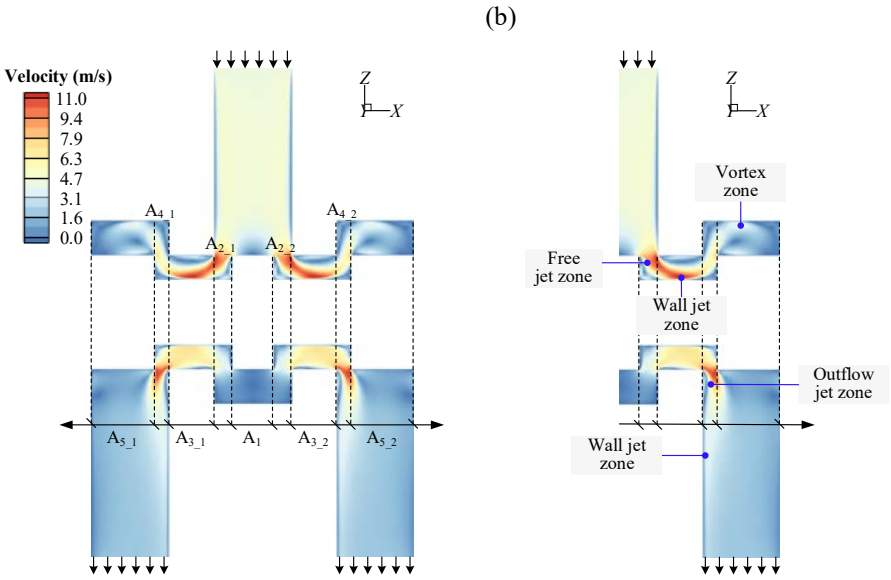

Figure 4.1. Average velocity and flow characteristics of the centre cross-section (Y=0 mm): (a) Flow zone division; (b) Flow characteristics. Especially, due to the symmetrical velocity contour distribution of the left and right parts, figure (b) only shows the right fluid domain.

The RFF is dominated by the pressure component and the viscous component, and Figure 4.2 shows the values and percentages of these two components in the Z-direction for different wall parts (W_1-W_5). Due to the symmetrical contour distribution of the spool wall left and right parts, pressure and WSS-Z contours are placed in a separate contour. From Figure 4.2(a) and (b), the RFF on each spool wall is mainly dominated by the pressure force component, and the viscous force only has a certain contribution (23%) in the middle shoulder (W_1), while the viscous force in the rest walls accounts for less than 10%. Among them, valve neck wall jet zones ($W_{3\text{-}1}$ and $W_{3\text{-}2}$) are the main positive RFF sources, showing significant positive pressure force component (3.34 N), and the viscous force contribution is small but in the same direction (+Z). Conversely, outlet shoulder zones ($W_{5\text{-}1}$ and $W_{5\text{-}2}$) show the most significant negative RFF (-4.28 N). Especially, the middle shoulder (W_1) has a smaller force value but possesses the opposite viscous force direction.

In short, the overall spool wall exhibits positive RFFs, with pressure still dominating (89% of the total). The above analyses indicate that there is a significant pressure asymmetry in these zones, which is the main source of unbalanced RFFs. In addition, since the spool is in the neutral position, the RFF on each region of the spool is symmetrically distributed, further indicating that the simulation is reliable by taking 1/2 flow domain as Figure 3.1.

It should be noted that the pressure values reported in this study are expressed in terms of gauge pressure, with the outlet pressure specified as 0 MPa. Under this formulation, negative pressure values may appear in regions of strong flow acceleration, jet impingement, or local flow separation. These negative values represent pressure levels lower than the outlet reference pressure and do not correspond to negative absolute pressures.

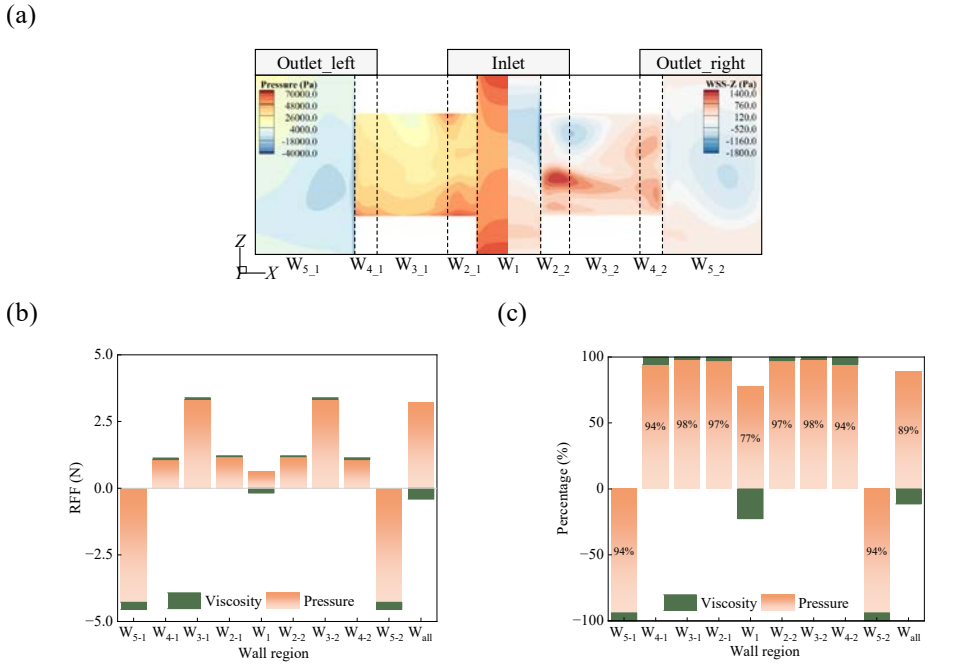

Figure 4.2. Pressure and viscous components of RFF on the spool wall and their proportion: (a) Spool walls division; (b) Pressure and viscous force value; (c) Pressure and viscous force value proportion. Especially, figure (a) exhibits the wall pressure and *Z*-direction wall shear stress (WSS-*Z*) in the *XOZ* view.

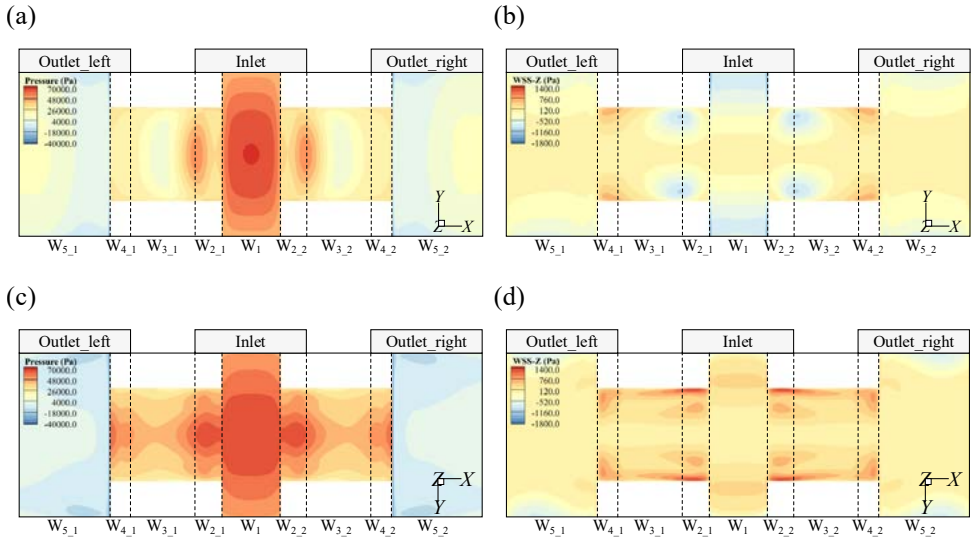

Figure 4.3. Pressure and WSS-*Z* distribution of the upper and lower spool walls: (a) and (b) Pressure and WSS-*Z* distribution of the upper spool wall; (c) and (d) Pressure and WSS-Z distribution of the lower spool wall.

The wall pressure and *Z*-direction wall shear stress (WSS-*Z*) of the upper and lower spool walls in Figure 4.3 further reveal the asymmetry in the spatial distribution of pressure and shear stress. From Figure 4.3 (a) and (c), a more pronounced pressure difference is visible at the upper and lower walls in W_3, corresponding to the larger radial positive force here in Figure 4.2. In W_5, the lower spool wall pressure decreases significantly, creating a significant negative RFF. In contrast, the high WSSs shown in Figure 4.3 (b) and (d) are mainly concentrated in the throttling regions of W_2 and W_4, and despite the large local gradients, their values are much lower than the pressure differences, verifying that the contribution of viscous forces is relatively small.

4.2. Spool radial unbalanced flow force reduction

Above analysis of pressure distribution relative to the middle shoulder clearly reveals that elevated pressure difference predominantly occurs within the central region of the upper and lower walls. To effectively reduce unbalanced RFF, optimization of these specific areas is required. Figure 4.4(a) shows the original valve spool (D_0). Figure 4.4(b) presents an optimized model (D_1) incorporating two perpendicular through-holes (diameter: 2.5 mm) positioned at the mid-section of the shoulder. This design aims to minimize the pressure differential between the upper and lower wall surfaces, thus reducing the unbalance RFF.

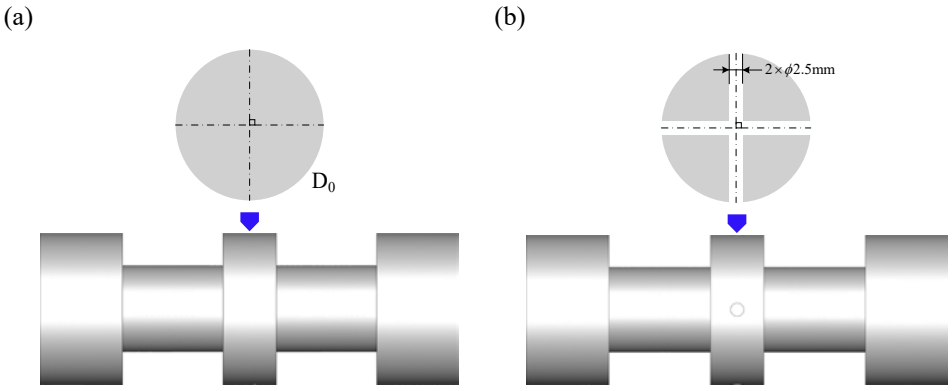

Figure 4.4. Original and optimized valve spool: (a) Original valve spool D_0; (b) Optimized valve spool D_1 with two perpendicular ϕ2.5mm through-holes.

4.2.1. Effect of balanced through-holes structure

Figure 4.5(a) and (b) shows the wall RFF components of two different shoulder structure. The optimized model shows a 20.3% decrease in pressure component, a 15.5% decrease in viscosity component and a 22.8% decrease in net RFF compared to the original model. It is shown that the balanced through-hole structure effectively guides the fluid diversion through the orifice and reduces the pressure gradient and shear effect of the shoulder upper and lower walls, thus weakening the unbalanced RFF. For the entire spool, the pressure component is reduced by 7.3%, the viscous component by 7.0%, and the combined force by 7.3%. Although the overall RFF change is relatively small, the local optimisation effect of the shoulder region is significant. This study is more concerned with an analysis of the effect of pressure on the middle shoulder, given the high pressure-RFF share.

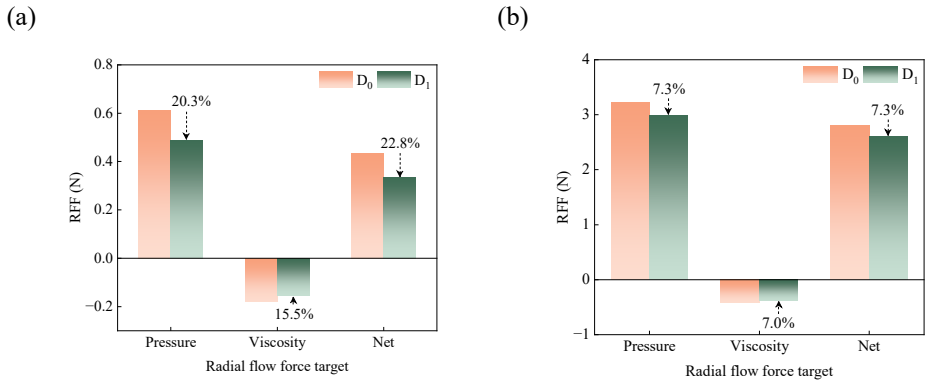

Figure 4.5. RFF on the middle shoulder wall (W_1) and the overall spool (W_{all}) of spools D_0 and D_1: (a) RFF components on the W_1; (b) RFF components on the W_{all}.

Pressure distribution on the upper and lower walls of two shoulder models are shown in Figure 4.6. It can be found that the centre area of the upper and lower walls shows an elliptical high-pressure region, and the boundary pressure decreases abruptly, indicating that the main flow passes around the shoulder resulting in a pressure build-up at the stagnation point. Meanwhile, the area of the high-pressure region on the lower wall is larger than that on the upper, especially at the edge position, resulting in a radial pushover trend (Figure 4.6a and b). With the interference of the through-holes structure, the pressure at the centre is effectively released as the pressure relief channel guides the fluid across the convex shoulder (Figure 4.6c and d). The reduction of the high-pressure areas improves the symmetry and balance of the upper and lower walls, which helps to reduce the RFF difference.

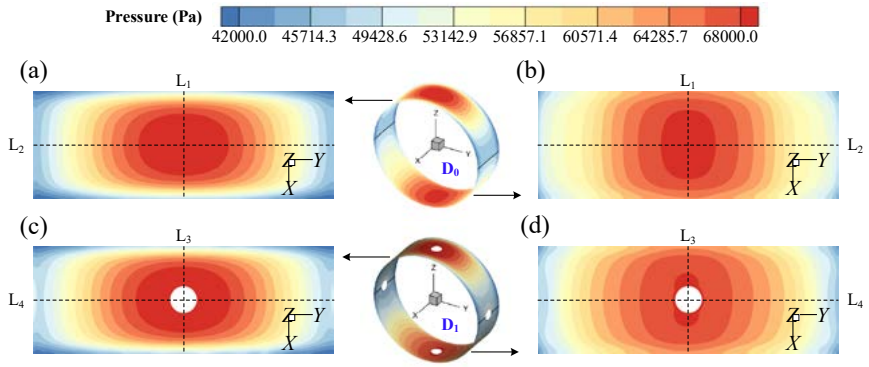

Figure 4.6. Pressure distribution on the upper and lower walls of two shoulder models: (a) and (b) Pressure distribution on the upper and lower walls of D_0; (c) and (d) Pressure distribution on the upper and lower walls of D_1.

The pressure values on the vertical bisectors (L_1~L_4) of the upper and lower walls are further extracted, as shown in Figure 4.7. From Figure 4.7(a), the optimisation resulted in an overall decrease in the lower wall (L_3) pressure and an overall increase (L_1) in the upper wall pressure. Meanwhile, the pressure difference of L_3-L_1 can be found in Figure 4.7(b). It can be found that the positive (+Z) pressure difference is reduced as a whole (near -5<X<-3mm

and 3<X<5mm), and the negative (-*Z*) pressure difference is increased (near -3<X<3 mm), which indicates the positive RFF decrease (+*Z*) as the negative RFF (-*Z*) increase. Then, the overall RFF decrease (+*Z*). The polar plots of L_2 and L_4 are shown in Figure 4.7(c) and (d). The inhomogeneity is defined to measure the pressure difference, which is shown as

$$\sigma_i = \frac{\left|A_{\text{lower}} - A_{\text{upper}}\right|}{A_{\text{lower}}} \times 100\% \tag{4.1}$$

where A_{lower} and A_{upper} are closed curve area enclosed by L_2 and L_4 and the coordinate axes, *i* represents the spool model.

Specially, $\sigma_0 = 1.39\%$ and the $\sigma_1 = 0.67\%$, which indicates that the overlapping cross area of the graph lines increases and the radial symmetry is enhanced after optimisation.

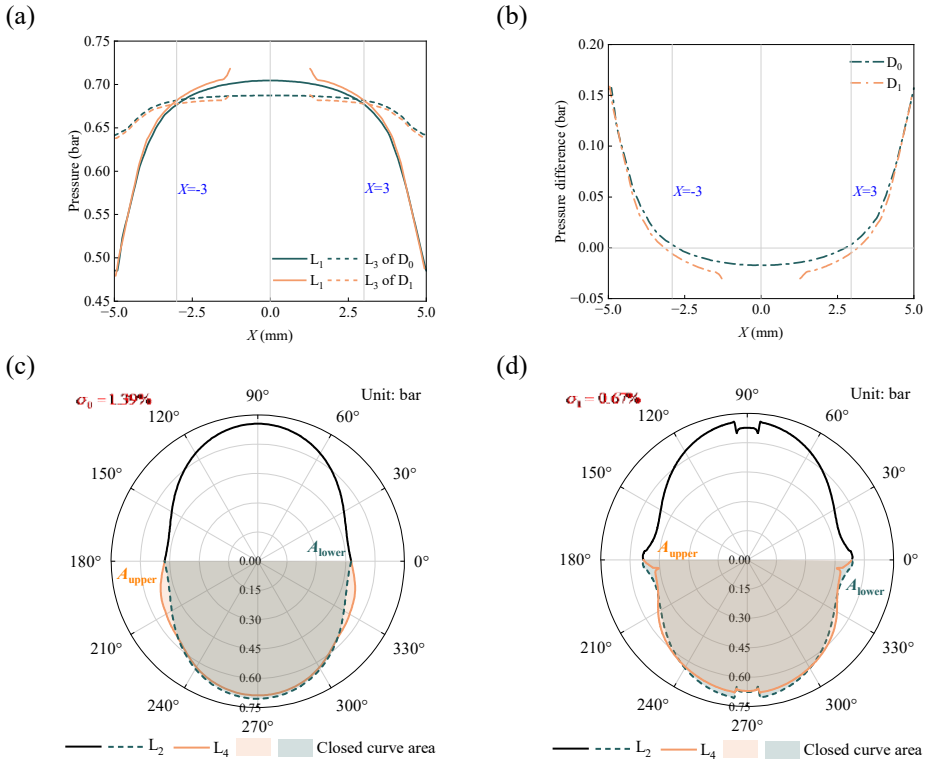

Figure 4.7. Pressure value extracted from L_1~L_4 of the shoulder D_0 and D_1 walls: (a) Pressure value extracted from L_1 and L_3; (b) Pressure difference of L_1 and L_3; (c) Polar plots from L_2 and L_4 on model D_1; (d) Polar plots from L_2 and L_4 on model D_2. Especially, in figure c and d, the cross areas are drawn for identifying the pressure difference between L_2 and L_4.

4.2.2. *Effect of balanced through-hole angle*

In this section, the effect of different through-hole angles on the suppression of radial unbalance force is comparatively analysed. The four through-hole angle models used in this study are shown in Figure 4.8. They are named as model D_0~D_4.

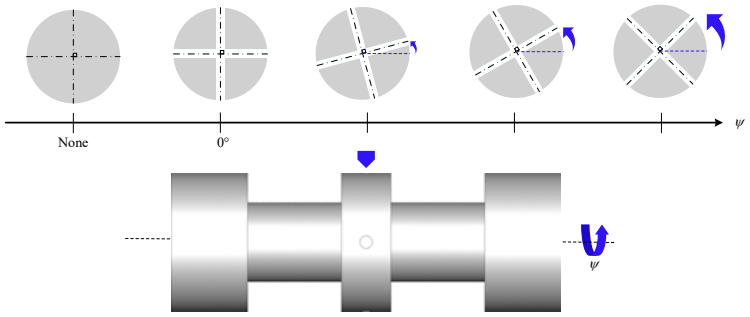

Figure 4.8. Original model and four different balanced through-holes angle (ψ) models.

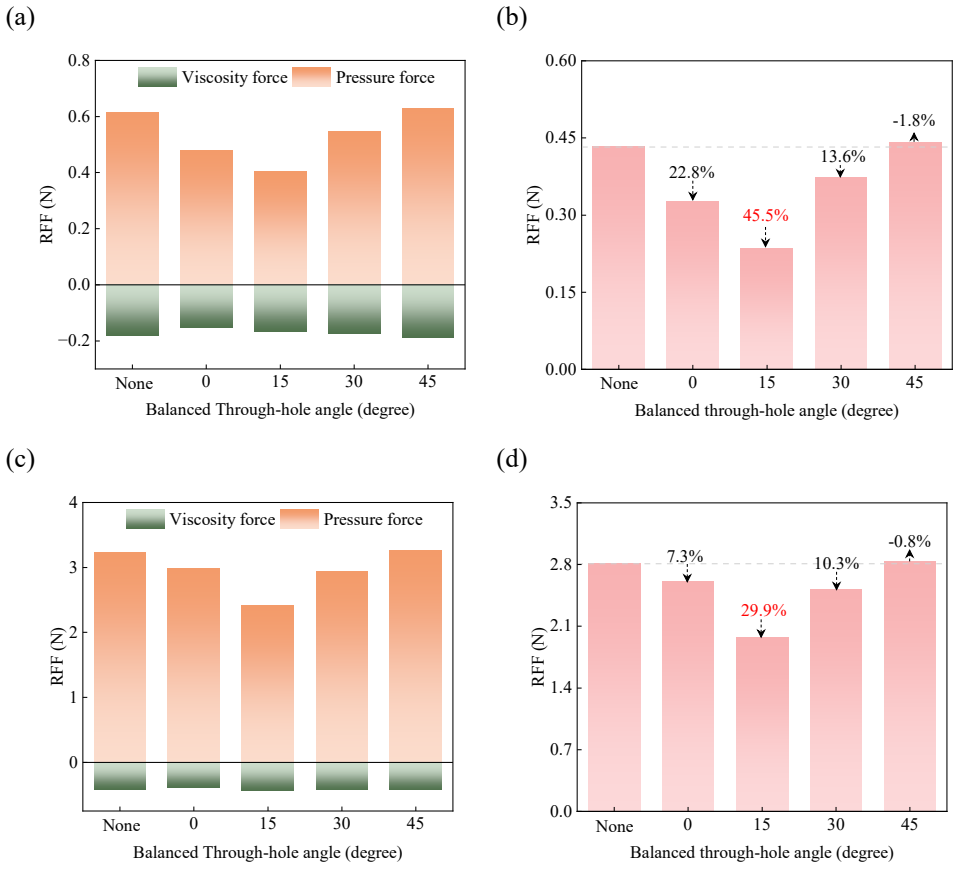

Figure 4.9. RFF (F_r) on the middle shoulder wall (W_1) and overall wall (W_{all}) of different balanced through-hole angle model: (a) Pressure and viscosity RFF components of W_1; (b) Overall RFF of W_1; (c) Pressure and viscosity RFF components of W_{all}; (d) Overall RFF of W_{all}.

The spool RFFs (comprising pressure force and viscous force) for different through-hole angles are demonstrated in Figure 4.9. As illustrated in Figure 4.9(a) and (c), the pressure force component remains predominant in the RFF, and the trend in the performance of the pressure component for each angle structure is consistent with the trend in the total RFF change. The viscous force component is less affected by the through-hole angle and remains stable, indicating that the viscous effect varies weakly within the range of structural parameters in this study. As the through-hole angle is adjusted, the total RFF undergoes a corresponding alteration from Figure 4.9(b) and (d), reaching its most significant decline (W_1 reduce by 45.5% and W_{all} reduce by 29.9%) of D_2. This observation signifies a substantial RFF balancing effect. Notably, For D_4, the RFF approaches the level observed in a structure devoid of holes.

5. CONCLUSION

This study presents a comprehensive investigation of the generation and mitigation for unbalanced RFFs in open-neutral HSVs. Through detailed CFD simulations, the research reveals that RFF is primarily caused by asymmetric pressure distribution across the spool shoulder surfaces, especially in regions with strong vortex formation and abrupt geometric transitions. The viscous component, while present, is comparatively minor. A novel structural strategy introducing through-holes in the mid-shoulder region was proposed to alleviate this imbalance. These through-holes create a preferential flow path that effectively redistributes pressure, promotes local flow symmetry, and reduces radial pressure differentials. Among the tested configurations, the 15° inclined through-hole model demonstrated the most effective performance, reducing local middle shoulder RFF by up to 45.5% and total spool RFF by 29.9%.

In contrast to traditional groove-type pressure balancing methods, the proposed design is more adaptable to compact valve architectures and complex multi-step throttling geometries. It also avoids secondary pressure peaks often introduced by overly steep hole angles, thus ensuring stable flow transition and minimal disturbance. Experimental validation of the proposed through-hole design will be conducted in a subsequent stage of this research to further assess its effectiveness under practical operating conditions.

Modelling and Analysis of the Performance for a Pressure Compensated Flow Control Valve

K. Bhaskar[1,2], N. Johnston[1], A. Plummer[1], S. Westwood[2]

1. University of Bath, 2. Hydraulic System Products Ltd

Abstract.

Pressure compensated flow control valves are an essential requirement in the areas where flow control is necessary to achieve constant speeds regardless of the change in pressure difference or the load on the system. However, maintaining a constant flow rate remains a challenge with increasing pressure drop which directly impacts the performance of the system. The aim of this study is to integrate numerical modelling into the design process for a hydraulic valve in order to predict and optimise its performance. The example of a pressure compensated flow control valve is presented in this paper. The effects of flow forces and flow coefficients on the pressure compensation and flow control are examined. Computational Fluid Dynamics (CFD) models were created and used to obtain the flow forces and flow coefficients for different designs and spool displacements under constant flow rate conditions, and a system model was created in order to examine the performance, incorporating coefficients predicted from the CFD study. Lastly, experimental studies were carried out with the proposed design changes and their impact on the flow control across different pressures were studied.

Keywords. Flow forces, CFD, mathematical model, Orifice, Pressure compensated flow control valve

1. INTRODUCTION

Pressure-compensated flow control valves play an important role in the speed control of hydraulic systems. The output flow rate remains nearly constant, regardless of variations in the inlet pressure. The constant rate of flow is ensured by the adjustment of orifice area depending on the fluctuations in the system pressure. However, it is quite challenging to design a simple, stable valve which maintains the flow within a specified tolerance. As the pressure increases, the compensation by reduction of the orifice area introduces flow forces that act on the displacing element such as a spool or a poppet and contribute to deviations in the flow rate. These flow forces arise due to low pressure regions around the exit of the flow and directly influence the performance characteristics of the valve. Accurate prediction of these flow forces requires combining mathematical models, CFD simulations and validation data from experimental tests. Earlier analytical studies on a system level laid the fundamental approach for the modelling of compensated valves. Weber, Johnston and Edge

All Open Access articles are peer-reviewed, distributed under the Creative Commons Attribution-Non Commercial 4.0 International

[1][2] developed steady state CFD models that were used to extract the effective jet angles and discharge coefficients for use in valve dynamic models. The jet angle was identified as the crucial parameter that led to significant changes in the flow force acting on the spool. Faulkner, Johnston and Weber [3] applied this methodology to pressure cartridge valves showing that the geometric parameters such as chamfers and introduction of fillets in place of sharp corners altered the discharge coefficients. The research also emphasised the sensitivity of valve performance to manufacturing tolerances.

Cheng [4] proposed analytical models linking the damping orifice flow characteristics to the transient response time. Parameters such as the spring constant and the pre-compressed length of the spring directly affect the steady flow rate, demonstrating how the behaviour of the flow forces influences compensation accuracy. Borghi et al. [5] conducted CFD-based numerical analysis and experimental studies to determine axial flow forces on compensated spool valves. The dependency of the flow forces on the geometry was modelled and verified through measurements from experimental studies. The Coanda effect was noted to be a significant influence on the actual flow at small openings of the valve. CFD studies and experiments on spool valves by Heraković et al. [6] concluded that the implementation of simple changes to a combination of geometrical parameters of the spool reduced the axial flow forces in the valve and helped eliminate the non-linear digressive flow-force characteristics. The CFD results agreed well with the experimental results. Further studies using CFD and mathematical models implemented in Matlab/Simulink were carried out for a proportional flow control valve by Lisowski et al. [7]. The study explored a triangular shape for the spool opening which reduced the dynamic flow forces acting on the spool. The jet angle was also studied and found to vary with the throttle gap width of the opening area; it was concluded that the functional relationship between the two may be obtained with an approximation.

Mao et al. [8] analysed a bidirectional throttling slide valve using CFD and experiments. It was found that the asymmetric vortices formed caused unequal steady flow-force curves and a guiding shoulder with an annular cavity was proposed that effectively reduced the asymmetry in the flow forces. Altare, Rundo and Olivetti [9] coupled the 3D CFD studies with a 0D dynamic model to study the effects of flow force compensation on a conical poppet pressure relief valve. The research experimentally explored the use of a deflector geometry for reducing the flow force. The data extracted were supplied as an input to a lumped parameter model of the valve. The study highlights the important role of the relation between the geometry, the flow forces and the deflection of the flow jet. Amirante et al. [10] described a CFD analysis of flow forces in a hydraulic proportional valve with circumferential notches. The CFD predictions were validated with experimental flow rate data. A reduction in the flow forces was observed at large valve openings, but smaller benefits were obtained at small openings. There was a decrease in the discharge coefficient with the valve opening due to changes in the flow direction. The study further shows that alterations to the spool profile could help in further reductions of the flow forces.

Across the studies, flow forces are shown to have a direct effect on the flow performance of the valve, and the jet angle as well as the geometry emerge as the principal contributors. The present study adopts an approach for the estimation of the flow forces and the flow coefficients and combining them with a mathematical model using Matlab/Simulink to optimise the performance of the pressure compensated flow control valve.

2. DESCRIPTION OF THE VALVE MODEL

The pressure compensated flow control valve examined in this study was developed jointly by Hydraulic System Products Ltd and University of Bath. The valve is of cartridge type with a flow control range between 20 lpm to 30 lpm and a working pressure up to 250 bar. The valve consists of a main body with large radial holes as the outlet, a sliding spool with smaller radial holes which would act as the variable metering orifice, a needle and a sliding 'hat' that would form the fixed orifice. There is an adjustable spring to set the flow limit manually. Figure 1 shows the cross-section of the valve.

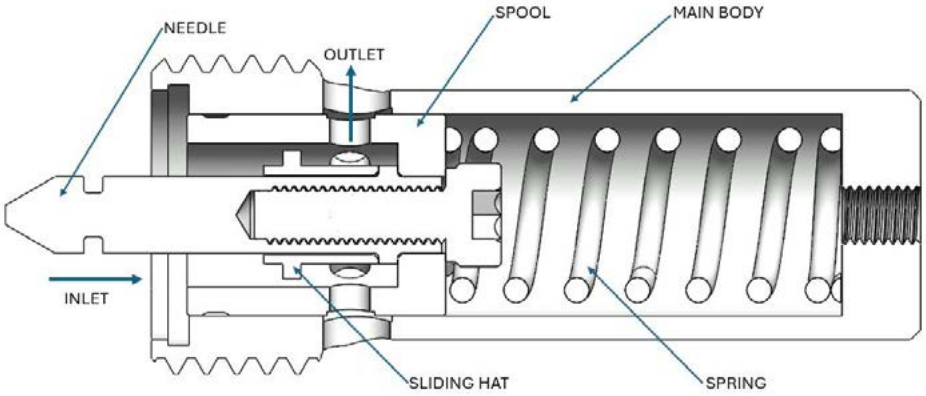

Figure 1: Cross-section of the pressure compensated flow control valve.

3. ANALYSIS OF FLOW USING CFD MODELLING

3.1. CFD model for the geometry and flow paths

A parametric CFD model was developed by tracing the flow path from the CAD model. The model consists of an inlet, radial outlets for the spool and the radial outlets for the main body. The interface between the radial outlets of the spool and the body are connected by a 0.2 mm deep groove. The spool displacements are set from 0 mm from the fully open, normal position as shown in Figure 1, to 3.25 mm which leaves a smaller orifice opening of 0.15 mm, with the displacement of the spool for closing the orifice completely being 3.4 mm. Separate CFD simulations are conducted for each opening of the valve based on the spool displacement under steady flow conditions to test the entire range of the valve opening. A quarter model was used for the CFD studies as the model is axisymmetric, and this saves computational resources and time. Figure 2 shows the quarter model used in the CFD studies.

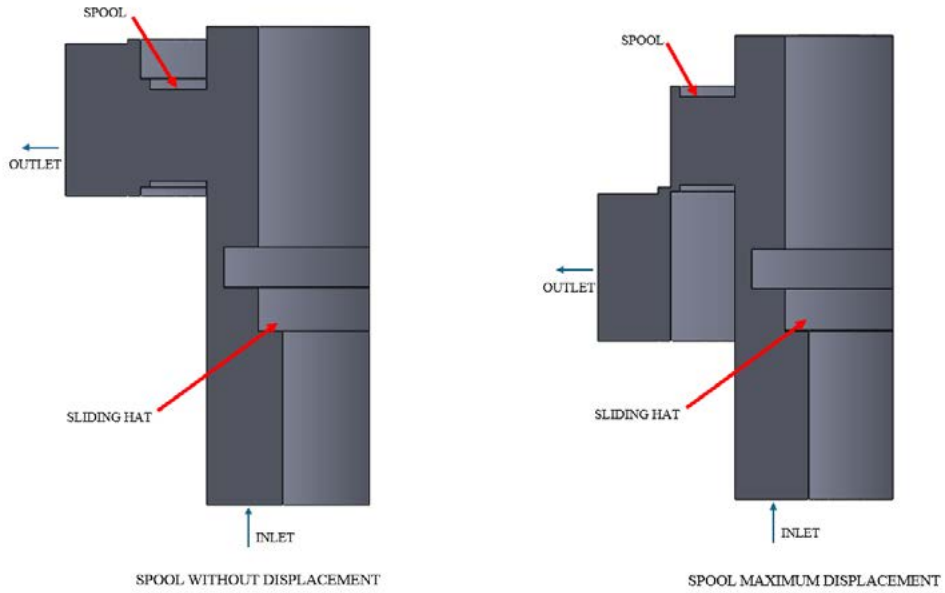

Figure 2: CFD quarter model

3.2. Mesh and mesh settings.

The meshing of the model and the CFD studies were carried out using the ANSYS FLUENT software which also enabled the application of local mesh refinements. The smallest element size was limited to 0.005mm with the largest size being 0.08mm. 5 boundary layers were added to the wall regions with an initial height of 0.005mm for better resolution near the boundary layers. Each model consisted of about 1.4 million poly-hexcore cells with a maximum skewness of 0.56 and a minimum orthogonal quality of 0.5. Figure 3 shows the mesh for the quarter model of the flow path.

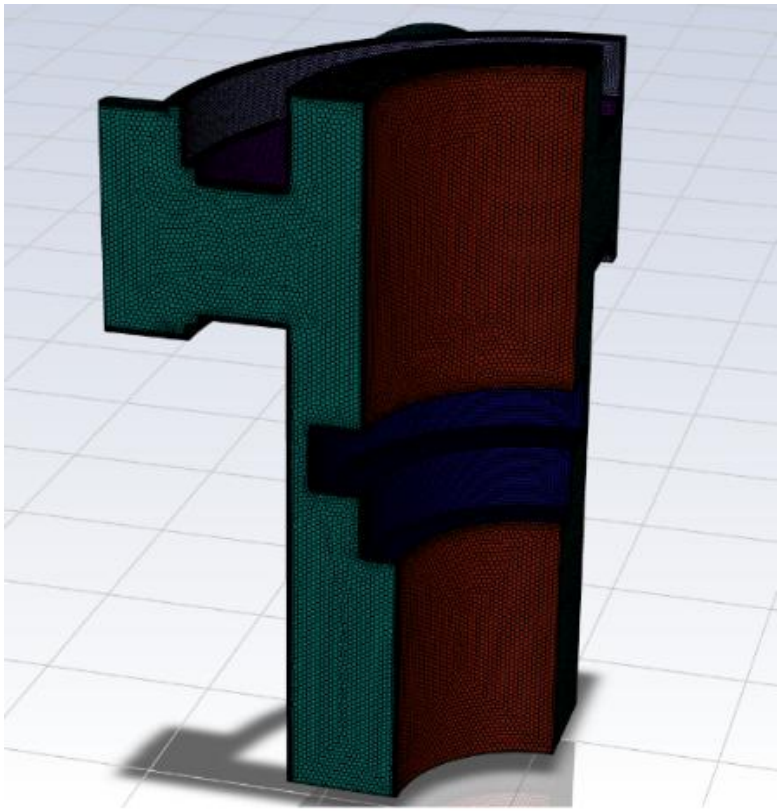

Figure 3: Mesh geometry for the CFD quarter model

3.3. CFD model parameters

A pressure-based model was used for the studies. There are many different turbulence models which can be used for the flow through the valve. The 'Realisable k-ε' model is equipped with enhanced wall treatments and considers the pressure gradient effects. Several CFD studies including [1], [7], and [10] support the use of this model for internal flow through valves, and so this model was chosen.

This turbulence model has been validated thoroughly for a wide range of flows and has been found to perform better than the standard k-ε model [11].

The fluid viscosity is set to 32 centistokes with a density of 860 kg/m^3. The inlet velocity is set at 11.7 m/s while the pressure at the outlet is set to 0 Pa gauge pressure. The convergence criteria were set to 10^{-4} for the momentum and the forces acting on the spool surface. It was found to be difficult to obtain valid, converged CFD results for openings less than 0.15 mm.

3.4. CFD results

The CFD results provided pressure and velocity distributions throughout the flow path. The pressures acting on the spool, the forces acting on the spool, the pressure drops across the orifices and the flow rate at the outlet were extracted from the CFD simulations. The pressure drops across each orifice were determined from the CFD pressure distribution plots.

The total force acting on the spool extracted from the CFD is the resultant force which includes the flow force. The flow force (F_f) is calculated by subtracting the pressure force from the resultant force (F_T) on the spool as shown in equation 1. Figure 5 shows a plot of flow force versus spool displacement, where the displacement of the spool increases as the pressure increases.

$$F_f = F_T - PA_s \qquad (1)$$

Where F_f is the total force acting on the spool, F_T is the total resultant force acting on the spool, P is the pressure acting on the spool at the inlet and A_s is the diametrical area of the spool. Whilst this flow force is related to the axial momentum flux entering as well as leaving a control volume within the spool, it is convenient to relate it to the downstream radial orifice. The effective jet angle is calculated using the flow force relation given by the equation:

$$F_f = \rho Q V \cos\theta \qquad (2)$$

where ρ is the density of the fluid, Q is the flow rate at the exit of the valve, θ is the jet angle and V is the velocity of the flow through the orifice which is calculated by the equation:

$$V = \sqrt{\frac{2\Delta P}{\rho}} \qquad (3)$$

Here, ΔP is the pressure drop across the orifice. The flow coefficient C_q is calculated using the orifice equation (Equation 4) with an approximation of the orifice area (Equation 5) which resembles the lateral surface area of a cylinder formed by the internal grooves on the spool and the main body as shown in figure 4.

$$Q = C_q A_{orifice} \sqrt{\frac{2\Delta P}{\rho}} \qquad (4)$$

$$A_{orifice} = \pi D_o x \qquad (5)$$

Where, $A_{orifice}$ is the orifice area, D_o is the outer diameter of the spool and x is the opening displacement of the orifice. This equation for the area is an approximation to the true orifice area to establish a functional relation between the flow and the orifice area. Any error in the approximation is compensated for in the flow coefficient C_q.

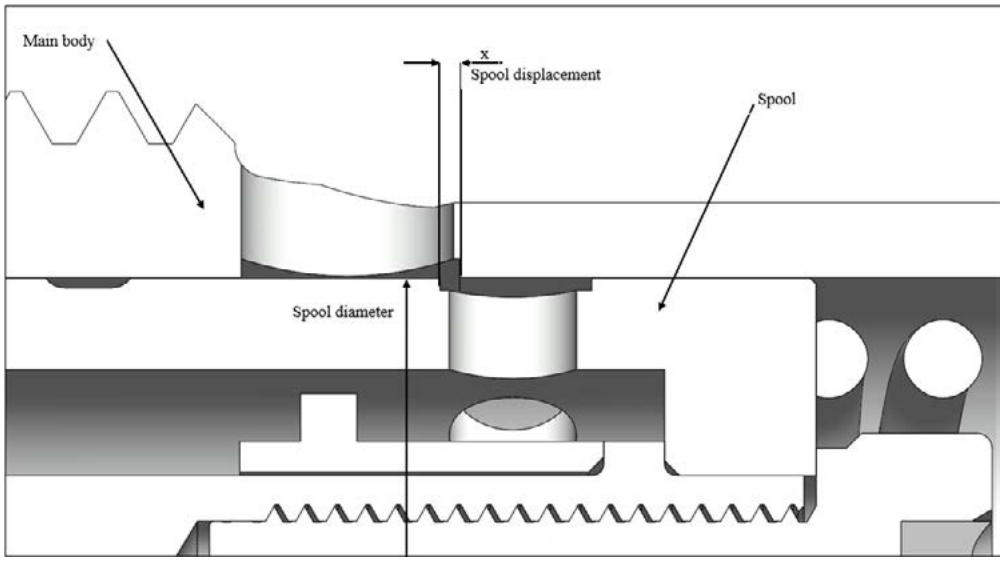

Figure 4: Flow path through the valve for the CFD model.

Figure 5 shows the plot of the flow force against spool stroke for different valve openings. Positive flow force indicates the force is acting from left to right in figure 4 helping to close the orifice, while negative flow force indicates the force is acting from right to left helping to open the orifice. It was observed that the flow force steadily increases with a decrease in the outlet orifice area, but for very small openings, the flow force dips to a negative value. This effect is largely due to the change in the jet angle (Figure 6) of the exit flow [1],[2],[7], except that for large openings the inlet momentum is significant.

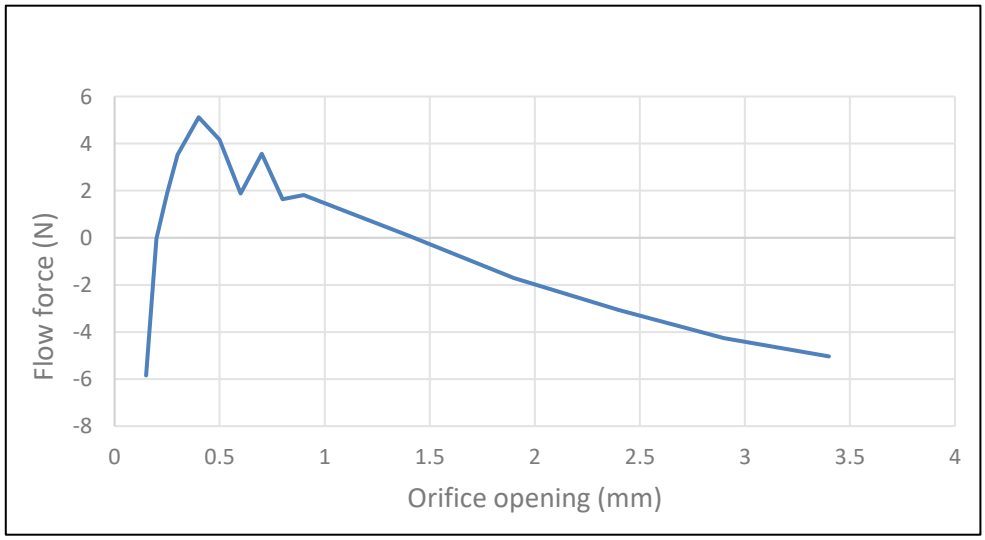

Figure 5: Spool v/s Orifice opening

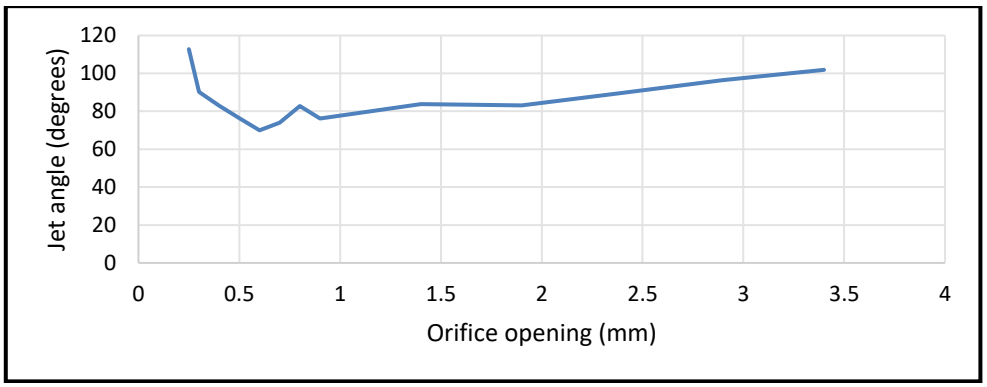

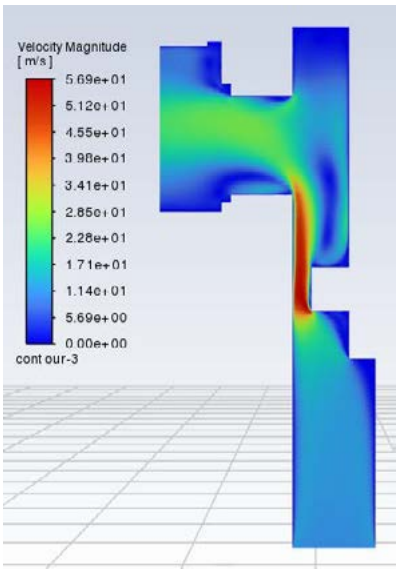

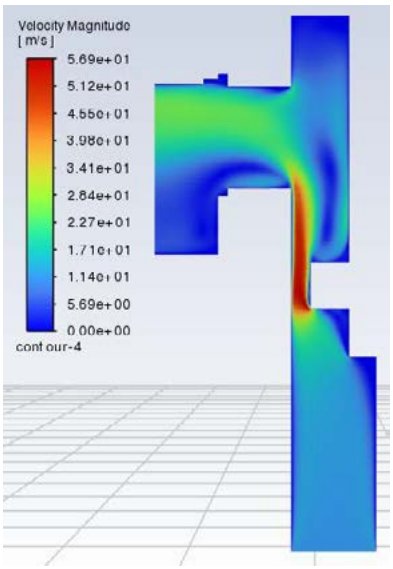

Figure 6: Jet angle v/s Orifice opening

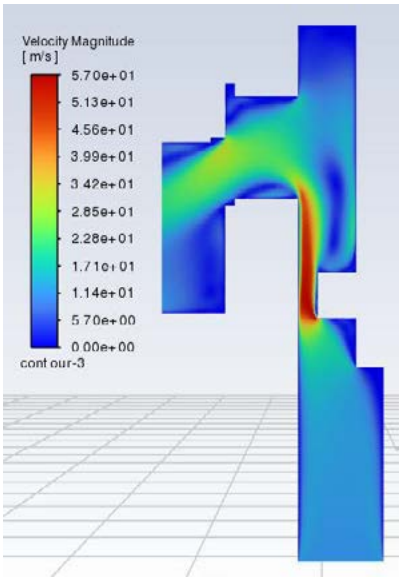
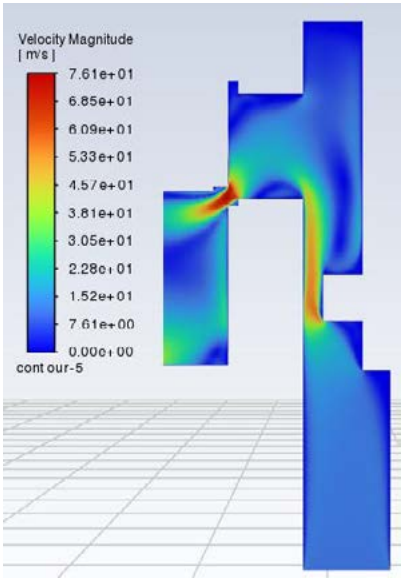
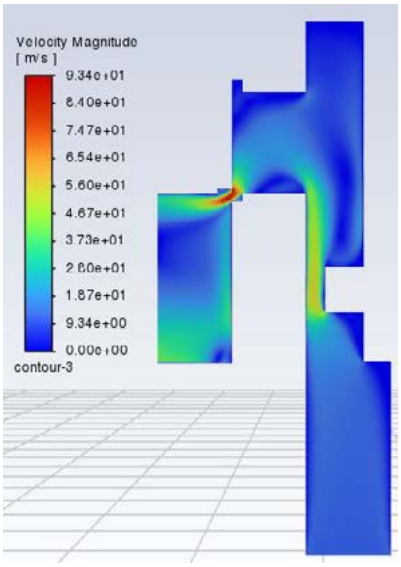


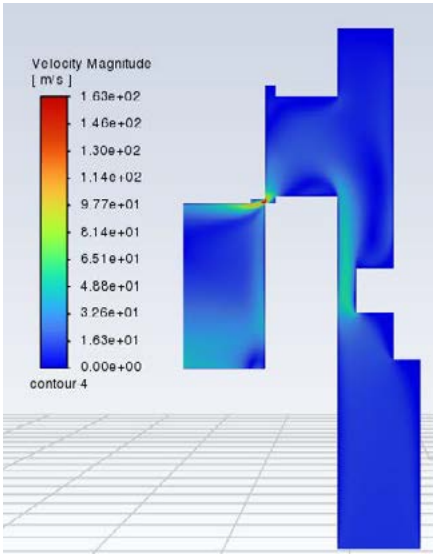
The figures from 7(a) through 7(f) show the velocity distribution of the flow through both the orifices. The angle of the jet is considered as the angle made from the inlet flow line to the line the exit jet follows at the exit of the second orifice.



(a): Orifice fully open



(b):Orifice 2.4mm open



(c): Orifice 1.4mm open

(d): Orifice 0.4mm open

(e): Orifice 0.15mm open

(f): Orifice 0.1mm open

Figure 7: CFD flow patterns through a radial plane, for different openings.

It is observed from the velocity distribution figures that the jet angle starts off greater than 90° and reduces as the area of opening for the variable orifice reduces. The reduction in the jet angle increases the value of $\cos\theta$ in equation (2). This would indicate smaller quantity of flow forces for large opening of the valve. However, for openings less than 0.4 mm, the jet angle can be seen to increase towards the radial direction, and this correlates with the increase in angle in figure 6. It should be noted that the orifice geometry and jet patterns are

complex and three-dimensional because of the radial holes in the spool and housing (figure 3), so the 2D plots in figures 7(a) to 7(f) do not tell the full story.

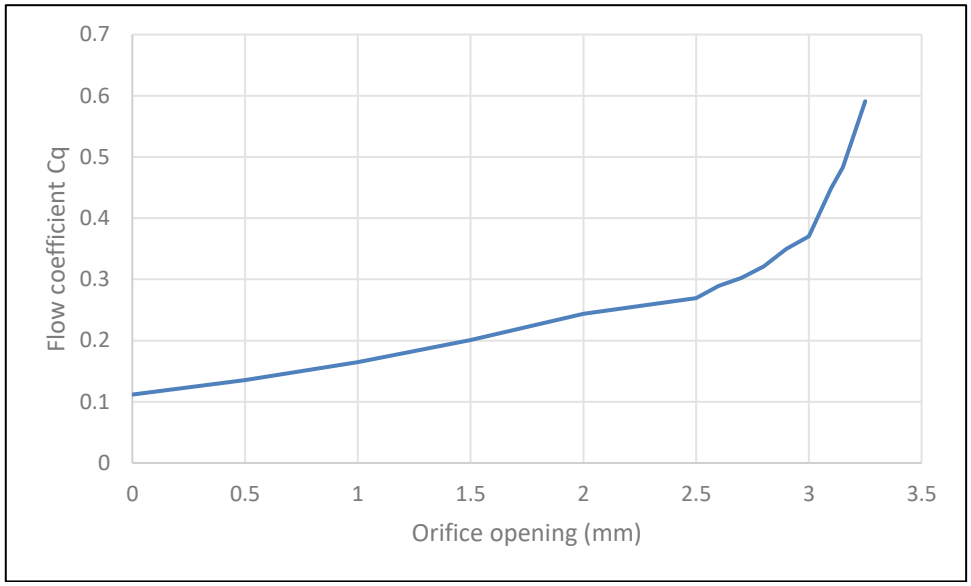


Figure 8: Flow coefficient vs orifice opening

Figure 8 shows the flow coefficients calculated from equation (4) plotted against the opening of the orifice which is a result of the displacement of the spool. The flow coefficient is calculated for flows across the variable orifice. The value of the flow coefficient C_q is observed to increase steadily as the area of opening for the decreases. This change observed is mainly due to the approximation in the calculation of the orifice area. The values of the jet angle and the flow coefficients were input as a table into the mathematical model.

4. MATHEMATICAL MODEL

A mathematical model was developed and implemented in Matlab® Simulink. The model consists of a pressure ramp at the inlet as the input, pressure drop across the input (sliding hat) orifice as well as the variable orifice, a spring-mass system to derive the displacement of the spool, a leakage model and the flow at the outlet of the second orifice. Figure 9 shows the block diagram for the mathematical model.

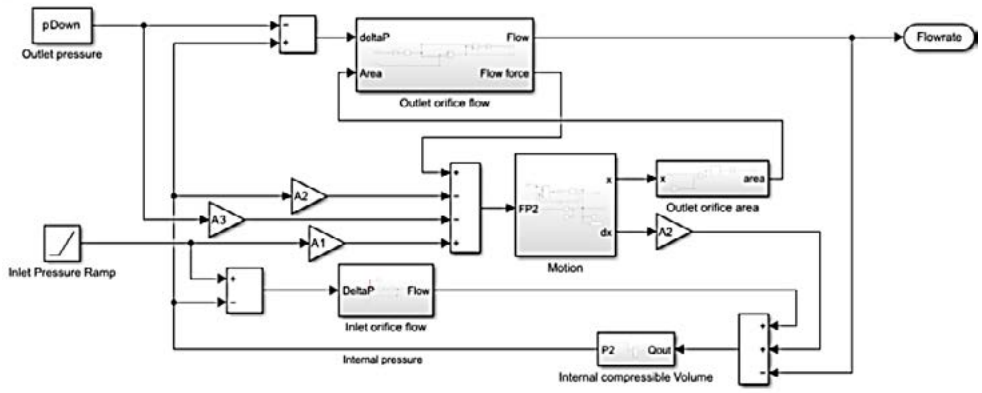

Figure 9: Matlab® Simulink block diagram of valve model

The pressure ramp values are converted to force acting on the sliding hat and the spool which pushes the spring. The displacement of the spool is derived with the equation

$$F = m\ddot{x} + c\dot{x} + kx \qquad (6)$$

Where, m is the mass of the spool and the sliding hat, c is the damping coefficient, k is the spring stiffness, x is the displacement of the spool and $\ddot{x}$ and $\dot{x}$ represent the acceleration and the velocity of the spool. The inputs for the flow coefficient and the jet angle were taken from the CFD results and compiled into a 1-D table for different points of displacement and approximate area value for the variable orifice. The flow force is calculated using the equation (1) and is subtracted from the pressure force acting from equation (6). The flow across the orifice is calculated using the equation (4). A curve for the flow vs the pressure drop is obtained from the Simulink model shown in figure 10, for upward and downward pressure ramps.

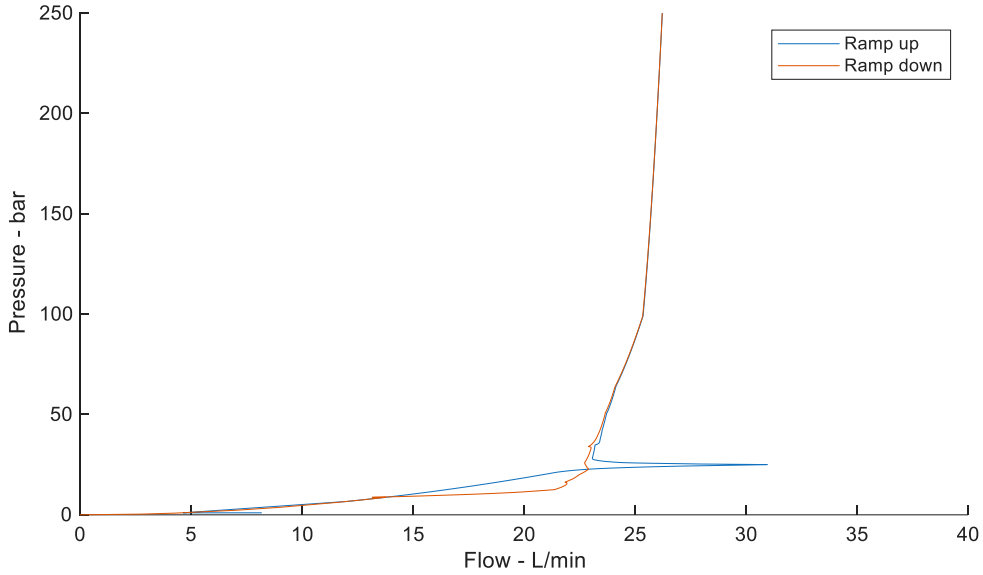

Figure 10 – predicted pressure-flow characteristics

From the figure, it is observed that for pressures above about 30 bar the valve meters the flow close to the setpoint of 25 L/min as desired, with a slight increase in flow with pressure. It was found that this variation was quite sensitive to the flow force. For pressures below about 30 bar there is insufficient pressure force to compress the spring, so the valve is fully open, and the flow is not controlled. There is some hysteresis apparent between about 10 bar and 30 bar, and for increasing pressure ("ramp up") a large spike is observed in the flow. This is because the predicted flow coefficient (figure 7) decreases with opening for large openings, such that as the spool starts to move in the direction to close the orifice, the flow resistance decreases resulting in a spike in flow for increasing pressure. This spike is not observed for decreasing pressure.

5. EXPERIMENTAL RESULTS

The experimental rig was setup at the premises of Hydraulic System Products Ltd. The rig was driven by an axial piston pump capable of achieving a maximum flow of 300 lpm and a maximum pressure of 350 bar. The measurements for the flow and the pressure were recorded using a Webtec HPM4000 data logger with a sampling rate of 60 Hz. The schematic of the test rig and assembly of the valve is shown in figure (11).

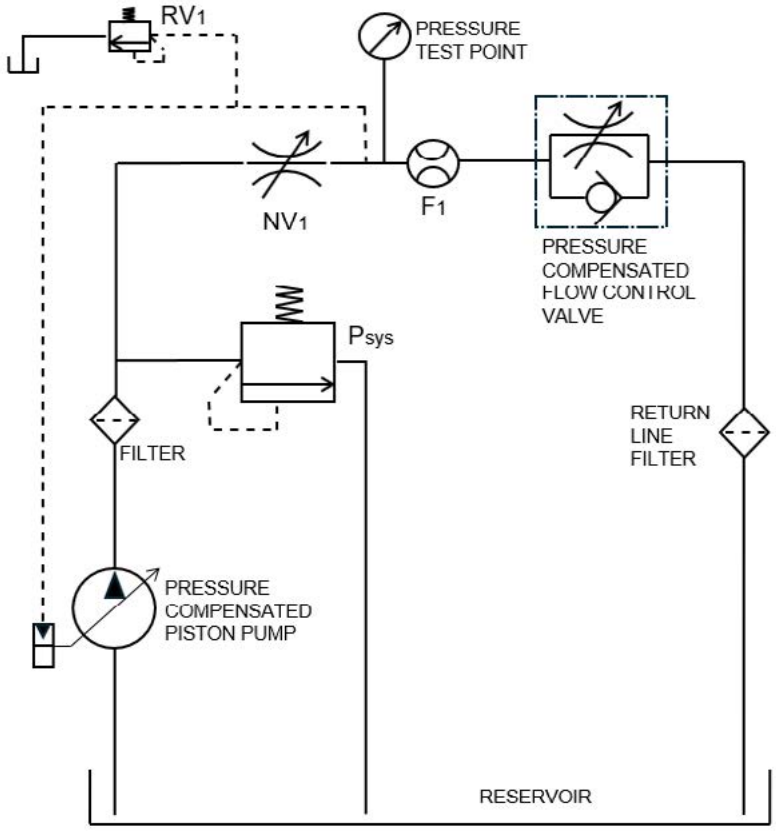

Figure 11: Schematic diagram of the hydraulic test rig

The oil is pumped from the reservoir by the piston pump through the system relief valve P_{sys} and a flowmeter F_1 into the valve. The flow is controlled by the needle valve NV_1 and the pressure through a restrictor valve RV_1. The outlet of the valve is connected back through the tank. The image of the valve on the test rig is shown in figure (12).

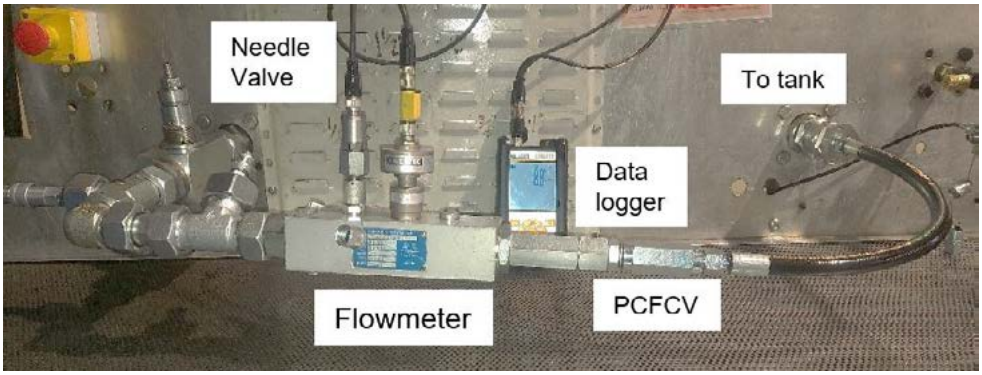

Figure 12: Hydraulic test rig at Hydraulic System Products LTD

The pressure was increased in small increments from 0 to 250 bar while recording the values of the pressure and flow. The recorded data form the data logger was used to plot the graph of flow versus the pressure as seen in figure (13).

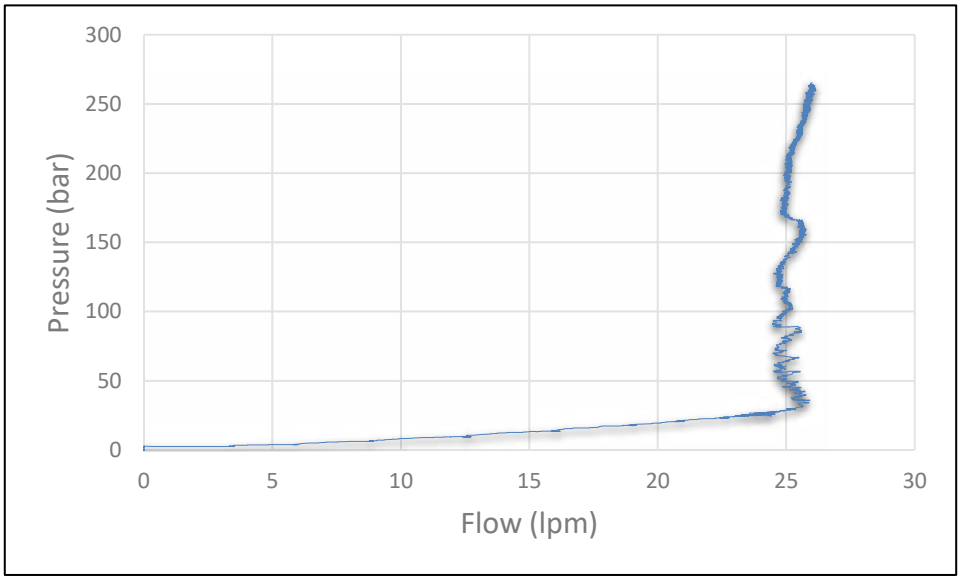

Figure 33: Experimental results - flow v/s pressure.

From the experimental results, it is observed that the behaviour of the valve follows closely with the results of the mathematical model. The flow is found to increase as the pressure increases and a slight overshoot at the set flow. The slight increase in the flow until the maximum pressure of 250 bar is observed. The spike in flow and hysteresis in the 10-30 bar region were not observed in the experimental results. The deviation from the set constant flow suggests the flow forces impacting the performance of the valve at higher inlet pressures and lower area of the exit orifice.

6. CONCLUSION

A method to integrate Computational Fluid dynamics (CFD) and mathematical modelling approach for analysing and optimising the performance for a pressure compensated flow control valve is presented. The study demonstrates that combining fluid parameters form the CFD simulations with a mathematical model provides an accurate and reliable method of predicting the valve behaviour. The CFD analysis quantified the forces acting on the spool which allowed for the calculations of the flow force and the jet angle. The results show that the flow force increases as the orifice area reduces but may reverse the direction at very small openings due to an increase in the jet angle. The calculated jet angles and the flow coefficients were integrated into the Simulink based mathematical model which produced the compensation behaviour of the valve, predicting the gradual increase in flow with an increase in the pressure. Experimental testing confirmed the accuracy of the model with the measured characteristics of the flow v/s pressure curve closely matching the results of the mathematical model. The findings show that the jet angles and the flow forces were the core contributors to the deviations from the ideal constant flows at higher pressures, and the predicted valve performance was very sensitive to the flow force.

The mathematical modelling was a key part of the design process. It highlighted the importance of flow force on the valve performance and helped to produce a design in which the flow force was reduced resulting in a good pressure-flow characteristic. Overall, this methodology offers a design framework for prediction of flow performance with the jet angle, flow force and the flow coefficient that would aid in optimising the valve geometry for future designs of the pressure compensated flow control valve. Future work will expand on the current methodology to parametrise the design and optimise the orifice geometry.

Abstract.

The thermal behavior of the deflector jet servo valve (DJSV) is influenced by complex interactions among electromagnetic, fluid, and thermal fields, making accurate temperature prediction challenging under wide operating conditions. However, most existing simulations rely on simplified assumptions (such as omitting the internal air region, assuming constant oil viscosity, or ignoring the coil heat source) without quantitatively assessing their effects on the predicted thermal field. In this study, a three-dimensional steady-state thermal-fluid coupled model of a DJSV is developed to evaluate the influence of these modeling simplifications. Six simulation schemes are designed by varying the treatment of the internal air domain, oil viscosity-temperature dependence, and coil heat generation, and are assessed under six representative operating conditions covering combinations of inlet oil temperature, ambient temperature, and pressure. Results show that omitting the internal air region mainly affects electromagnetic components, while neglecting temperature-dependent oil viscosity and coil heating causes distributed deviations across multiple parts. The coil and armature exhibit the highest thermal sensitivity. These findings clarify the thermal implications of modeling simplifications and provide reference for selecting appropriate model fidelity in engineering-oriented DJSV analyses.

Keywords. Deflector jet servo valve, thermal-fluid coupling, temperature field prediction, temperature dependence

1. INTRODUCTION

As a core component of electro-hydraulic servo control systems, the deflector jet servo valve (DJSV) critically determines system precision and reliability. In aerospace applications, hydraulic oil temperatures can vary widely, from below -50 °C to above 120 °C, and may even exceed 200 °C in high-performance systems. Excessive temperature rise can lead to severe consequences, such as spool jamming and degradation of electromagnetic components. Therefore, accurate prediction of the temperature field is essential for effective thermal management and reliable system design.

Numerous studies have investigated thermal effects in servo valves. Li et al. [1] developed a thermodynamic model that takes throttling losses and convective heat exchange into account and has been experimentally validated. Zhang et al. [2] applied a heat-fluid-solid FEM and found that thermal deformation of the spool-sleeve pair reduced the clearance and caused clamping above 80 °C. The zero-drift model in [3] attributed over 15 % control error (20-270 °C) to variations in flow coefficient and magnetic reluctance. An AMESim-based model [4] demonstrated that temperature reached equilibrium within 2.5 hours, with pressure having a strong influence. Recent efforts have focused on DJSVs. A nonlinear ninth-order model [5] demonstrated that temperature-induced flow-coefficient variation and pilot-stage deformation jointly degrade accuracy by over 30 %. Temperature-dependent flow-force evolution was quantified in [6], and wide-temperature modeling [7] linked magnetic-flux loss and air-gap deflection to temperature drift. Other studies [8-12] linked thermal friction and clearance reduction to jamming, demonstrated that reduced viscosity enhances self-excited oscillations, and clarified the leakage-clamping trade-offs at elevated temperatures. Collectively, these works confirmed that oil temperature significantly affects valve dynamics and stability.

However, most existing thermal analyses emphasize the hydraulic stage while neglecting the torque motor and its internal air region. The internal air region is often omitted or solidified, overlooking its role in convective heat transfer. Moreover, many models are confined to zero-opening conditions, where oil flow and heat convection are minimal, and oil viscosity is treated as constant rather than temperature-dependent. Such simplifications limit the accuracy of temperature-field prediction, particularly for electromagnetic components under realistic operating states. To address these limitations, this study establishes a three-dimensional steady-state thermal-fluid coupled model of a DJSV. Six simulation schemes with different simplifications, regarding the internal air region, oil-viscosity-temperature dependence, and coil heat generation, are evaluated under representative conditions to quantify their respective effects and clarify component-level thermal sensitivities.

2. THERMAL GENERATION AND HEAT TRANSFER IN DJSV

2.1. Operating Principle

The DJSV mainly consists of three functional subsystems: a torque motor, a jet prestage, and a power spool stage. The feedback rod passes through a pair of high-pressure jets and receiver ports on the jet pan, with V-shaped grooves machined on its surface. When an electric current flows through the coils, electromagnetic torque is generated in the magnetic circuit, producing a small angular deflection of the armature assembly. This deflection causes a displacement of the V-groove, which changes the pressure difference between the two receiver ports and consequently drives the spool motion in the power stage. During this energy conversion process, multiple heat generation and dissipation phenomena occur simultaneously. These include Joule heating within the coils, iron losses in the magnetic conductors, and throttling-induced viscous dissipation within the valve body. The generated heat is dissipated through several mechanisms: heat conduction, forced convection through hydraulic oil flow, and natural convection from the external surfaces of the valve to the surrounding air.

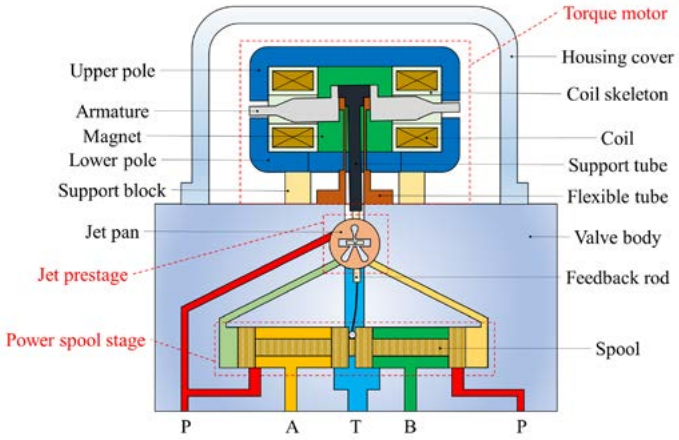

Figure 2.1. Structure of the deflector jet servo valve.

2.2. Heat Generation

(a) Electromagnetic Losses

When an electric current I passes through the coil, Joule heating occurs, with the instantaneous power expressed as:

$$P_{cu}=I^2R \tag{1}$$

The resistance of the coil varies with temperature according to:

$$R=R_0[1+\alpha(T-T_0)] \tag{2}$$

where R_0 is the resistance at the reference temperature T_0, and α is the temperature coefficient of resistivity. Assuming uniform current density and homogeneous heating, the winding region is treated as a uniformly distributed volumetric heat source. The volumetric heat generation rate is then expressed as:

$$q_{\mathrm{cu}}=\frac{I^2R}{V} \tag{3}$$

where V is the coil volume.

The present model neglects dynamic magnetic losses (iron losses) but incorporates the temperature-dependent copper loss to account for the resistivity-temperature coupling in the windings.

(b) Throttling-Induced Heat Generation

Viscous dissipation during throttling arises from viscosity-induced energy losses. As hydraulic oil flows through the orifice, the abrupt reduction in flow area accelerates the fluid and produces a high shear rate. Viscous stresses resist the velocity gradient, converting flow work and turbulent kinetic energy into internal energy and heat. The resulting temperature rise inside the valve due to viscous dissipation is given by:

$$\Delta T=\frac{\Phi}{\rho c_{\mathrm{p}}} \tag{4}$$

where ρ is the oil density, c_p is the specific heat at constant pressure, and Φ is the viscous dissipation function:

$$\Phi=\mu\{2[\left(\frac{\partial u}{\partial x}\right)^2+\left(\frac{\partial v}{\partial y}\right)^2+\left(\frac{\partial w}{\partial z}\right)^2]+\left(\frac{\partial u}{\partial y}+\frac{\partial v}{\partial x}\right)^2+\left(\frac{\partial u}{\partial z}+\frac{\partial w}{\partial x}\right)^2+\left(\frac{\partial v}{\partial z}+\frac{\partial w}{\partial y}\right)^2\} \quad (5)$$

where μ is the fluid dynamic viscosity, u, v, w are the velocity components of the fluid in the x, y, z directions. The dynamic viscosity is treated as temperature-dependent, according to the fitted viscosity-temperature relation in Section 3.2.

2.3. Heat Transfer

(a) Forced Convection

Within the valve body, hydraulic oil flow driven by the pressure differential transfers heat away from internal components. The convective heat flux can be expressed by Newton's law of cooling:

$$q=h(T_w-T_f) \quad (6)$$

where h is the convective heat transfer coefficient, T_w is the wall temperature, and T_f is the fluid bulk temperature. The coefficient h can be estimated using a Nusselt number correlation of the form:

$$N_u=\frac{hL_c}{\lambda}=CR_e^mP_r^n \quad (7)$$

where L_c is the characteristic length, λ is the thermal conductivity, R_e is the Reynolds number, P_r is the Prandtl number, C, m, n are the empirical coefficients. The dynamic viscosity of the hydraulic oil varies exponentially with temperature and is described by:

$$\mu(T)=\mu_0e^{-b(T-T_0)} \quad (8)$$

where μ_0 is the viscosity at the reference temperature T_0, and b is the empirical constant.

(b) Natural Convection

Heat dissipation from the external surfaces of the valve to ambient air occurs primarily via natural convection, which can be described as:

$$q=h_{nat}(T_s-T_\infty) \quad (9)$$

where h_{nat} is the natural convection coefficient, T_s is the surface temperature, and T_∞ is the ambient air temperature.

(c) Heat Conduction and Internal Air Domain

Heat conduction follows the Fourier's law:

$$q=-k\nabla T \quad (10)$$

where k is the thermal conductivity, ∇T is the temperature gradient vector.

Within the enclosed housing, natural convection is limited, allowing the air to be approximated as a solid with low thermal conductivity.

3. NUMERICAL SIMULATION MODEL AND METHODOLOGY

3.1. Modeling Overview and Meshing strategy

The model preprocessing of the DJSV is shown in **Figure 3.1**, ignoring non functional details such as chamfers, screw holes, and fillets. Assuming an input current of 40 mA, the corresponding displacement of the spool valve is set to -0.5 mm, and the displacement of the jet prestage deflection is set to +0.025 mm. Consequently, the computed temperature field reflects a quasi-steady-state thermal balance at a representative operating point.

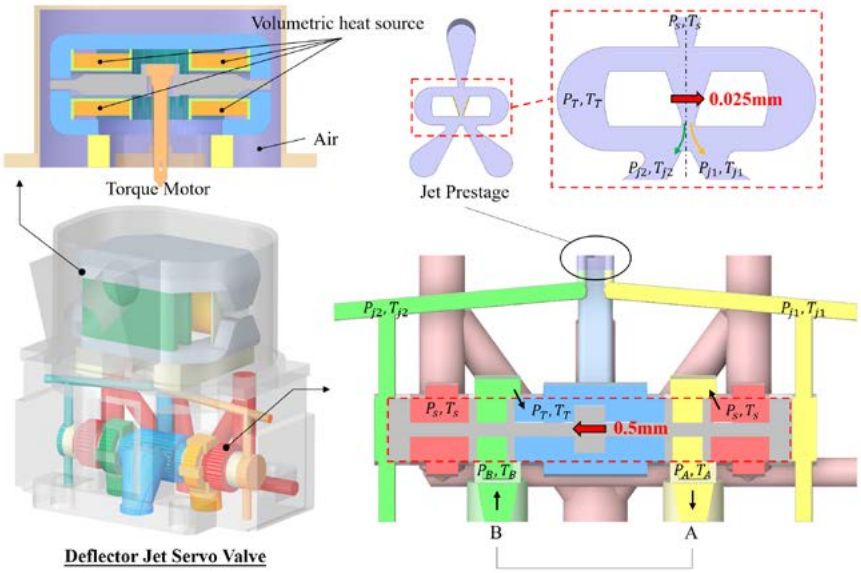

Figure 3.1. Model preprocessing of the DJSV

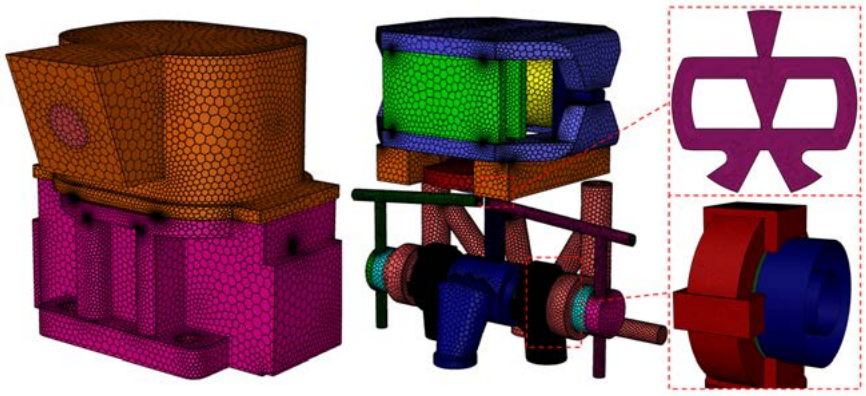
The mesh generation result for the entire valve is shown in **Figure 3.2**. Local refinement was applied to the orifices of the jet pilot stage and the spool, and the total number of grid cells reached 2 million.



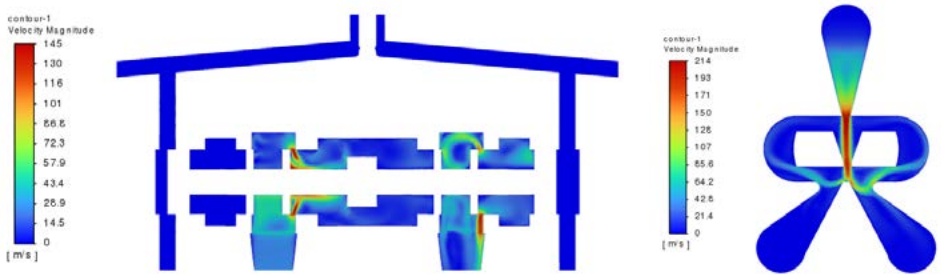


Figure 3.2. Mesh generation and local refinement

The velocity contour results in **Figure 3.3** confirm that the mesh adequately resolves the flow structures and velocity gradients within the critical regions, including the jet prestage and throttling orifice.

(a)valve body section (b) jet prestage section

Figure 3.3. Representative velocity contour results

3.2. Material Properties

The thermal physical properties are summarized in **Table 1**. The component "Solid-air" is the equivalent solid region.

Table 1: Materials settings

Component	Material	Density (kg/m^3)	Specific heat capacity (J/(kg·K))	Thermal conductivity (W/(m·K))
Housing cover Support block	0Cr18Ni9	7930	500	21.5
Upper pole Lower pole Armature	1J50	8100	460	15
Magnet	LNG32	7500	465	32.7
Support tube Feedback rod	3J1	8100	460	30
Flexible tube	Qbe2	8300	380	100
Spool	9Cr18	7700	470	29.3
Valve body	440C	7800	480	24.2
Coil	Copper	8930	385	390
Coil skeleton	Polyimide	1400	1150	0.25
Solid-air	-	1.205	1012	0.026
Oil	YH-15 aviation hydraulic oil	850	1880	0.12

The hydraulic medium is YH-15 aviation hydraulic oil, the temperature dependence of the oil viscosity was obtained from experimental data (see **Table 2**). A double-exponential correlation derived by least-squares fitting (R^2=0.99996) is expressed as:

$$\mu(\mathrm{T})=0.0017e^{-0.1182T}+0.0389e^{-0.0312T} \tag{11}$$

where $\mu(\mathrm{T})$ is the viscosity of the oil (kg/(m·s)), T is the temperature of the oil (℃).

Table 2: Viscosity test results of YH-15 aviation hydraulic oil [13]

Temperature/℃	Viscosity/(mm^2/s)	Temperature/℃	Viscosity/(mm^2/s)
-55	1620.993	60	9.683
-40	390.924	80	7.088
-20	111.064	100	5.579
0	42.734	120	4.460
20	22.482	135	4.027
40	13.928		

3.3. Boundary Conditions and Simulation Settings

The energy equation with viscous dissipation was activated, and the Realizable k-epsilon model was employed as the turbulence model. The boundary condition settings are as follows:

Table 3: Boundary condition settings

Boundary Location	Type	Parameter	Value
Port P	Pressure inlet	pressure temperature	**inlet_pressure** **inlet_temp**
Port A	Pressure outlet	pressure	(**inlet_pressure**+0.5MPa)/2
Port B	Pressure inlet	pressure temperature	(**inlet_pressure**+0.5MPa)/2 Outlet A temperature
Port T	Pressure outlet	pressure	0.5 MPa
Outer surfaces	Convection	temperature coefficient	**ambient_temp** 10 W/(m²·K)

All solid-fluid and solid-solid interfaces employed shared topology to ensure continuous heat flux. The temperature-dependent volumetric heat source of the coil was expressed as:

$$q_v(T)=(I^2\cdot\frac{234+T}{254}\cdot R_{20})/V=160000\cdot\frac{234+T}{254} \quad (12)$$

where $q_v(T)$ is the volumetric heat power (W/m^3), T is the temperature of coil (℃), I is the current (A), R_{20} is the resistance of the coil at 20℃ (Ω), V is the coil volume (m^3).

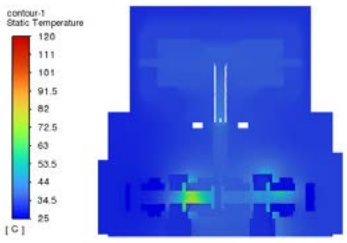
Table 4: Multiple operating conditions

Condition	**ambient_temp**/℃	**inlet_pressure**/MPa	**inlet_temp**/℃
C1	25	21	25
C2	25	35	25
C3	300	21	25
C4	25	21	135
C5	25	35	135
C6	300	21	135

As shown in **Table 4**, the boundary conditions cover six representative operating environments (C1-C6) to evaluate the modeling assumptions under normal, high-pressure, and high-temperature conditions. Case C3 (300 °C ambient, 25 °C inlet oil) reflects hot external exposure with a relatively low inlet-oil temperature, creating a high-ambient and low-supply contrast to quantify the oil-cooling effect and the resulting temperature gradients. To systematically assess the influence of modeling assumptions, six simulation

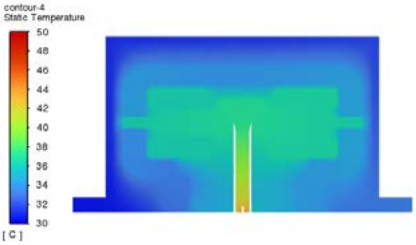
schemes (S1-S6) were constructed as shown in **Table 5**. Each scheme isolates one or more simplifications related to the internal air region, oil viscosity–temperature dependence, and coil heat-source modeling. Scheme S1 serves as the reference model, while S2-S6 progressively omit selected coupling effects.

Table 5: Summary of simulation schemes



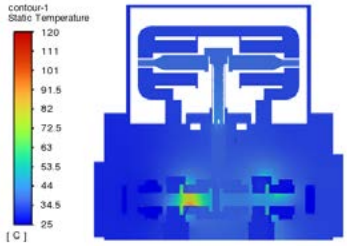
Scheme	Air region treatment	Viscosity model	Coil heat source
S1	Equivalent solid	Variable $\mu(T)$	Variable $q_v(T)$
S2	Equivalent solid	Constant μ	Constant q_v
S3	Equivalent solid	Constant μ	Ignored
S4	Ignored	Variable $\mu(T)$	Variable $q_v(T)$
S5	Ignored	Constant μ	Constant q_v
S6	Ignored	Constant μ	Ignored

4. SIMULATION RESULTS AND DISCUSSION

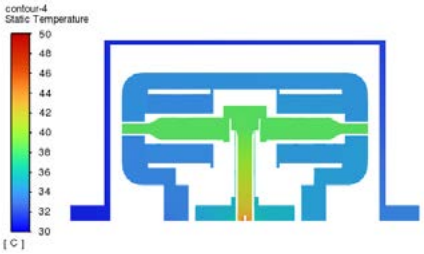


4.1. Overall Temperature Distribution under Typical Condition

To intuitively demonstrate the influence of model simplification on thermal field prediction, the temperature distributions obtained from the most detailed scheme (S1) and the most simplified scheme (S6) were compared under two representative operating conditions: C1 and C6. These two cases correspond to the normal and high-temperature extremes, enabling a direct comparison of the valve's thermal behavior under ordinary and harsh environments.

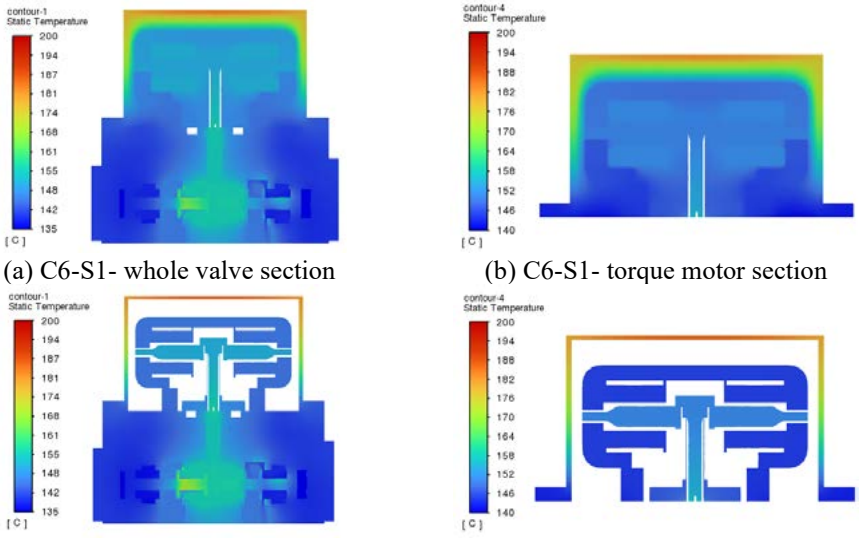


As shown in **Figure 4.1**, under the normal temperature condition, the overall temperature gradient across the valve is relatively small. The high temperature zones are mainly concentrated at the spool throttling orifice and the jet prestage, where viscous dissipation is strongest. A temperature gradient exists along the feedback rod within the torque motor, whereas the temperature distribution in the remaining components is relatively uniform.



(a) C1-S1-whole valve section

(b) C1-S1-torque motor section



(c) C1-S6-whole valve section

(d) C1-S6-torque motor section

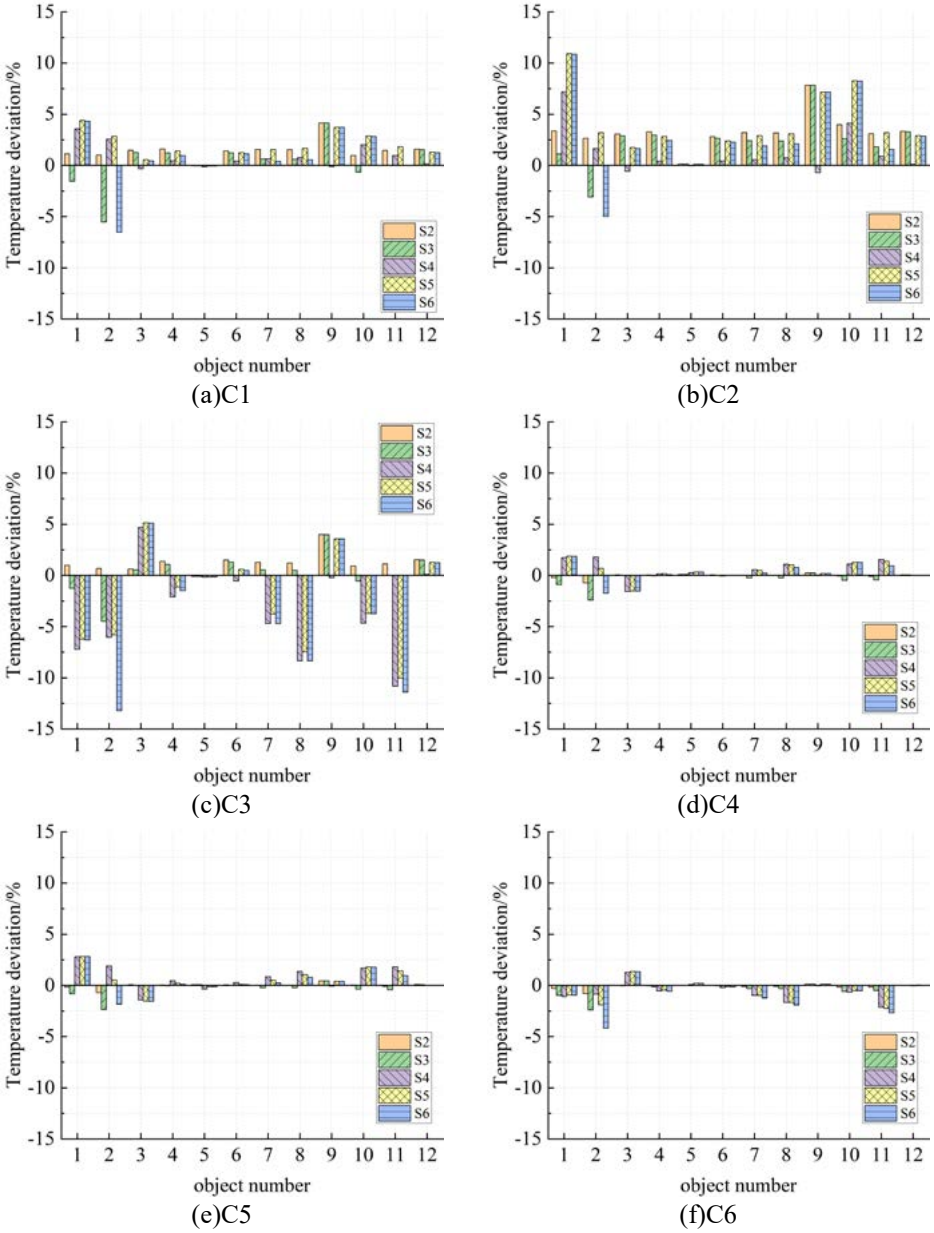
Figure 4.1. Temperature contours under C1 between S1 and S6

As shown in **Figure 4.2**, under the high temperature condition, however, the thermal gradient becomes much more pronounced. The highest temperature occurs at the top of the housing cover, while the return oil region in the valve body is also relatively hot.

(a) C6-S1- whole valve section (b) C6-S1- torque motor section

(c) C6-S6- whole valve section (d) C6-S6- torque motor section

Figure 4.2. Temperature contours under C6 between S1 and S6



When comparing S1 and S6, the global temperature distributions of the valve appear similar under both C1 and C6, suggesting that at a macroscopic level the main heat-transfer paths and primary hot zones are preserved in the simplified model. Nevertheless, the torque motor cross section reveals localized discrepancies between the two schemes. To assess these deviations, a quantitative comparison of component-level temperatures is presented in the next section.

4.2. Deviation Analysis of Different Modeling Schemes

Twelve structural components of the DJSV were defined as monitoring bodies for thermal evaluation, as listed below: (1) armature, (2) coil, (3) housing cover, (4) support block, (5) feedback rod, (6) flexible tube, (7) lower pole, (8) magnet, (9) spool, (10) support tube, (11) upper pole, and (12) valve body. The volume averaged steady-state temperature of each component was extracted under all modeling schemes (S1-S6) and operating conditions (C1-C6) for quantitative comparison.

Figure 4.3 presents the relative temperature deviations of twelve components under six operating conditions (C1-C6). Under the conventional condition C1, temperature deviations mainly occurred in the armature, coil, spool, and support tube. When the pressure increased (C1→C2), The deviations of the armature and support tube became larger, while other components remained nearly unchanged. During ambient temperature elevation (C1→C3), a wider range of components showed pronounced changes. The deviations of the armature, coil, magnet, and both magnetic poles shifted significantly, with several instances of sign reversal and magnitudes up to 10-12%. However, under high-temperature oil conditions, the transitions C4→C5 and C4→C6 produced negligible changes. When comparing oil

temperature increase pairs (C1→C4, C2→C5, C3→C6), several components demonstrated evident deviations. For example, the armature and support tube showed large variations in C2→C5 (-8%), while in C3→C6 the coil, magnet, and upper pole exhibited positive deviations up to 9%.

1-armature; 2-coil; 3-housing cover; 4-support block; 5-feedback rod; 6-flexible tube; 7-lower pole; 8-magnet; 9-spool; 10-support tube; 11-upper pole; 12-valve body

Figure 4.3. Bar charts of temperature deviations relative to S1 under condition C1-C6

4.3. Average Absolute Deviation and Sensitivity Evaluation

To further quantify the global influence of model simplifications, the average absolute deviation (AAD) of the twelve components was calculated for each scheme under all six operating conditions, as shown in **Figure 4.4**. The AAD provides a single comprehensive metric representing the overall discrepancy introduced by each modeling assumption.

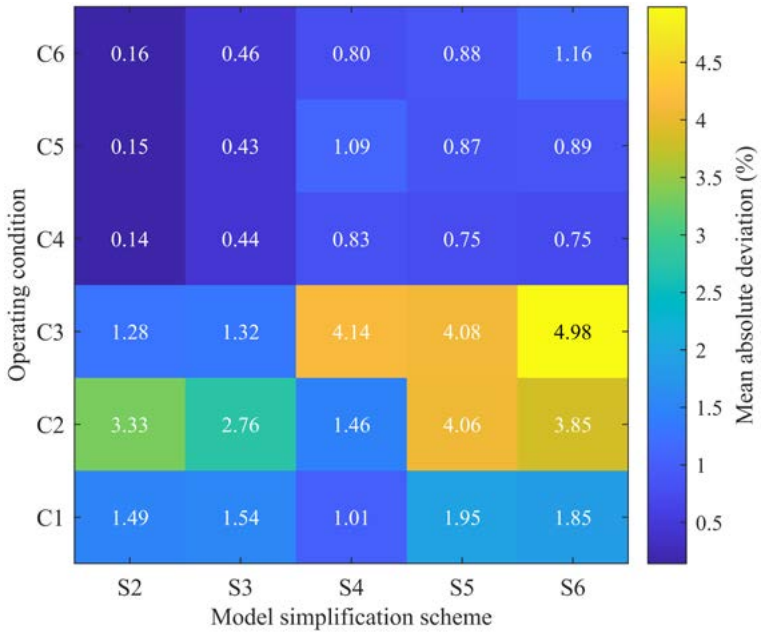


Figure 4.4. Heatmap of average absolute deviation under C1-C6

Under high oil inlet temperatures (C4-C6), the AAD values of all simplified schemes remain relatively low, suggesting that the convective heat transfer of the hot oil plays a primary role in shaping the valve's overall thermal response. In this regime, the temperature viscosity dependence of the oil tends to stabilize, diminishing the impact of the assumed viscosity model on thermal dissipation. Therefore, neglecting the internal air domain and the temperature dependence of viscosity and coil resistance has a negligible impact on the overall error. In contrast, under moderate thermal conditions (C2 and C3), the deviation increases notably, particularly for the more simplified schemes (S4-S6), reaching up to about 5%. This indicates that, when the inlet oil temperature remains at room temperature while the ambient temperature intensifies, neglecting the internal air region removes an important thermal resistance path, thus introducing a discernible discrepancy in the predicted temperature field. Moreover, under high pressure conditions (C2 and C5), the intensified viscous dissipation in the throttling orifices elevates local temperatures, which may be inadequately represented if the temperature dependence of oil viscosity is ignored.

To isolate the influence of each modeling factor, including the omission of the internal air region, the neglect of temperature-dependent effects (for both viscosity and coil heat generation), and the complete omission of the coil heat source, pairwise comparisons were conducted such that only the factor of interest varied while the other two remained fixed.

The scheme pairings used for each isolated factor are summarized in **Table 6**. This approach ensures that the extracted deviations reflect the individual contribution of each simplification rather than the combined influence of multiple assumptions.

Table 6: Scheme pairs used for single-factor sensitivity analysis

Factor	Scheme Pair for Comparison
Omit air region	S4-S1, S5-S2, S6-S3
Temperature dependence(Viscosity/Coil heat source)	S2-S1, S3-S1, S5-S4, S6-S4
Ignore coil heat source	S3-S2, S6-S5

As shown in **Figure 4.5**, the coil consistently exhibits the highest temperature sensitivity, with deviations exceeding 1.6% for all factors and reaching up to 2.9% when the coil heat source is completely neglected. The armature demonstrates pronounced sensitivity primarily to the air-domain omission, with deviations up to 2.75%. When the temperature-dependent effects of viscosity and coil heating are ignored, deviations are moderate but widely distributed across multiple components, particularly the spool, support tube, and magnet, reflecting the system-wide influence of assuming constant material properties. In contrast, the valve body, flexible tube, and feedback rod exhibit minimal changes across all factors. Therefore, accurate inclusion of both the air domain and temperature dependent effects is essential for reliable prediction of local thermal gradients within the torque motor assembly.

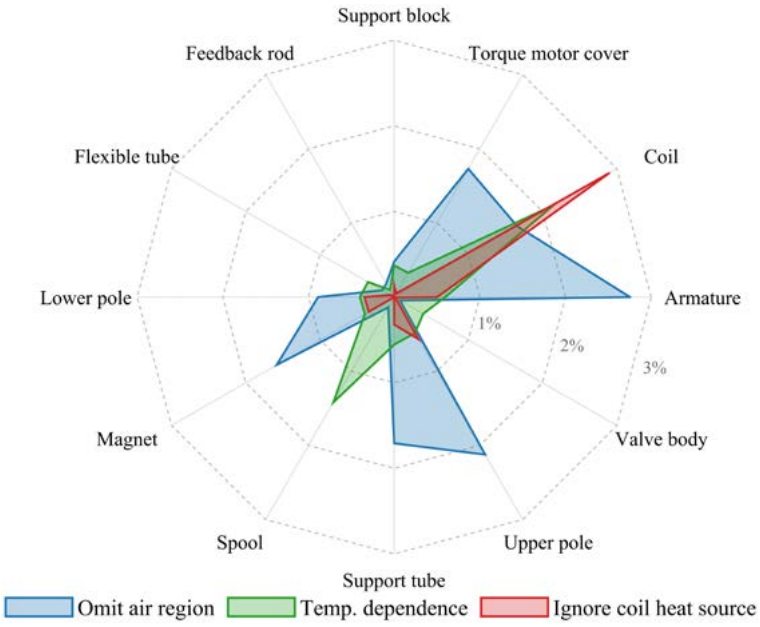

Figure 4.5. Sensitivity of component temperature deviation to modeling simplifications

5. CONCLUSIONS

A steady-state three-dimensional thermal-fluid coupled analysis of a deflector jet servo valve (DJSV) was performed. The analysis quantified the effects of common modeling simplifications, including the omission of the internal air domain, neglect of temperature-

dependent oil viscosity and coil heat generation, and complete exclusion of the coil heat source. Six simulation schemes were examined under six representative operating conditions to evaluate the resulting thermal deviations. The results indicate that the simplified models generally preserve the primary heat-transfer paths and dominant hot zones. However, neglecting the internal air region primarily affects electromagnetic components, particularly under elevated ambient temperatures. Ignoring the temperature dependence of oil viscosity and coil heating introduces distributed temperature deviations across multiple components. Among all factors, the coil exhibits the highest sensitivity, the armature is mainly affected by the omission of the air region, while the spool, support tube, and magnet show moderate deviations when temperature-dependent effects are disregarded. In contrast, the valve body, flexible tube, and feedback rod remain largely insensitive to these simplifications.

Abstract.

Conventional valve development includes measurements and computational fluid dynamics (CFD) simulations. Both are used in an iterative process to achieve the desired characteristic curve. To accelerate the valve development process considerably, data-based expert systems should be introduced. These models are trained with CFD simulation data of numerous geometries. Usually, CFD simulation parameters are tuned for one specific geometry.

This paper presents CFD simulation parameters applicable for a wide range of 2/2 directional poppet valve geometries. The parameters are validated with measurement data from both normally open (NO) and normally closed (NC) valves. Based on previous research, the theoretical background in CFD simulation and preliminary studies, the simulation parameters used in this study are carefully selected. For the validation, 164 points are generated from continuous measurements of nine industrial poppet valves. The comparison between the simulations and measurements show a very high accuracy in the prediction of the pressure difference with a mean deviation of 7.9 %. The accuracy in the simulation of flow forces is lower but the trends in the simulations are correct and high flow forces can be predicted accurately. The results prove that it is possible to use one set of CFD simulation parameters for different geometries. This makes CFD simulations suitable as a database for prediction models.

Keywords. Model-based valve design, poppet valves, flow forces, CFD simulation, validation.

1. INTRODUCTION

Oil hydraulic valves are used in a wide range of industrial and mobile hydraulic applications for simple switching functions as well as for control tasks. The variants within a valve series are often as diverse as the applications themselves. Nevertheless, there are always customer requirements that call for a further, adapted valve geometry. Being able to implement these requirements quickly and cost-effectively plays a decisive role in global competition.

Currently, developing valves for specific applications is time-consuming and costly. This is because valve development is an iterative process involving trials and CFD simulations,

All Open Access articles are peer-reviewed, distributed under the Creative Commons Attribution-Non Commercial 4.0 International

which requires expert knowledge and is usually based on the experience of individual company employees. Demographic change and a changing work environment with higher job fluctuation among employees requires knowledge to be documented and formalized [1]. In a recent study by PwC, almost three quarters of all respondents expect personnel costs to rise by 4.7 % in 2026 and see the shortage of skilled workers and increasing cost pressure as obstacles for corporate growth [2].

These challenges can be addressed with an innovation of the development process. So called expert systems can represent complex relationships in an easy-to-use single model. Such a model can calculate the same correlations in a few seconds with the same accuracy. An expert system for valve development could allow the user to define a customer-specific characteristic flow curve, which the system uses to calculate the optimum valve geometry.

To make this step, there is a lack of fast calculating models that can be inverted. Measurements take long but are still the most exact way to determine pressure losses and flow forces. CFD simulations are faster but a little less accurate [3]. Analytical equations are fast to calculate and invertible but not as exact, especially in the determination of flow forces [4].

The solution is a data-based approach, where data is collected and metamodels are trained. As such, CFD simulations should be used as the database, since geometries are easy to manipulate and data is easily gained across a wide range of geometries. When simulating hundreds of different geometries, it is not possible to tune the simulation parameters for each geometry. Thus, generally applicable CFD simulation settings are needed.

This paper presents the selection and validation of generally applicable CFD simulation parameters for 2/2 directional poppet valves with nominal flow rates from 20 l/min to 40 l/min. To determine optimal parameters, at first, previous research about CFD simulations of poppet valves is elucidated and a detailed review of CFD simulation parameters as well as their influence is given. The next chapter outlines the conducted simulations. The selection of points for simulation from continuous measurement data is explained, the preliminary studies on CFD simulation parameters presented and the methodology for the simulation of numerous operating points described. In the last chapter, the simulation results are compared to measurement data, and the accuracy of the simulations is discussed and improved.

2. FUNDAMENTALS

This chapter presents previous research about the CFD simulation of flow forces in poppet valves and gives an overview about the most important CFD simulation parameters and their influence on the simulation model. The focus of the reviewed literature lies on the flow forces and not the pressure difference since it is more challenging to achieve a high accuracy in the CFD simulation of flow forces [3]. The aim is to identify commonly used CFD simulation parameters as a basis for this study. For the flow forces, the convention used is that a positive flow force acts in the closing direction. The detailed definition and an example cross-sectional view of a valve with labelled ports are provided in [5].

2.1. Simulation-based Analysis of Flow Forces in Poppet Valves

The numerical simulation of flows in poppet valves started in the early 90s. Especially in the beginning, the focus was to show that simulated flow patterns equal the flow patterns

from measurements [6]. Recent research focusses on improving the accuracy of CFD simulations by implementing new models (e.g. turbulence or cavitation models) or optimizing components by varying selected geometrical parameters. In the optimization of valves, the pressure drop and the flow induced forces on the poppet are the most relevant quantities. Investigations show that the simulation of the flow forces is more inaccurate than the simulation of the pressure drop [7]. Particularly for the numerical simulation of flow forces, there is no generally valid combination of simulation parameters (e.g. mesh type, mesh size and turbulence model) for accurate results [3]. Zong et al. [8] show that the turbulence model has a strong influence on the results of the simulated flow force while the pressure drop was nearly unchanged. Therefore, the focus of this chapter lies on previous research that simulated flow forces in poppet valves and the employed simulation parameters. Due to large steps in CFD modelling and computing power in the last years, only recent research from 2010 and later is considered. Not all CFD simulation parameters are mentioned in the following brief content description of the papers but summarized afterwards in a table.

Domagala and Fabis-Domagala [9] published a detailed review of research about the CFD simulation of flow forces in both spool and poppet valves. The paper covers the theoretical background of flow forces in valves and of CFD methods as well as numerous publications about steady-state and transient flow simulations. The review results in commonly used assumptions in the CFD simulation of flow forces:

- The fluid is homogeneous, single-phase, incompressible and has constant properties.
- All valve geometries are ideal.
- The roughness of components is neglected, and walls are modelled as smooth.
- Heat transfer and phase changed are neglected.
- The turbulence models used are a standard k-ε or RNG k-ε

Bernad and Susan-Resiga [10] use a 2D CFD simulation to investigate cavitation in a highly simplified seat valve. The fluid is modelled as multi-phase and the main dynamics of the cavitating flow can be mapped. Hao et al. [11] examine three simple cone geometries in a water valve with the aim of reducing flow forces and cavitation in the valve. Steady-state 2D CFD simulations are performed with a two-phase (water and steam) mixture. On the third valve, two housing parameters at the valve outlet are varied individually. By combining the optimal parameters, the flow force is reduced by 44.2 %. Simic and Herakovic [12], [13] optimize the geometry of a normally closed (NC) valve geometry with the aim of reducing flow forces in static operation. The influence of five geometric parameters on the flow forces is investigated by using 3D CFD simulations. For one parameter, additional experiments confirm the accuracy of the CFD simulations with a maximum deviation of 7 %. Xie et al. [14] and Liu et al. [15] investigate basic cone geometries and vary different geometrical parameters in 3D CFD simulations. The method one-factor-at-a-time (OFAT) is used by both authors and the influence of the parameter changes on the flow forces are evaluated.

Rundo and Altare [16] compare two analytical flow force models (Bernoulli and momentum conservation) with stationary CFD simulations. Both flow directions and three poppet angles are considered. In flow direction 1-2, the analytical calculation according to Bernoulli achieves similar results to the CFD simulation, while in direction 2-1, Bernoulli calculates a flow force that is seven times greater. This shows that physical models are not well suited for the analytical calculation of flow forces. Roemer et al. [17] develop their own analytical

model for calculating the forces on the poppet of a fast-acting valve. This model considers flow-induced and motion-induced forces. The parameters for the analytical model are determined using a series of transient CFD simulations, which means that a one-time high simulation effort is required to obtain the analytical model.

Transient CFD simulations are used by Gomez et al. [18] to investigate the dynamics of a commercially available valve. In the simulations, the switching frequencies, inlet pressures and poppet angles of the valve are varied, and the pressure loss and flow force are evaluated. The poppet angle has little effect on pressure loss and mainly affects the flow force. Finesso and Rundo [19] develop a transient simulation of a pressure relief valve to predict the valve characteristics for different geometries and spring settings. The CFD simulation is validated with measurements and shows good agreement. Based on few CFD simulations, a 0D model is tuned and can predict the flow characteristics of the valve. Hirose et al. [20] use transient 3D CFD simulation to investigate the force hysteresis induced by flow patterns on the valve poppet. In preliminary steady-state simulations, the flow patterns described by Johnston et al. [21] are confirmed by simulation. The transient simulations show that the change in flow pattern occurs at different positions when the valve is opened and closed. All CFD simulation parameters mentioned in the presented papers, are summarized in **Table 2.1**. The properties not mentioned are marked with [-].

Table 2.1: Overview of CFD simulation parameters used in previous investigations

Based on the overview in the table it can be said that most of the simulations of poppet valves in the last years were 3D CFD simulations. Depending on the research objective, both steady-state and transient simulations were set up. The most used turbulence model was, as described by [9], some kind of k-ε model. Some publications name the fluid with the operating temperature and the resulting density and viscosity; others name only the density and viscosity or do not name any fluid properties. The discretization schemes used differ between the investigations, but for the momentum the second-order upwind scheme is the most common. The most commonly used simulation environment is Ansys® Fluent® and the mesh type an unstructured tetrahedron-mesh.

2.2. Simulation Parameters and Their Influence

The construction process of a CFD simulation entails a wide range of choices and parameters that require careful consideration and are essential for its success. This section will provide an overview of crucial decisions during the setup process of a typical CFD simulation in Ansys® Fluent®. The general workflow for a CFD simulation first involves the conception of a geometry which is then discretized into a mesh and finally examined by a CFD solver. The geometry is usually created with a CAD software and then imported into the CFD environment. Therefore, the focus of the simulation parameters lies on the mesh and solution settings. Mesh creation and numerical simulation in general is always a balancing act between accuracy and computational cost.

2.2.1. Mesh

Meshes can be categorized into two main mesh types – structured and unstructured meshes. In structured meshes the cell coordinates align with the cartesian coordinates and a cell always has a predefined number of neighbours. The structured grid is limited to simple geometries because both complex walls and tight spaces, that require the use of a finer mesh, would introduce unnecessarily small spacings in other parts of the solution domain in order to maintain the structured nature [22]. Structured meshes also minimize the effects of numerical diffusion when using the first-order upwind scheme for cell discretization, because the second-order derivatives from the Taylor series expansion, that cause numerical diffusion, are ideally one-dimensional when the flow is aligned with the grid [23].

Unstructured meshes are able to fit an arbitrary solution domain and are thus the most flexible of all grid types when it comes to meshing irregular geometries. They are not limited by the number of cell neighbours and allow for all types of cell shapes, including tetrahedrons or polyhedrons in three dimensions. This type of mesh involves a computational overhead during construction due to its arbitrary nature and lack of simple indexing system [24]. It also requires more complex methods for gradient computation as it is not able to rely on cartesian directions and is additionally very vulnerable to numerical diffusion when using first-order upwind schemes for cell discretization [25]. Despite these challenges, unstructured meshes have become increasingly popular and there are several methods to alleviate the drawbacks, as will be elaborated upon in chapter 3.2. Comparing tetrahedron- and polyhedron-meshes, polyhedron-meshes require more computation time during the mesh generation. This overhead is compensated, however, in the total computation time of the solution due to a lower overall cell count [24].

In all cases, when flow becomes oblique to the grid cells or is characterized by high gradients, the solution is prone to discretization errors [22]. Said errors are proportional to the truncation errors from the Taylor series expansion of the used discretization schemes. In the case of this first-order upwind scheme, the leading error term is a second derivative which corresponds to the mathematical description of physical diffusion. The truncation error thus adds a diffusion term to the solution making it overly diffusive. This effect is commonly referred to as numerical or false diffusion. A reduction of the overall spatial discretization error can be achieved by reducing the cell size or by the choice of the discretization scheme. Important differences are between the first- and second-order upwind scheme, because the first-order scheme introduces numerical diffusion effects, as previously explained, whilst the latter alleviates these effects by eliminating the second derivative in the truncation error [25].

Furthermore, it is important to appreciate that over-refining the mesh across the entire solution domain does not necessarily improve the overall results. Convergence of the solution depends on the residuals of the discretized conservation equations throughout the entire domain. When determining the appropriate mesh size and refinement regions, it is thus important to attempt a balance in the discretization error across the entire domain, namely a similar residual in all domain parts [22].

Finally, the design of a meaningful mesh requires the consideration of near-wall effects, in particular the adequate resolution of the viscous sublayer and buffer layer. To achieve this, meshes are typically either equipped with boundary-layer elements or with wall functions. Boundary layers essentially provide fine resolution in the wall-normal direction. In this way, near-wall effects can be represented accurately with only a modest increase in computational cost. Wall functions are semi-empirical formulas that interpolate the viscous sublayer and buffer layer, omitting the necessity of a complete resolution of the near-wall region [25].

2.2.2. Solution

This section focusses on the interpretation of the mesh in terms of discretized conservation equations and also endeavour to elucidate relevant decisions during turbulence modelling. Before beginning any type of solution, it should first be examined what kind of characteristics the flow is expected to have; strictly laminar or turbulent. If the flow is strictly laminar, the underlying conservation-equations are usually solved using any type of numerical solver. If the flow is presumed to assume turbulent characteristics at some point in the domain, the solution complexity increases drastically. The numerical examination of turbulent flow can generally be categorized into three types of simulation: the direct numerical simulation (DNS), the large-eddy simulation (LES) and the Reynolds-averaged Navier-Stokes (RANS)-approach [22].

The DNS is the most exact approach for turbulent simulations but entails significant computational cost. LES is a compromise between computational cost and accuracy. It is usually used in cases where the DNS is too computationally expensive like in high-Reynolds flows or for complex geometries. The RANS-approach is the least computationally expensive and entails the replacement of flow variables in the conventional Navier-Stokes equations by quantities that underwent Reynolds-averaging, namely the separation of flow variables into an averaged and a fluctuating quantity. During this averaging process an additional unknown quantity emerges called the Reynolds stress tensor (RST). This tensor can be approximated with the help of the turbulent kinetic viscosity which, in return, is then modelled with additional equations [22].

Said modelling can be implemented in the form of zero-, one- or even six-equation models, the most common, however, being the two-equation model. In the realm of two-equation-models, the most prominent are the k-ε and the k-ω models. Both cases institute two transport equations, one for the turbulent kinetic energy k and one for either the dissipation rate of k, namely ε, or the specific dissipation rate of k, namely $\omega = \varepsilon/k$. The k-ε is very popular in general industrial CFD applications because it provides reasonable accuracy for a wide range of simulation problems. However, it is not integrable through the viscous sublayer without the addition of further equations, limiting its accuracy in the prediction of near-wall phenomena. The k-ω model addresses this limitation and is conceived in a way that allows it to adequately predict the viscous sublayer, making it the better choice for simulations involving extensive wall-modelling [25].

3. CFD SIMULATIONS

The CFD simulation parameters should be validated based on the measurements of 9 poppet valves. Due to the measurement procedure with a moving poppet, required to capture the flow forces, the measurement data is continuous [5]. At first, this chapter shows how discrete points for CFD simulation are extracted from the continuous measurement data. Since generally applicable CFD simulation settings are needed, preliminary studies are conducted to determine most of the CFD simulation parameters. Finally, the methodology and procedure for the batch simulation of different valve geometries with different opening widths and boundary conditions are described briefly.

3.1. Determining the Point of Operation

The simulated points of operation should be as close as possible to the real point of operation. How the point of operation is determined, differs between NO und NC valves. For NO valves, the actual operating point can be easily read from the measurement data. It is the point at which the rod of the valve actuation and force measurement system lifts off the poppet. At this position, there is a balance of forces at the poppet between the flow force acting in the closing direction and the spring force acting in the opening direction. The measurements in [5] were conducted with different tank pressures and pressure differences over the valve.

Figure 3.1 shows the poppet position x, the flow rate Q and the measured force F plotted over time t for one cycle of a NO valve. The actual operating point is located at the position where these variables begin to change with the poppet position, since this is the point where the rod of the through-drive starts touching the poppet. From this point on, the measured position also corresponds to the poppet position.

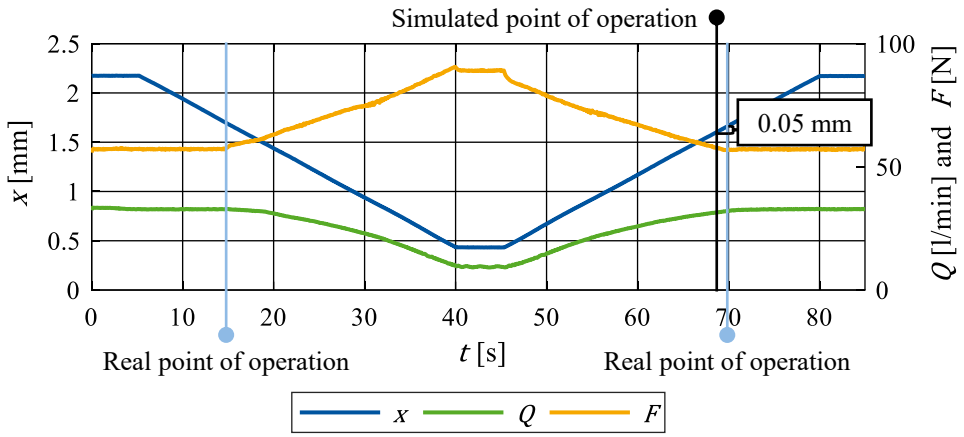

Figure 3.1: Position, force and flow rate curve from a NO valve, flow direction 1-2, tank pressure 30 bar, pressure difference 15 bar

The flow forces should be evaluated during movement, as there is no static friction in this case and the flow force can be calculated from the measurements with and without flow. For this reason, the point 0.05 mm away from the actual operating point is used for the CFD simulation. The actual operating point occurs once during both the closing and opening of the valve. For the simulation, the point at which the actuator extends is used, as there is less possibility of the rod tilting during the extension movement.

For NC valves, it is not possible to determine the actual operating point without further effort. The real operating point is established through a balance of forces between the flow force, spring force and actuator force. The force of the actual solenoid is position-dependent and unknown. For this reason, the actual operating point cannot be read from the measurements and must be assumed. The measurements of all NC valves show a buckle in the flow rate and force curve. This buckle occurs at the point where the valve is opened so far that the smallest cross-section is no longer at the sealing edge. It is assumed that the valves are designed so that point of operation is close to this point where the flow is stable and the flow rate reaches its maximum. This buckle lies at approximately 90 % of the maximum flow rate for all valves, which is why this point is used for simulation.

For validation, all cycles with a tank pressure of 30 bar are used. For nine valves, this results in 164 points that have to be simulated. Once the poppet positions of the operating points to be simulated have been determined, all other required values can be evaluated at these points. These are the flow rate, the flow force as well as the pressures and temperatures upstream and downstream of the test valve. For these variables, an average is calculated for each value using the 50 surrounding values.

3.2. Preliminary Studies

This section details the process and the choices that were made to establish the settings for the geometry, the mesh and the solution which are used for the simulations carried out in this paper. For all simulations Ansys® Fluent® and Fluent® Meshing were used.

3.2.1. Geometry

The simulated geometries belong to industrial poppet valves and were used in their original shape. During the preliminary studies, one geometric variation was tested for their impact on the simulation results. The variation was an extension of the in- and outlet of the manifold by an 80 mm pipe to ensure fully developed flow at the in- and outlet. The pipe influences both the pressure drop and the flow force on the valve. None of the results were implausible so that this variation is to be further investigated based on measurement data.

3.2.2. Mesh

Considering the vast number of simulations that should be conducted, the difference between polyhedron- and tetrahedron-meshes in terms of cell count is significant, facilitating the decision to use polyhedron-meshes. As mentioned in section 2.2.1, unstructured polyhedron-meshes are excessively vulnerable to numerical diffusion for first-order upwind schemes. However, the problem of numerical diffusion is a phenomenon that is limited to first-order upwind discretization schemes. Fluent® uses the second-order upwind scheme as the default discretization for convection terms. Higher order schemes were also tested but did not yield any noticeable effect in the simulation results. In summary, the unstructured polyhedron-mesh with second-order upwind discretization schemes proved to be the best fit for the underlying simulation task. This was also validated by measurements.

The choice of mesh size was an iterative process to find an optimum between desired accuracy and simulation time. A refinement region was placed around a reasonable radius of the poppet, separating the fluid domains with pipe flow and those with, partially turbulent, narrow gap flow. In the next step, both the reference cell size across the entire domain and the refinement factor of the refinement region were iteratively decreased, and increased respectively, until the accuracy of the simulation did not further improve. Said investigations

culminated in the establishment of a reference cell size of maximum 0.3 mm and minimum 0.005 mm. The chosen refinement was the factor two. This setup resulted in an average of around 10 million or less cells per simulation.

Another important manipulation of the mesh includes the definition of boundary layers. As mentioned in section 2.2.1, boundary layers are especially crucial for turbulent flows. Ten boundary layers with a growth rate of 1.2 and an aspect ratio of 15 are selected. The first simulations with and without boundary layers showed differences in pressure difference and flow force. In addition, boundary layers increase the number of cells, so the use of boundary layers is to be further investigated based on measurement data.

3.2.3. Solution

The main decision that was to be made in the solution process is the choice of turbulence modeling. An extensive analysis of the Reynolds number across the solution domain yielded the insight that turbulent flow was only present in narrow gaps at high flow rates. Due to the lowest computational costs, RANS simulations were chosen. As mentioned in section 2.2.2 for the turbulence model, the k-ω model is dominant in including near-wall effects. Especially in light of the fact, that boundary layers would not be included in every mesh, it was of vital importance that the turbulence model is able to accurately model near-wall effects in the narrow regions of the fluid domain. For this reason, the widely used k-ω SST (shear stress transport) turbulence model is employed. The alternative of wall functions was also tested by activating the tabulated choice in the near-wall treatment section of Fluent® Setup, however this did not affect the results in a meaningful way.

In the final step of the preliminary investigations, the boundary conditions were examined. Both a flow rate and a pressure boundary condition can be used at the inlet. The investigations showed that the simulations with the flow rate boundary condition converge more quickly, while the pressure boundary condition leads to slight oscillations in the solution. For this reason, the flow rate boundary condition is selected at the inlet. A pressure boundary condition is used at the outlet. A pressure of 500 bar is specified so that positive pressures are always present throughout the solution area during the calculation, and the solution can be calculated more stably. The solver is pressure-based, and all calculations are caried out as steady-state simulations. As convergence criteria, a residual of 0.0005 was used for the outlet flow rate, the pressure difference between inlet and outlet, and the axial flow force acting on the poppet. All CFD simulation parameters specified in the preliminary investigations are summarised in **Table 3.1**. The parameters that are examined in detail in chapter 4 are shown in italics.

Parameter	**Selection**
Simulation environment	Ansys® Fluent®
Mesh type and form	Unstructured polyhedron-mesh
Discretization scheme	Second-order upwind scheme (pressure / momentum / turbulent kinetic energy / specific dissipation rate)
Mesh size	Maximum 0.3 mm; Minimum 0.005 mm
Mesh refinement	In the area of turbulent flow around the poppet with a factor of 2
Type of simulation	RANS
Turbulence model	k-ω SST
Boundary conditions	Inlet: flow rate; Outlet: Pressure 500 bar
Solver	Pressure-based, steady-state
Convergence criteria	Residual of 0.0005 for outlet flow rate, pressure difference, poppet flow force

Boundary layers	*With and without boundary layers, count 10, growth rate 1.2, aspect ratio 15*
Inlet and outlet	*With and without 80 mm pipe*

Table 3.1: Preselected simulation parameters for all simulations

3.3. Methodology and Procedure

This chapter gives a brief overview of the workflow used for the CFD simulations of nine different valve geometries with varying opening widths and boundary conditions. The goal of the simulations is the computation of the pressure loss over the valve and the flow force in axial direction on the poppet. These two quantities are used to validate the CFD simulations with measurement data.

The CAD files for all valves were either provided by the manufacturer or self-created, based on precise measurements. Acute angles in the geometry are to be avoided for a good mesh. Therefore, the geometries were adapted if required. To make the simulations as comparable as possible, the valves are screwed in the manifold with the angle recorded during the measurements [5]. This CAD model is imported to Ansys® with the opening width of the poppet set as a variable. Based on this model, the volume fill is created. The filled area is meshed with the parameters named in Table 3.1.

The CFD simulation uses the poppet position, flow rate and temperatures from the measurements. Before the meshing, the poppet is positioned according to the measured value, and the flow rate is used as an input boundary condition. An ideal Fuchs RENOLIN B 15 VG 46 oil with constant density and viscosity is used in the simulations. The two fluid parameters are determined in advance by a calculation depending on the temperature, and the fluid is modelled as single-phase without cavitation. The temperature used for the calculation is the average of the temperature measured before and after the test valve. After setting the remaining simulation parameters, a so called case-file is exported from Fluent®. The case-file contains the information about the geometry, mesh and all simulation parameters. This file was used to execute the simulations on the High-Performance Computing (HPC) cluster of RWTH Aachen University.

4. RESULTS AND DISCUSSION

A total of 164 points from the measurements of all valves are available for validating the CFD simulations. 86 of these points belong to flow direction 1-2 and 78 to the opposite direction. The 164 points are simulated with four different meshes, but otherwise with the same settings. In the first variant, the geometries are meshed between the male stud connectors using the parameters specified in the preliminary investigations (Table 3.1). In the second variant, an 80 mm inlet and outlet pipe is attached to each of the geometries at the male stud connectors. In variants three and four, the first two variants are each meshed with boundary layers. The parameters listed in Table 3.1 are used for the boundary layers.

In the following, the accuracy of the four different simulation setups will be compared to the measurements. The comparison is carried out individually for the pressure difference Δp and the flow force F_{flow}. Starting with the pressure difference, for a first overview, the simulated values were plotted over the measured values. For both flow directions, the values were evenly distributed around the ideal line and deviate more strongly from the ideal line as the pressure difference increases. A few points in flow direction 2-1 were an exception and had a larger deviation than the rest. These values all came from simulations with boundary layers. A closer look at the points revealed that they all belong to one NC valve. When

examining the mesh at this valve, it was found that it has a height of 0.55 mm at the smallest cross-section and that there is only one cell layer between the boundary layers. The lack of an adequate volume mesh between the boundary layers of opposite walls leads to increased deviations. Consequently, there is a systematic error in these simulations. However, all other points indicate that the simulations of the pressure differences are correct and that there is no fundamental error.

To identify which mesh provides the most accurate results, the relative deviation is calculated for each point with **equation 4.1**.

$$relative\ deviation = \left|\frac{simulation - measurement}{measurement}\right| \tag{4.1}$$

The results are illustrated in boxplots in **Figure 4.1**. The boxes mark the range from the lower to the upper quartile. 25 % of all values are below the lower quartile and 25 % of all values are above the upper quartile. The solid line within the box marks the median and the cross marks the mean. All values that are more than 1.5 times of the interquartile range (distance from the upper to the lower quartile) away from the upper or lower quartile are considered outliers. Within the remaining values, the whiskers mark the maximum and minimum values. In flow direction 2-1, the models without boundary layers are the most accurate.

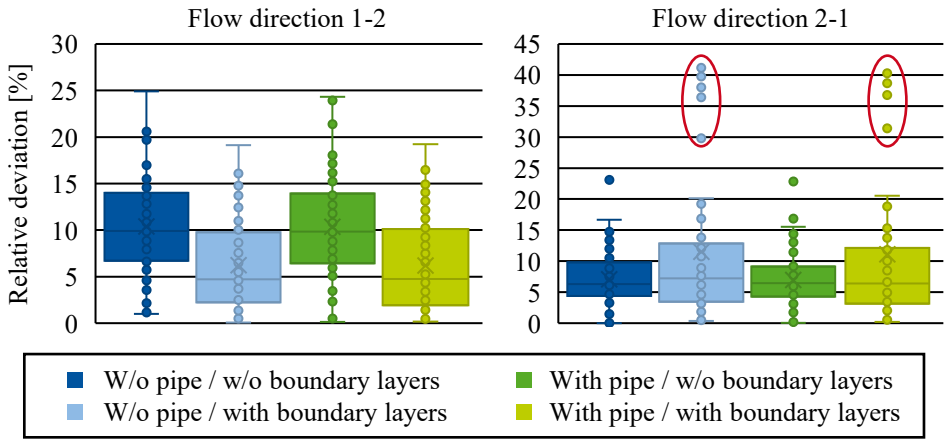

Figure 4.1: Relative deviation of simulated to measured pressure differences for four different meshes in flow direction 1-2 (left) and flow direction 2-1 (right)

The upper quartiles are each below 10 % deviation and the medians are around 6.3 %. The outliers in the models with boundary layers are the same points from the one NC valve already mentioned before. In flow direction 1-2, the simulations with boundary layers are the most accurate. Here, the upper quartiles are approximately 10 % and the medians 4.7 %. In both flow directions, the meshes with and without pipes achieve similar accuracies. In this case, the simulations without pipes are preferable because the mesh is smaller and therefore shorter computing times are possible. The biggest differences are in the simulations with and without boundary layers.

Regarding the accuracy in flow force simulation, **Figure 4.2** shows the simulated flow force plotted over the measured flow force. In contrast to the pressure difference, also negative

values are possible for the flow force. The measured values deviate from the ideal line by a similar amount across the entire range and do not converge in a funnel shape. In addition, there is a particularly large number of points at which a flow force close to 0 N was measured, while the simulation yields a larger or smaller value. This occurs in both flow directions, and the areas close to the measured 0 N are marked in red in both diagrams. When calculating the relative values, high percentage deviations would occur at these points, which would reduce the significance of the percentage deviation. For this reason, all points with a measured absolute force of less than 3 N are excluded from the calculation of the relative deviations. One notable feature is the points in flow direction 1-2, which deviate more strongly from the ideal line than the rest. These are also outlined in red and, after verification, could be assigned to the NC valve.

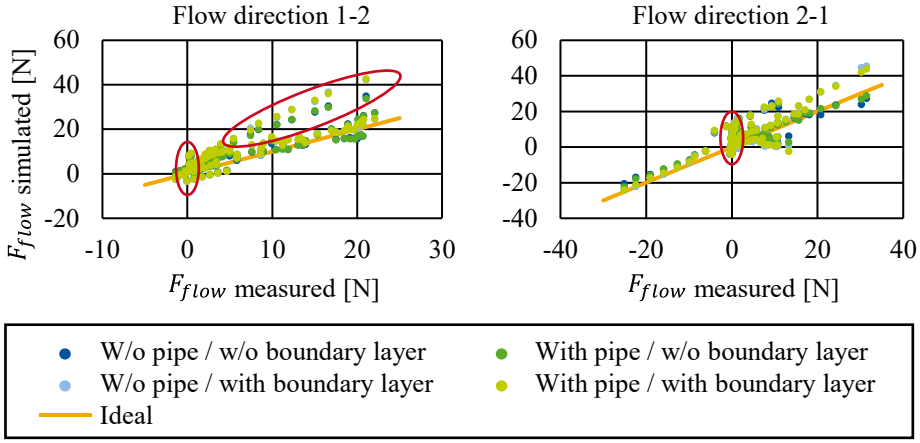

Figure 4.2: Simulated flow force over measured flow force for four different meshes in flow direction 1-2 (left) and flow direction 2-1 (right)

The relative deviation of the flow forces is shown in boxplots in **Figure 4.3**. As already described, all values for which the measured force was less than 3 N are excluded.

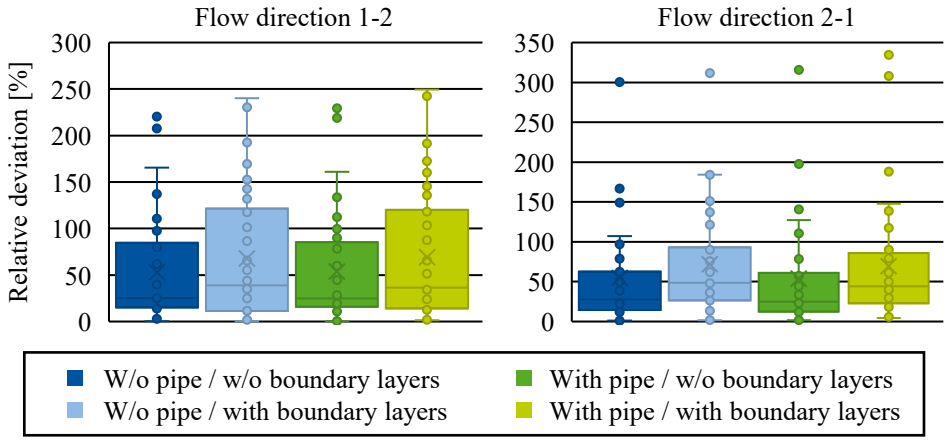

Figure 4.3: Relative deviation of simulated to measured flow forces for four different meshes in flow direction 1-2 (left) and flow direction 2-1 (right)

In flow direction 1-2, 50 of the initial 86 points are still used for the evaluation, and in flow direction 2-1, 44 of the 78 points are still used. The figure shows that the relative deviations in the flow force simulation are significantly greater than in the pressure differences. In both flow directions, the simulations without boundary layers are the most accurate. For these meshes, the upper quartile in flow direction 1-2 is approximately 85 % and the median is approximately 25 %. In the opposite direction, the simulations are more accurate, with the upper quartile at approximately 60 % and the median also at approximately 25 %. This raises the question whether the accuracy of the flow force simulation is sufficient. To clarify this, it is examined which relative deviations occur at which flow forces. It was found that from a measured flow force of 15 N, the relative deviation at each point is less than 26.6 %. High flow forces can therefore be reliably predicted by the simulations.

In summary, in three out of four cases, the mesh without boundary layers was the most accurate. In the case of the pressure difference in direction 1-2, the meshes with boundary layers are more accurate, but the meshes without boundary layers still deliver very good results with an upper quartile of approximately 13 %. For these reasons, a mesh without boundary layers is selected. There are marginal differences between the meshes with and without pipes. Since the mesh without pipes is smaller and the simulations therefore have a shorter calculation time, the mesh without pipes and without boundary layers is ultimately selected for the following simulations which create the database for the prediction models.

Deviations of around 10 % between a CFD simulation and measurements of the real system are currently state of the art in the CFD simulation of pressure differences. This is achieved by the conducted simulations. The accomplished deviations are greater for the flow force, which is why the reason for the deviations should be investigated and discussed at this point.

The first suspicion was a numerical error in the flow force calculation due to different mesh sizes on the poppet surface. For this reason, the poppet geometry and the zone of the mesh refinement were adjusted. Before the adjustment, small shoulders on the poppet led to a locally finer mesh on the surface of the poppet in the pressure compensation area. In addition, the zone of the mesh refinement ended in the pressure compensation bore. During the adjustment, the shoulders were removed in the CAD model and the refinement zone extended, resulting in a mesh with equal size around the poppet.

These changes lead to better matching flow forces, but it is noticeable that the simulations calculate higher values, especially around the range of 0 N measured flow force (Figure 4.2). For this reason, simulations were specifically carried out in which the expected flow force is close to 0 N. This is the case with a low flow rate, which is why all valves were simulated with flow rates from 1 l/min to 5 l/min in 1 l/min increments. The poppet position used was the position that was also used in the simulation with the lowest pressure difference. For two valves, the results show constant flow forces between 6 N and 10 N for these flow rates. These results are implausible and a systematic error in the simulation must be assumed.

Upon closer inspection of the CAD models of the valves, it was noticed that in both models, the manufacturer had also depicted the fits, resulting in clearance between the poppet and the sleeve and thus a gap. This gap was removed for the CFD simulation. To do this, the diameter of the poppet was increased by 0.1 mm so that the poppet and the sleeve overlap. The overlap means that the pressure compensation no longer works, and the poppet is no longer free of forces under static pressure. This problem was solved by matching the poppet diameter with the diameter of the hole in the sleeve exactly.

Another possible reason for the larger percentage deviations in the simulation of the flow forces may be the hysteresis in the flow force [5] in some valves. Previously, the value at the simulated operating point was used as the measured value for comparison. The force hysteresis was not considered. In the following, force hysteresis is taken into account by calculating the mean value of the flow forces between the closing and opening movements and using this as the comparison value.

Overall, the mean average error (MAE) and the mean average percentage error (MAPE) are used to present the final accuracy of the CFD simulation with all the discussed improvements. The two characteristic values are listed for each valve type and flow direction for the pressure difference and flow force in **Table 4.1**. The MAE in the simulation of the pressure difference is between 0.7 bar and 1.7 bar, depending on the valve type and flow direction. This corresponds to average percentage errors of 5.5 % to 11.1 %. The accuracies achieved are mostly below this value and, in the case of NC valves in flow direction 1-2, just above it. When simulating the flow forces, there are greater deviations from the measured values. The average deviation is between 2.8 N and 3.6 N. In percentage terms, this results in a deviation of between 36.6 % and 67.3 %. Bordovsky [7] obtains a $MAPE$ of 32 % with a simulation optimized for one valve. So, the $MAPE$ achieved with general simulation settings applied on nine different geometries can be rated as good. Despite the higher deviations, the trends in the flow force simulation are correct. This means that values in this accuracy range are also suitable for setting up a prediction model.

Δp	NO 1-2	NO 2-1	NC 1-2	NC 2-1	F_{flow}	NO 1-2	NO 2-1	NC 1-2	NC 2-1
MAE [bar]	1.1	0.7	1.7	0.7	MAE [N]	3.5	3.4	2.8	3.6
$MAPE$ [%]	8.8	6	11.1	5.5	$MAPE$ [%]	38.4	58.3	67.3	36.6

Table 4.1: MAE and $MAPE$ of simulated to measured values of pressure difference and flow force divided according to valve type and flow direction

In summary, it can be said that CFD simulations have potential as a database for prediction models. The achieved accuracies are satisfactory. For an individual valve, the simulation parameters could be further improved. Since the results originate from nine different valves, the CFD simulation parameters for the various geometries of this type and size of 2/2 directional poppet valves are validated. It can be assumed that simulations of other geometries using the same CFD simulation parameters will achieve similar accuracies.

5. CONCLUSION AND OUTLOOK

In this paper generally applicable CFD simulation parameters for 2/2 directional poppet valves were acquired. In extensive preliminary investigations, several simulation parameters, such as a polyhedron-mesh with a maximum size of 0.3 mm, were selected. An overall number of 164 points, generated from measurement data, were simulated with four different meshes. The mesh without an additional pipe and without boundary layers turned out to be the best compromise between accuracy and computing efficiency. The simulation of the pressure difference has a mean deviation of 7.9 % to measured data. The flow force simulation has a mean deviation of 50.2 %, but the trends in the flow force simulation are correct. This makes CFD simulations with the presented parameters suitable as a database for pressure drop and flow force prediction models of 2/2 directional poppet valves. The CFD simulations are particularly reliable for the pressure drop and for flow forces above 15 N. In future work, the determined simulation parameters can be applied to a variety of

geometries and thus create a database for prediction models of 2/2 directional poppet valves. Before using the determined parameters in CFD simulations of other valves, the parameters must be validated separately.

6. ACKNOWLEDGEMENTS

The IGF research project 01IF22852N of the research association Forschungskuratorium Maschinenbau e. V. – FKM, Lyoner Straße 18, 60528 Frankfurt am Main was supported from the budget of the Federal Ministry of Economic Affairs and Climate Action through the DLR within the scope of a program to support industrial community research and development (IGF) based on a decision of the German Bundestag.

Computations were performed with computing resources granted by RWTH Aachen University under project rwth1768.

Experimental Comparison of Polymer and Non-Ferrous Metal Slippers for Oil-Hydraulic Axial Piston Machines

Felix Schlegel*,[1], Katharina Schmitz[1]

*[1] institute for fluid power drives and systems, RWTH Aachen, Campus Boulevard 30, 52074 Aachen; *corresponding author: felix.schlegel@ifas.rwth-aachen.de,*

Abstract.

In many hydraulic machines, particularly axial piston units, tribological contacts commonly rely on leaded non-ferrous metal alloys. Increasing legislative restrictions, accelerated oil-aging and copper-corrosion are motivating the search for alternatives. This study demonstrates, using single-piston test rig experiments, that carbon-fiber-reinforced PEEK can replace copper-alloys in the slipper–swashplate contact. It is shown, that polymer slippers show only about 1.3 % lower efficiency than a non-ferrous metal reference but exhibit reduced friction in the mixed lubrication regime. Wear is slightly higher yet remains within the same order of magnitude ($\approx 10^{-10}$ mm³/Nm), indicating suitability for long-term operation. Wear mechanisms were analyzed using scanning electron microscopy and energy-dispersive X-ray spectroscopy. The results also reveal that polymer deformation significantly influences the effective hydrostatic relief. Variations of several percent with pressure and speed must be considered in polymer slipper design to ensure functional stability.

1. INTRODUCTION AND STATE OF THE ART

Hydraulic drive systems are widely employed in mobile, industrial, and aerospace applications due to their high power density, controllability, and efficiency. They operate by converting mechanical into hydraulic energy and vice versa, enabling the transmission of large forces and torques within compact systems. Among hydraulic units, axial piston machines (APMs) are the most prevalent design, capable of functioning as both pumps and motors.

The structure of the most common APM type, the swashplate machine is shown in Fig. 1. In pump mode, the drive motor rotates the shaft and cylinder block, moving the pistons, which are pushed outward by the chamber pressure. The inclined swashplate converts this rotation into a reciprocating motion so that fluid is drawn in during the outward stroke and discharged during the return stroke. The stationary valve plate directs the flow to the high-pressure (HP) line during delivery and to the low-pressure (LP) line during suction. In motor mode, the principle reverses when the swashplate is tilted beyond zero in the opposite direction, causing the pistons to be driven outward by pressurized fluid and retracted as the fluid expands. The high hydrostatic forces on the pistons are supported by slippers. Together, the

All Open Access articles are peer-reviewed, distributed under the Creative Commons Attribution-Non Commercial 4.0 International

piston–bushing, cylinder block–valve plate and slipper–swashplate interface form the three main tribological contacts determining machine efficiency and lifetime. [X]

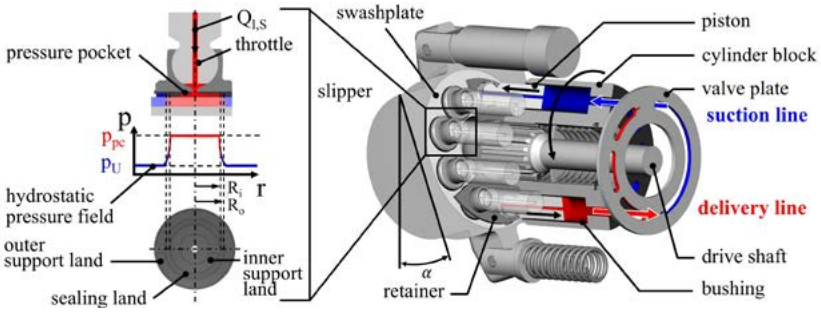

Figure 1.1: Structure of a swashplate type axial piston machine

To enable slippers to follow the swashplate with six degrees of freedom, they are connected to the pistons via spherical joints. This results in complex micro-motions influenced by frictional, centrifugal, and flow forces. This joint may be located on the piston (conventional) or on the slipper (inverse), with the latter allowing larger swashplate angles but leading to less favourable deformation. Because of the high normal loads and the need for operation at low speeds, the slipper–swashplate contact cannot rely solely on hydrodynamic lubrication. A small leakage volume flow from the displacement chambers is routed through bores in piston and slipper to form a hydrostatic pressure field beneath the running surface. There, the un-slitted sealing land defines the hydrostatic pressure drop, achieving 92–105 % load compensation [1, 2]. This hydrostatic relief represents a balance between leakage and friction reduction. Excessive relief may cause lift-off, resulting in leakage, high tilting induced wear or malfunction, which can be prevented by a retainer or, where feasible, an integrated limiting-orifice restricting flow. However, the latter cannot be implemented in all slipper geometries due to manufacturing constraints. Usually, slotted support lands increase slipper stiffness, promote hydrodynamic lift, and reduce local contact pressure. Mechanical slipper failures include joint or neck fracture, whereas tribological failure occurs when wear degrades sealing or alters hydrostatic balance, leading to loss of function.

Afterwards, Sec. 1.1 outlines the calculation of hydrostatic relief, efficiency, and wear of slippers, followed by material selection and the state of research on polymer slippers in Sec. 1.2. The experimental setup and test specimens are described in Sec. 2.1 and 2.2, and the experimental results are presented in Sec 3. Sec 4 provides a critical discussion, followed by Sec 5 concluding with a summary and outlook.

1.1. CALCULATION OF SLIPPERS

This section introduces only the equations required to interpret the results in Sec. 3, details in slipper dynamics are provided in [1]. In general, the hydrostatic pressure field $p(r)$ of a slipper can be described as a potential field along the sealing land radius r with the boundary pressures (pocket p_i, ambient p_a) and the gap height profile $h(r)$, as shown in Eq. (1.1).

$$p(r) = p_i - (p_i - p_a) \cdot \int_{R_i}^{r} \frac{1}{r \cdot h(r)^3} dr \cdot \left(\int_{R_i}^{R_o} \frac{1}{r \cdot h(r)^3} dr \right)^{-1} \tag{1.1}$$

This yields the leakage flow through the annular gap Q as a function of viscosity η and the

sealing land geometry defined by inner radius R_i and outer radius R_o (Eq. (1.2)).

$$Q = \frac{\pi}{12\,\eta}\left(\int_{R_i}^{R_o} \frac{1}{r \cdot h(r)^3}\,dr\right)^{-1} (p_i - p_a) \tag{1.2}$$

The hydrostatic force F_S reducing the slipper normal force F_N is obtained by integrating the pocket pressure profile and the sealing land pressure profile, as shown in Eq. (1.3).

$$F_S = \int_0^{Ro} 2\,\pi\,r\,p(r)dr = \underbrace{\int_0^{Ri} 2\,\pi\,r\,p_i\,dr}_{\text{pocket pressure}} + \underbrace{\int_{Ri}^{Ro} 2\,\pi\,r\,p(r)\,dr}_{\text{sealing land}} \tag{1.3}$$

According to Manring [1], this yields Eq. (1.4), and Eq. (1.5) for an even parallel gap.

$$F_{S,even} = p_i\,\frac{\pi(R_o^2 - R_i^2)}{2\ln(R_o/R_i)} \tag{1.4}$$

$$Q_{even} = \frac{\pi}{6\,\eta}\,\frac{h_G^3}{ln(R_o/R_i)}\,p_i \tag{1.5}$$

Based on this, the static degree of hydrostatic relief B_S can be defined with Eq. (1.6) [1] using the piston force loading the slipper F_P and the swashplate angle α.

$$B_S = F_S \cdot F_P^{-1} \cdot \cos(\alpha) \tag{1.6}$$

Beyond this simple approximation, a logarithmic (Eq. (1.7)) and two polynomial gap profiles of third (Eq. (1.8)) and fifth order (Eq. (1.9)) were studied, representing simulated deformed gaps [3]. The minimum gap height h_o is defined at R_o, and the maximum height h_i at R_i results from deformation (Eq. (1.10)). The scaling factor k (Eq. (1.11)) describes the latter as a function of socket height $H_{S,1}$, layer height $H_{S,2}$, and the young's moduli of socket E_1 and layer E_2. Eqs. 1 and 2 were solved analytically with Eq. (1.7), while Eqs. (1.8) and (1.9) were integrated numerically.

$$h(r) = h_a + \frac{p_i \cdot H_S}{E} \cdot \frac{ln(R_a/r)}{ln(R_a/R_i)} = h_a + k \cdot \frac{ln(R_a/r)}{ln(R_a/R_i)} \tag{1.7}$$

$$h(r) = h_a + k \cdot (8.75\,x^3 - 15.3\,x^2 + 7.12\,x) \tag{1.8}$$

$$h(r) = h_a + k \cdot (3.77\,x^5 - 18.23\,x^4 + 30.32\,x^3 - 20.24\,x^2 + 3.83\,x + 0.78) \tag{1.9}$$

$$h_i = h_a + k \tag{1.10}$$

$$k = p_i \cdot \left(\frac{H_{S,1}}{E_1} + \frac{H_{S,2}}{E_2}\right) \tag{1.11}$$

$$x = \frac{r - R_i}{R_o - R_i} \tag{1.12}$$

Due to hydrostatic relief, the frictional coefficient μ of a slipper (CoF) cannot be determined from the ratio of friction F_R to normal force F_N (Eq. (1.13)). Instead, the degree of relief must be considered (Eq. (1.14), [1]), making the calculated friction coefficient dependent on the gap-height profile. All CoFs shown below refer to the definition of Eq. 14.

$$\mu = \frac{F_R}{F_N} \tag{1.13}$$

$$\mu_S = \frac{F_R}{F_N \cdot (1 - B_S)} \tag{1.14}$$

As slipper design involves a trade-off between friction, leakage, and wear due to hydrostatic relief, it is not useful to compare slippers solely by CoF. For consistent comparison, friction and leakage are evaluated jointly by introducing a slipper efficiency η_{total} (Eq. (1.15), [1]), analogous to APMs, combining hydromechanical η_{hm} and volumetric efficiency η_{vol}.

$$\eta_{total} = \eta_{hm} \cdot \eta_{vol} \tag{1.15}$$

The efficiency definitions applied here differ from those of APMs, as only a single tribological contact is considered. In multi-stage tribosystems, efficiency is defined in series ($\eta_{serial,i}$, Eq. (1.16)), requiring knowledge of both stage losses $P_{loss,i}$ and stage output power $P_{out,i}$. The latter differs from the total machine output power P_{out}, which is reduced by the losses of all stages. As the slipper is isolated here, neither the total input power nor the losses of other stages (e.g., valve plate or piston) are known, rendering this definition inapplicable. Instead, a relative efficiency $\eta_{rel,i}$ is introduced (Eq. (1.17)), referencing stage losses to the total machine output power and thus slightly overestimating efficiency.

$$\eta_{total} = \prod_{i=1}^{n} \eta_{serial,i} = \prod_{i=1}^{n} \frac{P_{out,i}}{P_{in,i}} = \prod_{i=1}^{n} \frac{P_{out,i}}{P_{out,i} + P_{loss,i}} \tag{1.16}$$

$$with: P_{out,i+1} = P_{out,i} - P_{loss,i+1}$$

$$\eta_{rel,i} = \frac{P_{out}}{P_{out} + P_{loss,i}} \quad with: \eta_{total} \leq \prod_{i=1}^{n} \eta_{rel,i} \tag{1.17}$$

The difference between $\eta_{serial,i}$ and $\eta_{rel,i}$ varies with the stage under consideration. For n identical partial losses, the maximum absolute deviation can be expressed by Eq. (1.18).

$$\Delta\eta_{max}(\eta_{total}) = \eta_{total} - \left(1 + \frac{1}{n}\left(\frac{1}{\eta_{total}} - 1\right)\right)^{-n} \tag{1.18}$$

Pump losses are assumed to be evenly distributed among four tribo-contacts here: slipper–swashplate, piston–cylinder, valve plate–cylinder block, and auxiliary components such as bearings. For total pump efficiencies of 95 %, 90 %, and 85 %, the maximum deviation between relative and serial slipper efficiency amounts to +0.00094 %, +0.0038 %, and +0.0086 %, respectively. This difference is therefore regarded as negligible.

The calculation of individual efficiencies in an APM differs depending on whether it operates in pump or motor mode. In pump mode, η_{hm} is derived from the theoretical drive torque $M_{th,p}$ (Eq. (1.19), [1]), while in motor mode it is based on the effective output torque $M_{th,m}$ (Eq. (1.20), [1]). In pump mode η_{vol} is determined from the effective discharge flow $Q_{th,p}$ (Eq. (1.21), [1]) and in motor operation from the theoretical intake flow $Q_{th,m}$ (Eq. (1.22), [1]). Here, M_l is the friction loss torque and Q_l the hydrostatic leakage flow.

$$\eta_{hm,p} = \frac{M_{th,p}}{M_{th,p} + M_l} \tag{1.19}$$

$$\eta_{hm,m} = \frac{M_{th,m} - M_l}{M_{th,m}} \tag{1.20}$$

$$\eta_{Q,p} = \frac{Q_{th,p} - Q_l}{Q_{th,p}} \tag{1.21}$$

$$\eta_{Q,m} = \frac{Q_{th,m}}{Q_{th,m} + Q_l} \tag{1.22}$$

In both operating modes, M_{th} and Q_{th} are expressed by Eqs. (1.23) [1] and (1.24) [1], based on the pressure difference Δp, displacement volume V, and rotational speed n.

$$M_{th} = \frac{\Delta p \cdot V}{2\,\pi} \tag{1.23}$$

$$Q_{th} = n \cdot V \tag{1.24}$$

In an APM, slipper losses vary with the rotational angle due to kinematics and commutation. In this study, they are derived from measurement data using Eqs. (1.25) and (1.26), assuming that half of the j slippers operate at low pressure (p_{LP}) and the other half at high pressure (p_{HP}) along the path radius R. The low-pressure level is set to 50 bar, as measurements below this value show reduced quality with the existing test setup.

$$M_l(n,p) = \sum_{j=1}^{k} R \cdot F_{R,j}(n,p_j) = \frac{j}{2} \cdot R \cdot F_R(n,p_{LP}) + \frac{j}{2} \cdot R \cdot F_R(n,p_{HP}) \tag{1.25}$$

$$Q_l(n,p) = \sum_{j=1}^{k} Q_{l,S,j} = \frac{j}{2} \cdot R \cdot Q_{l,S}(n,p_{LP}) + \frac{j}{2} \cdot R \cdot Q_{l,S}(n,p_{HP}) \tag{1.26}$$

In addition to efficiency, slipper wear is evaluated in this study. Therefore, the wear coefficient K_W is calculated according to Eq. (1.27) from the weight loss m_W, with v_r denoting the sliding speed, t the test duration, and ρ the density of the running surface.

$$K_W = \frac{m_W}{F_N \cdot (1 - B_{S,even}) \cdot v_r \cdot t \cdot \rho} \tag{1.27}$$

1.2. STATE OF THE ART FOR POLYMER SLIPPERS

Slippers in axial piston machines are typically designed as hard–soft material pairs, combining hardened steel with non-ferrous metals (NFM) such as brass or bronze to ensure run-in capability, particle embedding, and reduced adhesion [4]. However, many conventional alloys contain toxic lead and promote lubricant degradation or corrosion due to copper, motivating research alternative soft materials. High-performance polymers, particularly PEEK-based compounds, are being investigated to address these limitations.

Research on polymer slippers for oil-hydraulic systems remains scarce. Stryczek [5] demonstrated the general feasibility of plastic components in fluid power applications, with performance strongly dependent on design. More comprehensive work exists for water-hydraulic pumps. Rokala [6], Schoemacker [7], Guan et al. [8], and Ni et al. [9] examined polymer slippers in such systems, showing that their lower friction can offset water's poor lubricity. Among tested materials, carbon-fiber-reinforced (CF) PEEK exhibited the most favorable performance. Li et al. [10] compared CF-PEEK against various steels in both "pin-on-disc" and water-hydraulic APM tests, reporting wear coefficients on the order of 10^{-7} mm³/Nm and improved behavior under hydrostatic pressure.

Building on these findings, the authors introduced a "slipper-on-disc" test [11] under oil-hydraulic conditions, revealing substantially lower friction and wear than under dry and water lubricated conditions. The present study extends this work by examining functional sample polymer slippers on a component-level single-piston test bench, to evaluate polymer slipper performance and, if possible, to provide proof of functionality.

2. METHODOLOGY AND EXPERIMENTAL SETUP

The implementation of polymer slippers in this study was preceded by parametric simulations [3], which showed that fully polymer designs deform excessively, preventing a planar load-carrying surface and a defined hydrostatic relief. Therefore, hybrid slippers with a steel

socket and a thin polymer running surface were developed. As the ball joint connection could not be manufactured, commercially available NFM-slippers were modified by adapting the steel socket and removing the running layer. For high-resolution optical and gravimetric wear assessment and proper sensor integration, comparatively large slippers were designed with a piston diameter of 25 mm and a base diameter of 34 mm. The pistons originate from a 165 cm³ pump for mobile applications, rated at 450 bar, 3000 rpm, and 326 kW. The test rig for these slippers is described in Section 2.1, the design and manufacturing of the slippers in Section 2.2.

2.1. SINGLE-PISTON TEST RIG

The test rig (Fig. 2.1) represents a single slipper-swashplate contact in inverse kinematics to simplify measurements: the slipper (1) remains stationary while an interchangeable flat disk (2, lapped, 100Cr6) is driven up to 3000 rpm (sliding speed 16.6 m/s) without piston stroke.

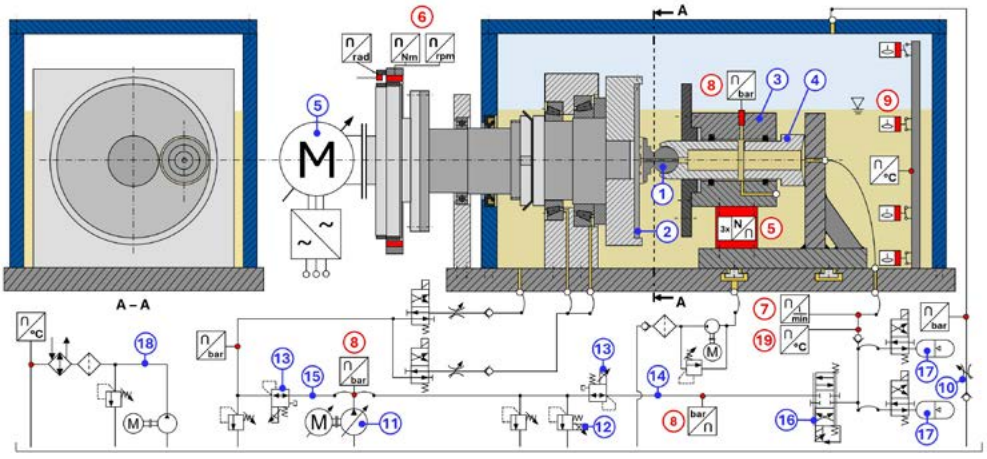

Figure 2.1: Structure of the single-piston polymer-slipper test rig

The slipper is mounted in a piston holder (3) that is axially force-balanced by a compensation piston (4) which is supported on a connecting plate. To enable the measurement of slipper friction with a three-axis force sensor (5, Kistler 9327C, ±8 kN, 0.5 % Full Scale Error (FSE)). A torque measurement shaft (6, Atesteo F1iS, 0-1 kNm, 0-20 krpm,0.03 % FSE, 60 ppr) provides an additional friction reference to validate the measurement principle and enables rotational speed measurement. As the compensating piston setup is inherently leaking and requires the piston holder's center of gravity to coincide with the force sensor centre, a second, sealed holder without force sensor is used to measure hydrostatic leakage flow by a volume flow sensor (7, VSE VS 0.1, 0.01-10 l/min, 0.3 %FSE), whereby the piston pressure is measured in both cases with a pressure sensor (8, Hydac HDA4744, 0-400 bar, 0.25 % FSE). Both holders are aligned by stops and pins for reproducibility. By float switches (9) and a variable throttle (10) in the case drain, the tests can be conducted under different fluid levels and with a controlled case pressure of up to 10 bar.

The hydraulic supply is provided by a pump (11) delivering up to 400 bar at 30 l/min. System pressure is controlled via an electro-proportional pressure valve (12, max. 350 bar), while two pressure-reducing valves (13) allow separate control of the slipper supply (14)

and external bearing lubrication (15). A fast servo valve (16) with a step response of 8 ms enables simulation of pump commutation and pulsing of the slipper. Optionally, pump pulsation can be damped with two accumulators depending on pressure (17). The fluid (HLP 46) is conditioned by a circuit (18) including 5 µm filtration, a 30 kW heater, and 40 kW cooling, controlling the slipper inflow temperature at 40 °C (19, Danfoss MBT3270, -50-300 °C, ±1 % FSE). Tests for friction and leakage are fully automated, measuring 30 sec speed ramps up to 3000 rpm at pressures from 0–300 bar in 50 bar increments

For long-term durability tests, the test rig is equipped with superimposed state controllers and enclosed in sound insulation. Surface changes and wear are assessed optically before and after testing using a focus variation microscope (lateral ±0.44 µm, vertical 10 nm) and a confocal profilometer (lateral ±0.5 µm, vertical ±1 µm). Mass loss is determined after ultrasonic cleaning in a class 7/8 DIN EN ISO 14644-1 cleanroom using a class I DIN EN 45501 analytical balance (σ = 0.016 mg).

2.2. POLYMER SLIPPER DESIGN AND MANUFACTURING

The running surfaces of the polymer slippers shown in Fig. 2.2 were machined from rod-extruded PEEK with a melt viscosity of 150 Pa·s at 400 °C (grade 150G). Higher-viscosity grades such as 450G, which offer improved wear resistance, are typically not extruded but could be suitable for mass production by injection molding. All polymer slippers share the same geometry as the NFM reference to ensure direct comparability. The hydrostatic relief degree of the functional samples amounts 92.75 %.

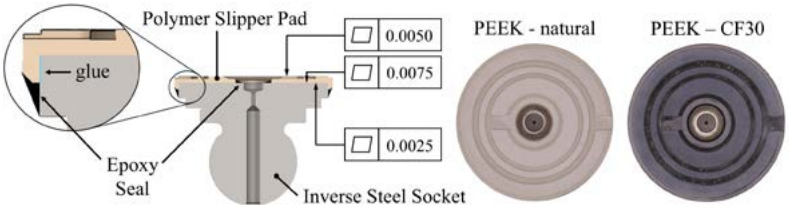

Figure 2.2: Structure of the polymer-slipper functional samples

Besides unfilled 150G PEEK, reinforced variants are tested: 30% carbon fiber (PEEK-CF30) and a composite with 10% carbon fiber, 10% graphite, and 10% PTFE (PEEK-CF10-GR10-PTFE10, HPV). After machining, the slippers were lapped, as surface finish significantly affects wear [11]. A critical challenge for the design investigated here is the tolerance chain involving flatness of the steel base and both pad surfaces. The achieved flatness, shown for the worst case in Fig. 2.2, remained below that of industrially grinded slippers. To avoid changing running surface flatness, the pads were glued only between the pad overhang and the socket outer diameter. The gap between both is sealed with epoxy resin to prevent detachment under pocket and case drain pressure. These steps were required only for the functional samples here, in industrial implementation, overmolding the steel base would enable higher flatness without the need of bonding or sealing.

3. EXPERIMENTAL RESULTS

This section first presents experimental results friction, leakage and efficiency of the polymer slippers in Sec. 3.1, followed by the evaluation of wear in Sec. 3.2.

3.1. FRICTION, LEAKAGE and EFFICIENCY

To evaluate friction and efficiency, the compensation-piston measurement principle introduced in Sec. 2.1 was first validated. Therefore Fig. 3.1 shows friction results of the commercial NFM reference slipper for acceleration (up, 0–3000 rpm) and deceleration (down, 3000–0 rpm) ramps, measured with both the force and the torque sensor. All shown data of this NFM slipper serve only as a reference within the observed conditions. Since material and surface finish of the disc differ, the presented results do not represent the commercial tribosystem. Tests were performed with the housing drained to eliminate flow-induced forces. The bearing friction of the test rig was characterized as a function of pressure and speed and subtracted from the torque data. The good qualitative and quantitative agreement between both methods confirms that the friction of the compensating piston is negligible.

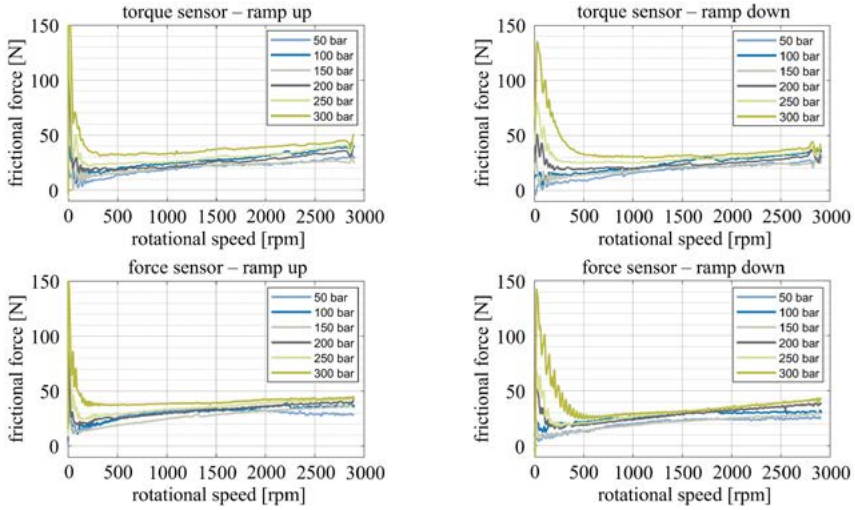

Figure 3.1: Comparison of friction measurements for non-ferrous metal

All curves in Fig. 3.1 show typical Stribeck behavior. During acceleration, the transition from mixed to full-film lubrication (release point) shifts with pressure from about 75 rpm at 50 bar to 250 rpm at 300 bar, consistent with previous findings [12]. A sensor-independent hysteresis is observed, where the difference between acceleration and deceleration at standstill represents static friction. This increases proportional with pressure up to 57 N at 250 bar and decreases afterwards to 16 N at 300 bar. In the mixed lubrication regime, the curves deviate due to hysteresis, leading to the release point occurring at higher speeds (≈450 rpm at 300 bar) during deceleration. As the NFM exhibits no significant viscoelasticity, the hysteresis is attributed to micro-motions of the slipper rather than material damping.

Fig. 3.2 compares the friction behavior of the NFM reference slipper with that of the polymer slipper functional samples during acceleration ramps. The natural PEEK slipper exhibits a distinctly different behavior compared to the reinforced variants. One reason is its poor machinability, which results in inferior surface flatness and sealing, leading to a significant increase in fluid friction. Additional contributing factors are discussed in Sec. 4. All polymer slippers show a pronounced pressure-dependent friction behavior, with a release point occurring below 100 rpm. At low speeds, the PEEK-CF30 slipper exhibits up to 43 % lower

friction compared to the NFM reference. In the full-film lubrication regime, however, its friction partially exceeds that of the NFM reference by up to 48 %.

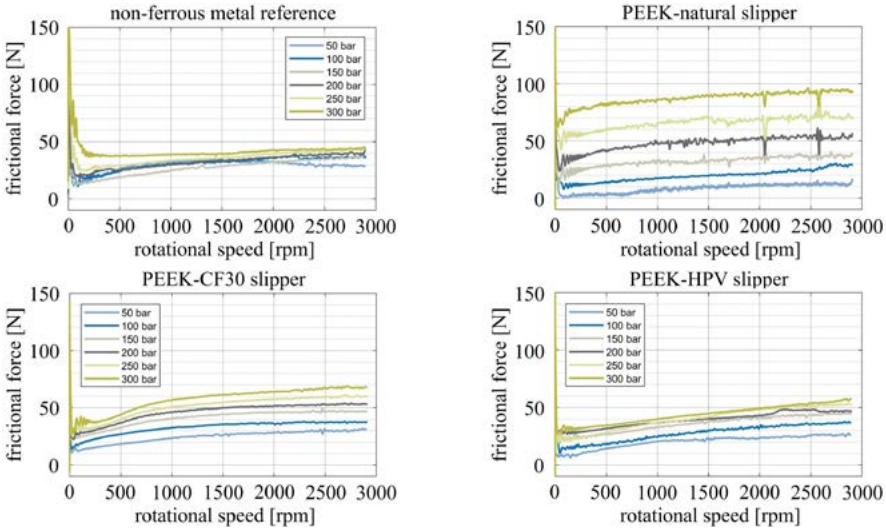

Figure 3.2: Friction comparison of the polymer slipper functional samples

Fig. 3.3 shows a comparison of slipper leakages. The measured leakage represents a superposition of the slipper–swashplate and ball-joint contact leakages. As all slippers were manufactured using pistons from the same production batch, the data is considered comparable.

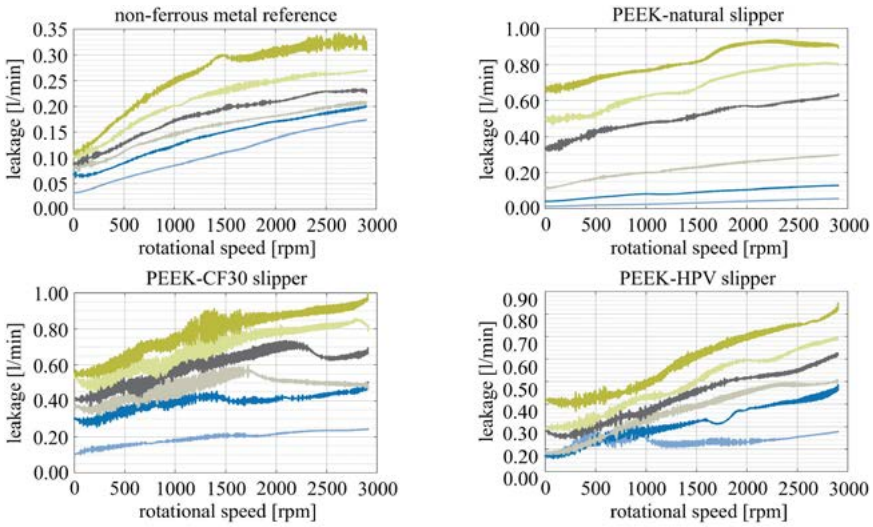

Figure 3.3: Leakage comparison of the polymer-slipper functional samples

The data shown is only lightly filtered, as leakage noise increased with pressure. A minor hysteresis between acceleration and deceleration was observed at low speeds too, with leakage being up to 10 % higher during deceleration but returning to the same value at standstill. Repeated tests revealed a reproducibility band of about ± 8 % for all slippers, including the

NFM reference. It is visible that at lower pressures, leakage increases almost linearly, while at higher pressures it tends to saturate. As expected from the limited flatness described in Sec. 2.2, the NFM reference exhibited the lowest leakage. However, the stronger pressure dependence of the polymer slippers suggests additional effects, discussed in Sec. 4. For the PEEK-CF30 slipper, leakage exceeded the NFM reference by about 26 % at 50 bar and 185 % at 300 bar, yet absolute values remain small compared to the pump's delivery flow (max. 495 l/min). That's why the resulting relative efficiencies are discussed in Fig. 3.4 using the equations from Sec. 1.1.

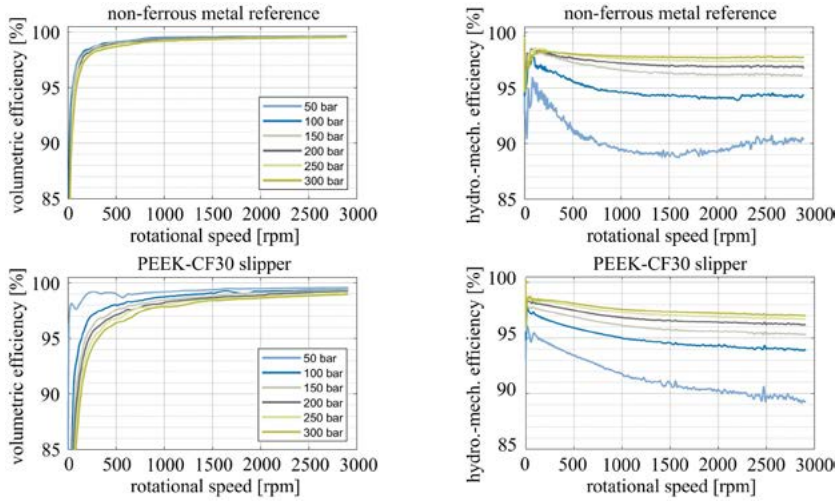

Figure 3.4: Comparison of volumetric and hydromechanical efficiencies

In addition to the partial efficiencies shown in Fig. 3.4, Fig. 3.5 presents a comparison of overall efficiency maps for all tested slippers.

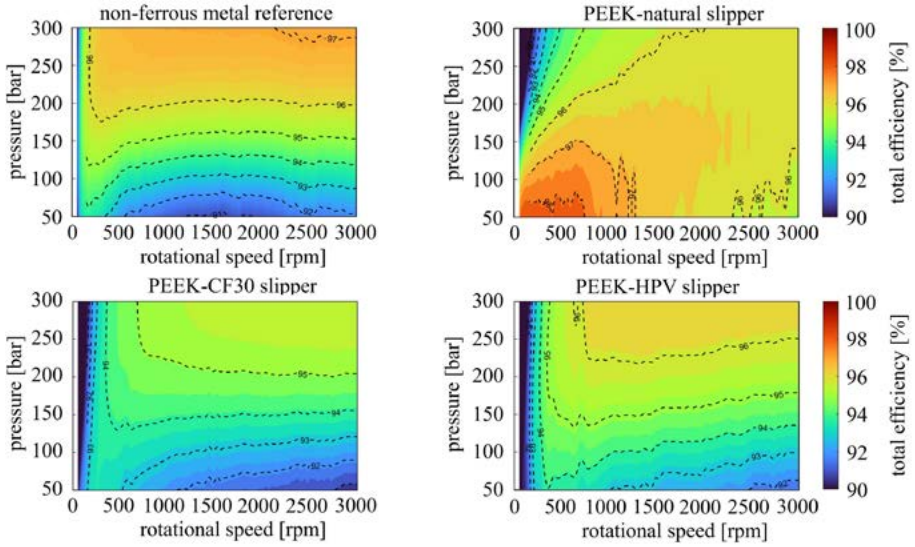

Figure 3.5: Comparison of total efficiencies

The volumetric and hydromechanical efficiencies exhibit the typical trends reported in the literature [1, 2]. Due to lower friction at low speeds, η_{hm} is higher for the polymer slippers, decreasing at higher speeds. However, η_{vol} reveals the stronger pressure dependence and increased leakage, resulting in lower overall efficiency.

The commercial pump is specified with a minimum operating speed of 400 rpm, consistent with the mixed lubrication regime and reduced total efficiency observed in this range. The recommended operating range is 1400–2200 rpm and 230–320 bar, where the overall efficiencies of the PEEK-CF30, PEEK-HPV, and natural PEEK slippers reach approximately 95.4 %, 96.1 %, and 96.2 %, respectively, being only slightly below NFM with 96.7 %.

3.2. WEAR

To assess wear behavior, the mass loss was first determined after 100 h of testing at 1450 rpm and 200 bar to evaluate the general material suitability. Due to the low density of polymers (PEEK-CF30 1.4 g/cm³ vs. NFM 8.1 g/cm³), shorter tests would not allow gravimetric resolution. Fig. 3.6 presents a boxplot with the resulting wear coefficients (Eq. 1.27) together with the friction coefficients over the entire speed range.

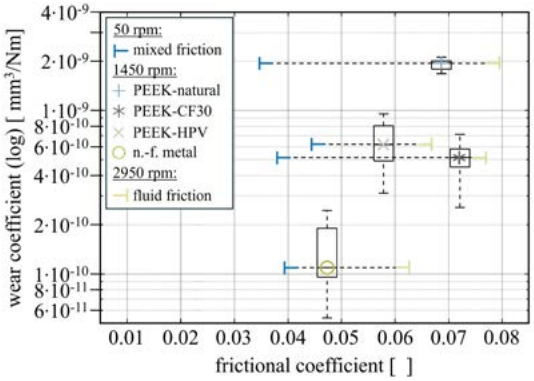

Figure 3.6: Gravimetric wear comparison after 100 h at 200 bar and 1450 rpm

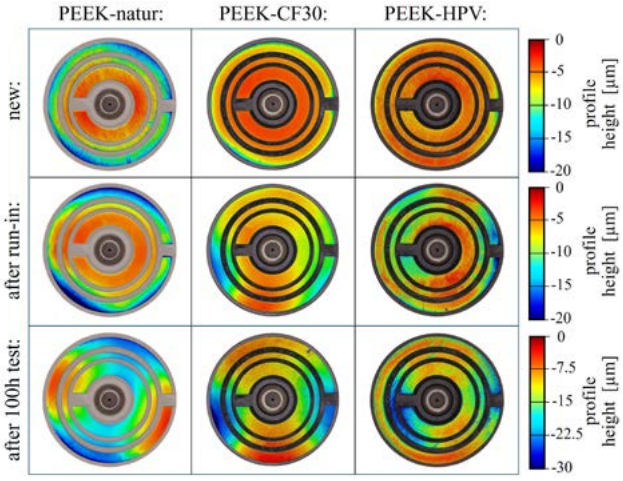

Figure 3.7: Optical wear comparison after 100 h at 200 bar and 1450 rpm

PEEK-CF30 and PEEK-HPV show wear coefficients in the same order of magnitude as NFM (< 10^{-9} mm³/Nm), typical for fully fluid-lubrication and suitable for long-lifetimes. On average, PEEK-CF30 exhibits roughly five-times higher wear, though the scatter indicates that gravimetrical evaluation mainly provides order-of-magnitude estimate in this wear range. In contrast, natural PEEK displays substantially higher wear and is deemed unsuitable. Accordingly, reinforced PEEK is generally suitable, though local wear at the sealing land may still limit durability. Therefore Fig. 3.7 presents optical wear localization.

The top of Fig. 3.7 shows the pronounced non-flatness of new slippers, especially for natural PEEK. Below it is evident that the local wear pattern forms mainly during the 30 min run-in procedure covering the entire operational range, with only quantitative changes thereafter. Wear concentrates near the pressure-relief grooves due to local deformation and stiffness loss, causing groove depression and partial wear transfer onto the sealing land. This may increase leakage or collapse hydrostatic relief over time. Therefore, polymer deformation necessitates geometric compensation as demonstrated in [3], meaning the NFM geometry cannot be directly adopted.

To identify the dominant wear mechanisms, scanning electron microscopy (SEM) and energy-dispersive X-ray spectroscopy (EDX) were performed before and after testing. The aim was to exclude thermal or chemical degradation and to determine whether the polymers form the thin transfer film, typically being responsible for the low wear of tribologically optimized polymers, even under the prevalent high gaps, hydrostatic relief, and smooth surfaces. Figs. 3.9–3.11 show the SEM images, and Figs. 3.12–3.14 the EDX spectra.

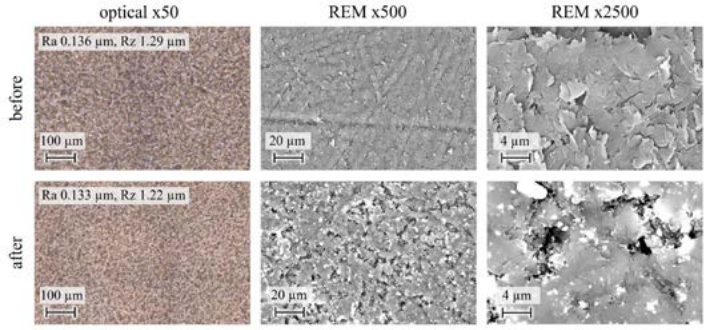

Figure 3.8: PEEK-natural surface before and after wear test

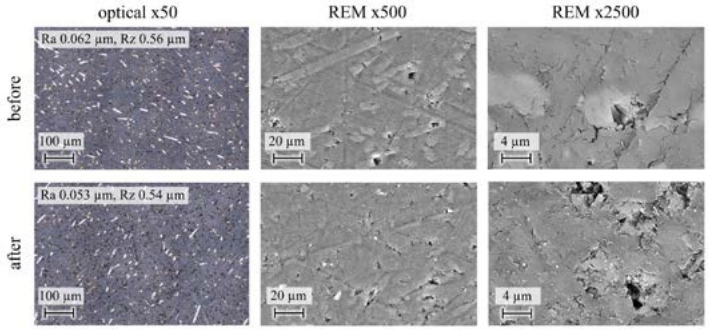

Figure 3.9: PEEK-CF30 surface before and after wear test

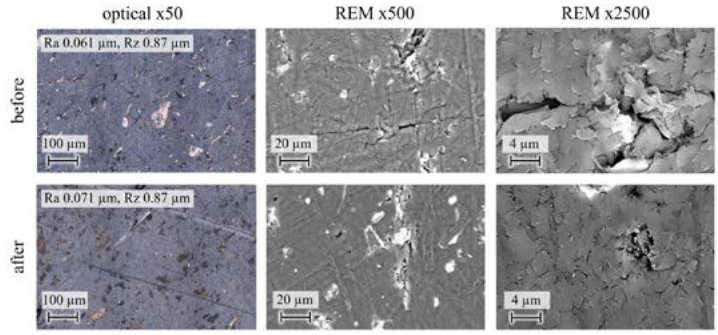

Figure 3.10: PEEK-HPV surface before and after wear test

The SEM images at 2500× magnification reveal surface smoothing for all polymers, with abrasion as the dominant wear mechanism and occasional fiber pull-out in reinforced grades. No signs of melting, structural damage, or chemical attack were detected.

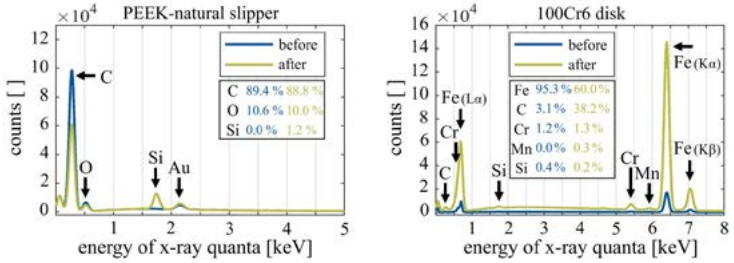

Figure 3.11: EDX-spectra of the PEEK-natural slipper and counter disc

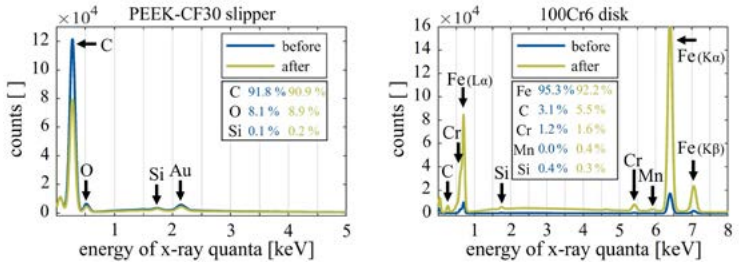

Figure 3.12: EDX-spectra of the PEEK-CF30 slipper and counter disk

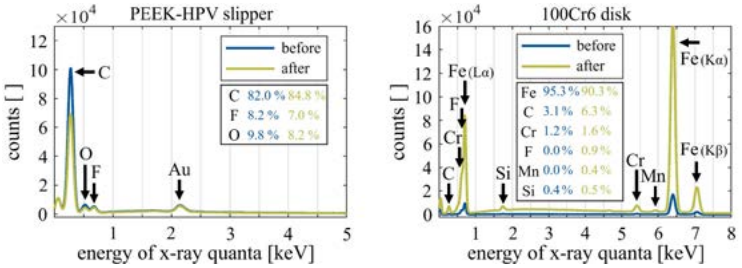

Figure 3.13: EDX-spectra of the PEEK-HPV slipper and counter disk

The EDX spectra peaks are semiquantitative, showing elemental presence. Calculated weight percentages are shown besides. Gold peaks originate from sputter coating for conductivity. All polymer slippers contain carbon and oxygen as main PEEK elements (hydrogen cannot be detected), with negligible compositional change during testing, as a thin graphite/PTFE layer forms already during lapping. Minor silicon traces may indicate reactions with silicone-based antifoam additives. On the 100Cr6 counter surfaces, increased carbon content after testing shows the formation of a transfer film. By locally dissolved measurements a continuous graphite/PTFE-based film could be confirmed, providing a stable, low-wear behavior in the slipper contact.

4. DISCUSSION

To explain the pressure-dependent behavior and differences between NFM and polymer slippers, leakage and hydrostatic relief were numerically evaluated using Eqs. (1.1)–(1.6) and (1.10)–(1.12) for deformed gaps with logarithmic (Eq. (1.7)) and polynomial (3rd- and 5th-order, Eqs. (1.8) (poly3), (1.9) (poly5) profiles based on simulated deformations from [3]. Fig. 4.1 shows the NFM and PEEK-CF30 gap geometries (left), the pressure dependence of the poly5 gap (center), and the resulting pressure profiles (right).

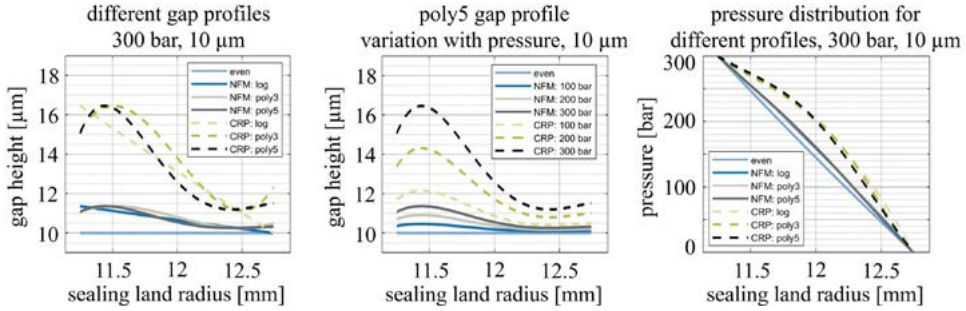

Figure 4.1: Comparison of pressure distributions for different gap profiles

The lower stiffness of polymers (NFM 80 GPa; natural PEEK 4.3 GPa; PEEK-HPV 5.9 GPa; PEEK-CF30 7.7 GPa) leads to significant pressure-dependent deformation, which enlarges the high-pressure area and shifts the hydrostatic pressure drop outward. This reduces flow conductance and leakage while increasing the hydrostatic relief (Fig. 4.2).

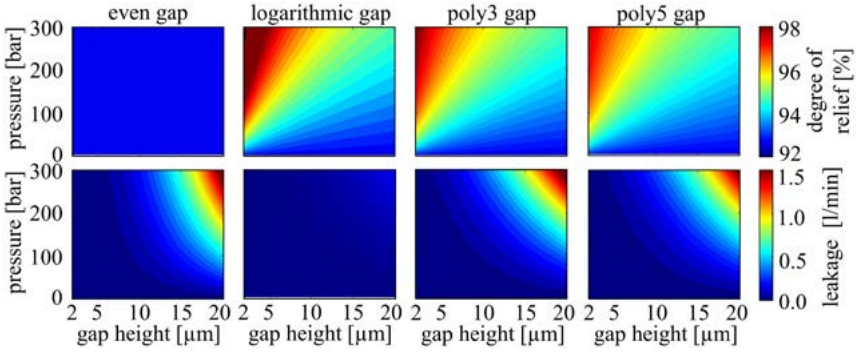

Figure 4.2: Influence of gap profile for PEEK-natural

Fig. 4.2 shows that the logarithmic gap poorly fits the measured leakage (Fig. 3.3), while the poly5 profile agrees reasonably. Moreover, for natural PEEK, the calculated hydrostatic relief deviates by up to 4.9 % at 300 bar and a 2 µm gap. Fig. 4.3 summarizes deviations for all materials: ≤ 2.2 % for NFM and up to 4.5 % for PEEK-CF30.

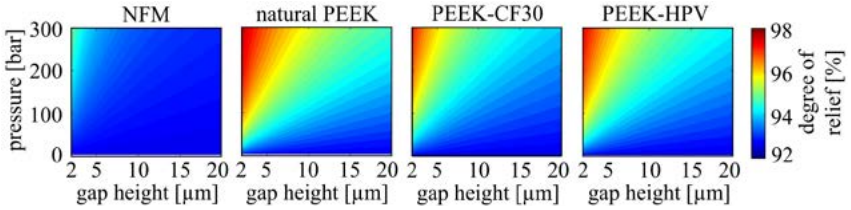

Figure 4.3: Comparison of relief change for different materials

Although approximate, these results highlight the deformation effects relevant for interpreting Sec. 3. Accurate relief design requires precise elastohydrodynamic (EHL) analysis. At 10 µm and 200 bar, PEEK-CF30 shows a 1.3 % higher relief than NFM, leading to 19 % lower residual load. Consequently, wear and friction coefficients become less comparable. Due to higher gaps and lower residual load, the transition to full-film lubrication shifts to lower speeds. The calculated leakage of PEEK-CF30 is 36 % higher than for NFM, indicating that surface non-flatness contributes at least similarly to leakage deviation. In summary, deformation effects can explain the measured results. While moderate deformation can be beneficial by enhancing pressure-dependent relief and reducing friction and wear, excessive elasticity, as seen for natural PEEK, renders the material unsuitable. Therefore, reinforced polymers are required, and uneven deformation must be prevented by geometric design adjustments to avoid non-uniform wear or early sealing land failure. Moreover, a precise lapping process is necessary to achieve even running surfaces.

5. CONCLUSION AND OUTLOOK

This study experimentally evaluated the potential of high-performance PEEK-based polymers to replace non-ferrous metals (NFM) in the slipper–swashplate contact of axial piston machines using a single-piston test rig. Polymer slippers showed a stronger pressure dependence due to deformation, making stiff grades such as PEEK-CF30 most suitable. PEEK-CF30 exhibited up to 43 % lower friction at low speeds and up to 48 % higher friction at higher speeds, the latter caused by increased fluid friction from higher manufacturing-related leakage. Leakage exceeded the NFM reference pressure dependent by about 26–185 %, yet remained small relative to the pump flow, yielding total efficiencies above 95 %, only about 1 % lower than NFM. The wear coefficient of PEEK-CF30 ($5.9 \cdot 10^{-10}$ mm³/Nm) is slightly higher, but in the same order of magnitude as NFM. SEM analysis revealed two-body abrasion as the main wear mechanism, with no thermal or chemical degradation, while EDX confirmed a thin transfer film, ensuring stable low friction and wear. Optical wear analysis indicated that the tested geometry is unsuitable for polymers due to excessive, asymmetric deformation. It can therefore be concluded that polymer slippers are feasible for use in axial piston machines, provided that geometric adaptations compensate deformation.

Future work will investigate PEEK-CF30 slippers with optimized geometry on the same test rig to quantify deformation compensation and achieve uniform wear for long-term operation.

Subsequently, full-machine tests will evaluate the efficiency and durability of pumps equipped entirely with polymer slippers.

6. ACKNOWLEDGEMENT

This work was created within the project “Improvement of oil-hydraulic polymer slippers using a physically based transient design method” (funding code 531424256) funded by the German Research Foundation DFG. The authors want to thank the DFG for this support.

Felix Schlegel received his bachelor's degree in 2020 and his masters degree in 2022 from RWTH Aachen University. For his master's thesis on slippers in high-speed axial piston pumps, he was awarded by the German Society for Tribology. Since 2023, he has been a research associate at the Institute for Fluid Power Drives and Systems (ifas), focusing on tribology of piston pums, and assumed leadership of the tribology group in May 2025. His current doctoral research investigates polymer slippers using several experimental test rigs and electrohydrodynamic simulations.

Prof. Katharina Schmitz studied mechanical and chemical engineering at RWTH Aachen University and Carnegie Mellon University, Pittsburgh (USA) and graduated 2015 as Dr.-Ing. at RWTH Aachen University. Since 2018, she is full professor at RWTH Aachen University and director of the Institute for Fluid Power Drives and Systems (ifas). In addition, she is Vice Dean of the Faculty for Mechanical Engineering at RWTH Aachen, a position she holds since 2020. Prof. Schmitz's awards and honors include several best paper awards and 2023 IMechE Joseph Bramah Medal award.

Modeling and Simulation of Oil Film Influence on Hydraulic Piston Pump Vibrations

Abstract.

This paper presents a comprehensive numerical and analytical study of the oil film behaviour within the distribution plate of a hydraulic piston pump, focusing on its critical influence on vibration characteristics. A dedicated finite difference solver was developed to solve the Reynolds equation under realistic operating conditions. For the baseline case (μ=7.7×10^{-4} Pa·s, ω=4000 rpm, p_p=21.5 MPa, γ=14°), the simulation yields a mean pressure (p_{mean}) of 4.72 MPa and a stable mean oil film thickness (h_{mean}) of 5.70×10^{-4} m. These results were used to estimate the equivalent stiffness and damping coefficients of the lubricating film through analytical relations derived from squeeze-film theory. After calibration, the model yields an equivalent stiffness of 1.97×10^{7} N/m and a damping coefficient of 3.21×10^{-3} N·s/m. These coefficients were integrated into a single-degree-of-freedom vibration model to evaluate the natural frequency and damping ratio of the pump's distribution plate-piston assembly. The system exhibits a high natural frequency of approximately 5.77 kHz and a nearly zero damping ratio, indicating strong elastic support but severely limited viscous attenuation. The study conclusively demonstrates that while the oil film provides significant stiffness, its intrinsic damping capacity is insufficient to suppress oscillations, underscoring the necessity of incorporating additional structural and fluid-borne damping effects into the design of stable, low-vibration hydraulic pumps.

Keywords. Oil Film, Piston Pump, Dynamic Coefficients, Vibrations.

1. INTRODUCTION

1.1. Context

Rotating machines are at the heart of modern industry and energy systems, where operational reliability and efficiency often depend on the control of friction, wear, and vibration phenomena. Within this category, fluid power pumps and motors are essential components in aerospace, automotive, and heavy machinery applications, ensuring power transmission through pressurized fluids [1,2]. Among these, hydraulic piston pumps are particularly valued for their high-pressure capability. Compared with gear or vane pumps, axial piston pumps offer superior performance and are therefore widely adopted in demanding environments [1,2]. Their reliability is crucial because unexpected vibrations can lead to wear, energy losses, and catastrophic failure[3,4,5]. The tribological interface between

All Open Access articles are peer-reviewed, distributed under the Creative Commons Attribution-Non Commercial 4.0 International

piston and cylinder, separated by a thin lubricating oil film, plays a central role [6,7,8]. This oil film simultaneously supports loads, damps vibrations, and prevents metal-to-metal contact. Lubrication plays a critical role in mechanical systems. Beyond reducing friction and wear, a proper lubricant film dissipates the heat generated at the contact interface, protects surfaces against corrosion, and prevents seizure during operation. The performance of this film directly influences energy efficiency, vibration stability, and the overall service life of the pump.

The lubrication behavior and vibration response of hydraulic piston pumps have been extensively studied using classical fluid power theory and hydrodynamic lubrication models [1,2,9]. More recent studies have further highlighted the importance of oil-film stiffness and damping in governing the dynamic response and stability of lubricated interfaces, particularly under oscillatory loading conditions [10,11]. These works confirm that lubrication-induced dynamic coefficients play a decisive role in the vibration behaviour of piston pumps and motivate the development of coupled lubrication–vibration modeling approaches.

1.2. State of the Art and Research Gap

Modeling of lubrication phenomena in hydraulic components is commonly based on the Reynolds equation, which describes the pressure distribution within thin fluid films and forms the theoretical foundation of hydrodynamic lubrication analysis. Various numerical strategies, including finite difference and finite element methods, have been developed to solve this equation for complex geometries and transient operating conditions [12]. These studies primarily focus on pressure fields, load-carrying capacity, and film thickness evolution under different pump configurations.

In parallel, extensive research has examined the dynamic and vibration behaviour of axial piston pumps under coupled mechanical-hydraulic excitation. Several investigations have analysed how operating conditions, pressure pulsations, and fluid-structure interactions affect the overall vibration response and noise generation of these machines [3,4,6,13,14,15]. Multibody dynamic formulations and numerical simulations have been applied to predict excitation mechanisms related to the swash-plate motion, piston reciprocation, and hydrodynamic pressure variations within the film [1,2,8]. Beyond pressure and kinematic analyses, lubrication theory also provides a dynamic description of the oil film response under oscillatory loading. Classical lubrication theory provides well-established analytical formulations for oil-film pressure, stiffness, and damping, which have been widely applied to hydraulic piston pumps and lubricated interfaces [2,9,11]. The tribodynamic coupling between the lubricating film and structural vibration has also been studied through elastohydrodynamic lubrication theory. Foundational models have described the elastic and viscous response of the oil film within hydraulic pumps, defining the equivalent stiffness and damping behaviour of the lubricated interfaces [1,2]. More recent analytical and experimental investigations have quantified the oil-film stiffness and damping in line or point contacts, linking film properties to vibration amplitude and frequency response [10,11]. These works confirm that oil-film stiffness and damping play a decisive role in the stability and dynamic response of lubricated systems. Despite these advances, most existing studies treat pressure as the primary simulation output [6,12,14],

while in vibration modeling, the time-varying film thickness governs the dynamic response and stability of the system. Only a few investigations explicitly incorporate lubrication-induced stiffness and damping into vibration analysis frameworks [10,11,13]. Therefore, a simplified yet physically consistent model coupling the Reynolds equation with a vibration analysis module remains necessary to predict the dynamic response of the oil film-piston system under realistic operating conditions.

1.3. Contribution of This Work

In this work, a finite difference solver is developed to compute the oil film thickness in a hydraulic piston pump, including contact correction effects to prevent non-physical film collapse. Based on the resulting hydrodynamic and contact forces, equivalent stiffness and damping coefficients of the lubricating film are estimated using analytical relations derived from classical squeeze-film lubrication theory. These coefficients are then integrated into a simplified single-degree-of-freedom vibration model to analyze the influence of lubrication-induced dynamic properties on the vibration response of the piston–distribution plate system. In this framework, pressure is not treated as a primary result, but rather as an intermediate variable required to update the oil film thickness and associated forces. The contribution of this work lies in providing a physically consistent coupling between lubrication modeling and vibration analysis, enabling a qualitative investigation of how oil-film stiffness and damping affect vibration regimes in hydraulic piston pumps. The proposed approach is intended as a preliminary modeling framework, highlighting key trends and limitations, rather than as a fully validated predictive tool.

2. THEORETICAL MODEL

2.1. Governing Reynolds Equation and Oil Film Thickness

The main computational basis for the distribution of the pressure field of the oil film gap is the Reynolds equation for fluid lubrication. The Reynolds equation is derived from the Navier-Stokes equation and the continuity equation under certain assumptions.

In this work, the form of the Reynolds equation in cylindrical coordinates is adopted:

$$\frac{1}{\mathrm{r}}\frac{\partial}{\partial \mathrm{r}}(\mathrm{rh}^3)+\frac{1}{\mathrm{r}^2}\frac{\partial}{\partial \theta}\left(\mathrm{h}^3\frac{\partial \mathrm{p}}{\partial \theta}\right)=6\mu\left(\mathrm{U}\frac{\partial \mathrm{h}}{\partial \mathrm{x}}+\frac{\partial \mathrm{h}}{\partial \mathrm{t}}\right) \tag{2.1}$$

where p is the hydrodynamic pressure, h is the film thickness, μ the viscosity, and U the sliding velocity. This formulation results from the standard thin-film lubrication assumptions, where the lubricant is considered Newtonian and incompressible, the film thickness h is much smaller than the piston radius, and inertial effects are negligible compared to viscous effects. Only the sliding velocity U between piston and cylinder and the squeeze effect $\partial h/\partial t$ are retained as sources of hydrodynamic pressure generation. A more general form of the Reynolds equation exists, including additional terms, as well as more complex film deformation contributions. While this extended formulation is appropriate for journal bearings under rotation or systems with significant multidirectional flows, it introduces additional unknowns and computational complexity. Since the hydraulic piston pump considered here is primarily subjected to axial translation, without imposed

radial or tangential velocities, these higher-order contributions can be neglected. Therefore, the simplified Reynolds equation is not only consistent with the physical operating conditions of the piston–cylinder system, but also well-suited for numerical solution with the finite difference method. It provides the necessary accuracy to evaluate the pressure distribution and to capture the coupled evolution of oil film thickness and vibration response, while avoiding unnecessary mathematical complexity.

The local oil film thickness between the piston and the cylinder is defined as:

$$\mathrm{h}(\mathrm{r},\theta) = \mathrm{H_c} - \mathrm{icos}(\theta)\tan(\alpha) - \mathrm{rsin}(\theta)\tan(\beta) \qquad (2.2)$$

where h is the instantaneous film thickness, H_c is the initial oil film thickness, and α and β are the tilt angles of the distribution plate with respect to the x and y axes, respectively.

When $\mathrm{h}(\mathrm{r},\theta)$ locally approaches a critical threshold h_{crit}, a corrective contact force is introduced to prevent non-physical negative film thickness:

$$\mathrm{h}(\mathrm{r},\theta) \geq \mathrm{h_{crit}} \qquad (2.3)$$

with h_{crit} representing contact limit. This mechanism captures the transition from hydrodynamic to mixed lubrication regimes, where partial solid occurs.

2.2. Finite Difference Method

For the numerical solution of the Reynolds equation, the finite difference method (FDM) is adopted because of its simplicity, stability, and suitability for structured cylindrical domains. The lubrication gap between piston and cylinder is naturally expressed in radial and circumferential coordinates, allowing the film to be discretized on a uniform two-dimensional grid. The FDM scheme ensures both accuracy and numerical stability through central-difference approximations of the pressure gradients and a consistent treatment of the film thickness derivatives. The discretized Reynolds Equation forms a sparse linear system of the form:

$$\mathrm{A} \times \mathrm{p} = \mathrm{b} \qquad (2.4)$$

where the matrix **A** depends on local film geometry $\mathrm{h}(\mathrm{r},\theta)$ and lubricant viscosity μ. An iterative relaxation procedure is applied at each time step until the residual between successive pressure fields falls below a predefined convergence tolerance (typically 10^{-6}). The choice of FDM is therefore motivated by its compatibility with the cylindrical geometry of the hydraulic piston pump, the reduced computational cost for time-dependent simulations, and its ability to capture pressure gradients and oil film thickness variations with sufficient accuracy for vibration analysis. It offers sufficient resolution to capture local pressure gradients and film thickness variations that directly affect stiffness, damping, and vibration response.

2.3. Dynamic Coefficients: Analytical Estimation of Stiffness K and Damping C

In a hydraulic piston pump, the oil film separating the rotating and stationary components behaves as a dynamic elastic–viscous layer. Its mechanical behaviour can be idealized as a

spring–damper system, where the stiffness K quantifies the resistance of the film to deformation, and the damping coefficient C represents the viscous energy dissipation during oscillatory motion. These coefficients govern the transmission of forces and the stability of the lubrication interface. In this work, these coefficients are estimated analytically from the mean pressure and film thickness obtained from the Reynolds solver. Assuming a circular equivalent contact region of effective radius R_{eff}, the hydrodynamic stiffness and damping coefficients are derived from the following closed-form relations:

$$K = \frac{3\pi R_{eff}^4 p_{mean}}{2h_{mean}^3} \qquad (2.5)$$

$$C = \frac{3\pi R_{eff}^4 \mu}{2h_{mean}^3} \qquad (2.6)$$

Where p_{mean} is the mean pressure, h_{mean} is the oil film mean thickness, and R_{eff} represents the effective film radius between the outer and inner sealing bands. These equations are derived from the analytical solution of squeeze-film theory, assuming laminar flow, negligible inertia, and small harmonic perturbations of the film thickness. The analytical expressions for stiffness and damping are derived from classical squeeze-film lubrication theory [9]. They reveal the cubic inverse dependence of both stiffness and damping on the film thickness, a fundamental characteristic of hydrodynamic lubrication behaviour. However, these idealized relations tend to over-predict real stiffness and damping, since they assume a fully loaded bearing area, uniform pressure over the contact surface, and negligible compliance of the structural components. It is well documented that such idealized formulations tend to overestimate effective dynamic coefficients due to assumptions of uniform pressure distribution and rigid surfaces [2]. A calibration factor of 10^{-4} is applied to align the theoretical predictions with experimental values reported in the literature for hydraulic piston pumps [4]. This scaling factor aligns the analytical predictions with experimental and numerical results reported in the literature, where typical oil-film stiffness and damping values for piston pumps range approximately from 10^6 to 10^8 N/m and 10^{-3} to 10^{-1} N·s/m respectively [10,11]. The analytical formulation offers a simple yet physically meaningful way to capture the viscoelastic behaviour of the oil film, and investigating how the operating parameters —viscosity, pressure, speed, and inclination angle — affect the equivalent stiffness and damping coefficients.

2.4. Vibration Model of the Oil Film System

Once the equivalent stiffness K and damping coefficient C of the oil film have been obtained from the analytical model (Section 2.3), a simplified single-degree-of-freedom (SDOF) dynamic system was constructed to predict the vibration behaviour of the distribution plate–piston assembly. The motion of the equivalent mass M is governed by the following differential equation:

$$M\ddot{x}(t) + C\dot{x}(t) + Kx(t) = F(t) \qquad (2.7)$$

where $x(t)$ represents the instantaneous displacement of the distribution plate, and $F(t)$ denotes an external excitation or imbalance force acting on the system. For a harmonic excitation $F(t) = F_0 \sin(\omega t)$, the steady-state vibration amplitude is obtained analytically as:

$$|X(\omega)| = \frac{1}{\sqrt{(K-M\omega^2)^2+(C\omega)^2}} \quad (2.8)$$

This expression defines the frequency response function (FRF) of the lubricated interface, where the amplitude $|X(\omega)|$ represents the steady-state displacement magnitude as a function of excitation angular frequency ω. The resonance peak occurs near the natural angular frequency, indicating the dynamic stiffness of the system. For free vibration, $F(t) = 0$, the displacement response is expressed as:

$$x(t) = X_0 e^{-\zeta\omega_n t}\cos\omega_d t \quad (2.9)$$

where the damped natural angular frequency is given by:

$$\omega_d = \omega_n\sqrt{1-\zeta^2} \quad (2.10)$$

and the parameters are:

$$\omega_n = \sqrt{\frac{K}{M}} \quad (2.11)$$

$$f_n = \frac{\omega_n}{2\pi} \quad (2.12)$$

$$\zeta = \frac{C}{2\sqrt{KM}} \quad (2.13)$$

Here, ω_n and f_n are the undamped natural angular and cyclic frequencies, respectively, and ζ is the dimensionless damping ratio. Since the damping coefficient C is relatively small, the system exhibits a nearly undamped oscillatory motion, characteristic of high stiffness and low energy dissipation in the lubricating film. The analytical vibration model provides direct access to two key quantities — the natural frequency f_n and the damping ratio ζ — which are essential indicators of the system's stability.

3. NUMERICAL SOLVER AND SIMULATION RESULTS

3.1. Computational Setup

To numerically evaluate the oil film behaviour in the distribution plate of a hydraulic piston pump, a dedicated solver is developed. This solver integrates the Reynolds Equation with oil film thickness correction and pressure boundary conditions under various operating parameters. Table 3.1. presents the list of parameters and variables used in the simulation:

Table 3.1. Parameters and Variables Description

Category	*Parameter Description*	*Symbol*	*Unit*
Geometry	Radial coordinate	*r*	m
	Circumferential coordinate	*θ*	rad

	Outer and Inner sealing band radius	R_1, R_2	m
	Outer and Inner inner-seal radius	R_3, R_4	m
	Piston and piston distribution radius	R_p, R_s	m
	Lenght Distribution plate	L_{dis}	m
	Number of pistons	z	-
	Angular pitch	$a = 2\pi/z$	rad
	Orifice opening angle	a_0	rad
Geometry Inclination	Initial central film	H_c	m
	Swash-plate inclination angle	γ	rad
Fluid & Contact	Dynamic viscosity	μ	Pa.s
	Density	ρ	$kg \cdot m^{-3}$
	Ambient pressure, suction and discharge pressure	P_{oil}, p_x, p_p	Pa
	Critical film thickness	h_{crit}	m
Kinematics	Rotational speed	ω	$rad \cdot s^{-1}$
	Piston force	F_{press}	N
Numerical Solver	Number of circumferential and radial nodes	N_θ, N_r	
	Mesh spacing (circumferential and radial)	$\Delta\theta$, Δr	rad, m
	Pressure solver tolerance	ε_p	
Analytical Dynamic Coefficients	Mean pressure and oil film thickness	p_{mean}, h_{mean}	Pa, m
	Effective equivalent radius	R_{eff}	m
	Analytical stiffness	K	N/m
	Analytical damping	C	N·s/m
Vibration Model	Moving mass	M	kg
	Natural angular frequency	ω_n	$rad \cdot s^{-1}$
	Natural frequency	f_n	Hz
	Damping ratio	ζ	
	External excitation	F(t)	N
Outputs	Pressure field	$p(r,\theta)$	Pa
	Oil film thickness field	$h(r,\theta)$	m
	Oil-film force and moment	F_{oil}, M_{oil}	N, N·m
	Contact force	F_c	N
	Stiffness and Damping	K, C	N/m, N·s/m
	Vibration response	X(t)	m

A schematic showing the computational process from initialization to convergence is also depicted in Figure 3.1:

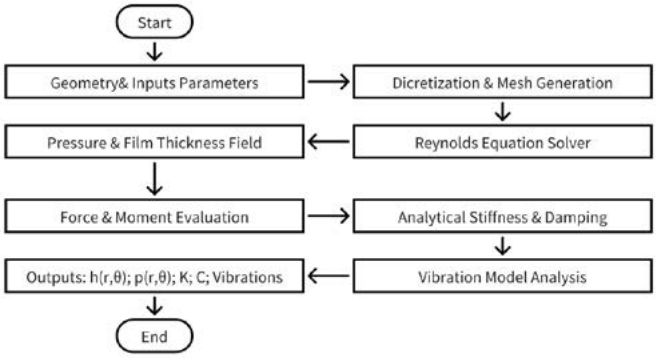

Figure 3.1. Flow Chart of the Numerical Model

The coupled Reynolds and elasticity equations were solved using FDM on a structured mesh with $N_r = 100$ radial and $N_\theta = 360$ circumferential nodes.

Convergence was achieved when both the total force and moment residuals were below the defined tolerance.

3.2. Oil Film Thickness and Pressure Distribution

This subsection analyzes the hydrodynamic field obtained from the Reynolds solver, focusing on the oil film thickness and pressure distribution across the sealing bands.

Figure 3.2 and Figure 3.3 illustrate the reference case corresponding to a discharge pressure of $p_p = 21.5$ MPa, rotation speed $\omega = 4000$ rpm, inclination angle $\gamma = 14°$, and oil viscosity $\mu = 7.7\times10^{-4}$ Pa·s. Under these conditions, the maximum hydrodynamic pressure reaches 21.5 MPa near the high-pressure crescent region, while the minimum pressure stabilizes at 0.2 MPa at the suction side. The pressure field exhibits a typical hydrodynamic wedge pattern, with a gradual pressure rise along the converging region and a sharp drop across the cavitation boundary. The corresponding oil film thickness varies between $h_{min} = 5.66\times10^{-4}$m and $h_{max} = 5.74\times10^{-4}$ m, with a mean value $h_{mean} = 5.70\times10^{-4}$ m, confirming that the interface operates entirely within the full-film lubrication regime.

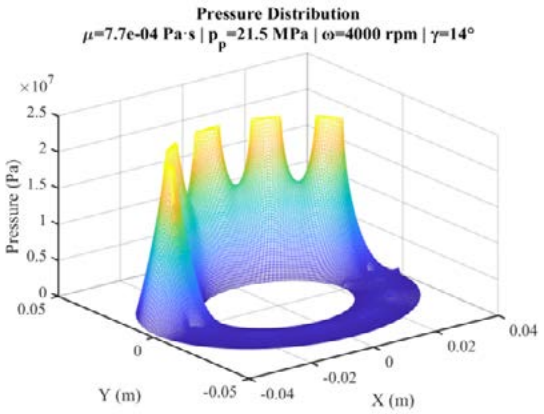

Figure 3.2. Pressure Distribution 1

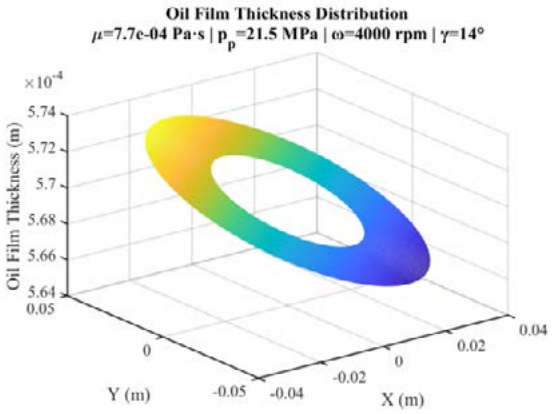

Figure 3.3. Oil Film Thickness Distribution 1

To assess the impact of operating parameters, additional simulations were simulated by varying discharge pressure, viscosity, rotational speed, and swash-plate inclination angle. Results are shown in Figures 3.4, 3.5, 3.6 and 3.7.

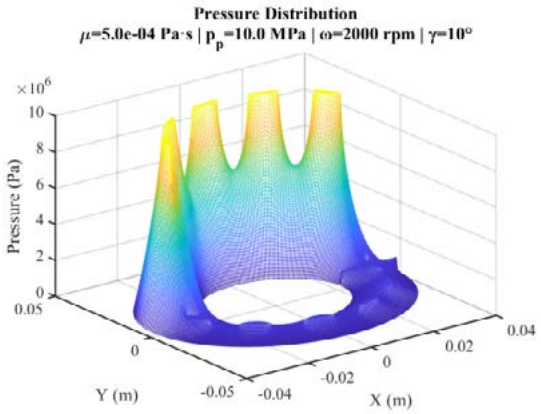

Figure 3.4. Pressure Distribution 2

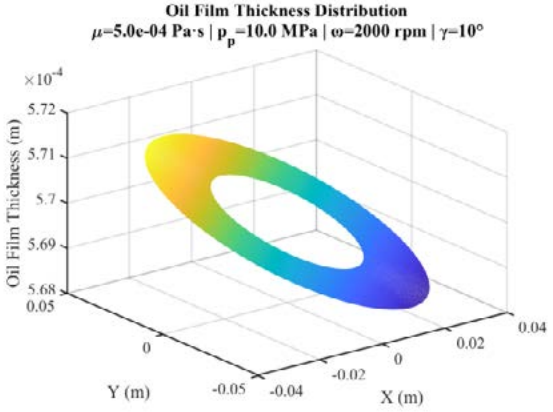

Figure 3.5. Oil Film Thickness Distribution 2

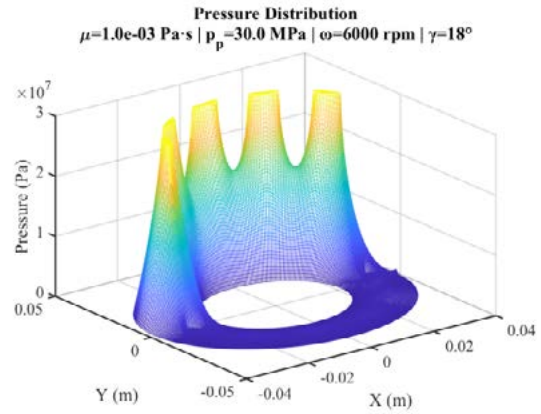

Figure 3.6. Pressure Distribution 3

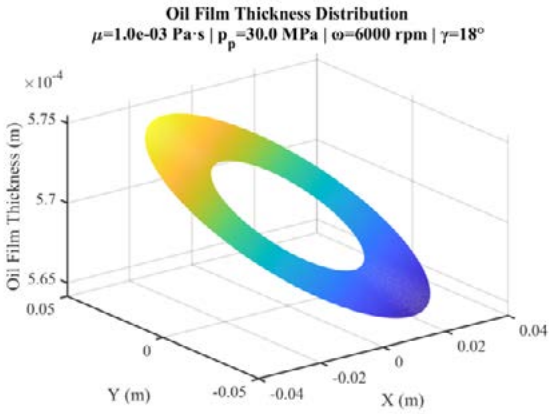

Figure 3.7. Oil Film Thickness Distribution 3

Table 3.2. Key Results for the Oil Film Thickness and the Pressure Distributions

Simulation	μ (Pa•s)	p_p (MPa)	ω (rpm)	γ (∘)	p_{mean} (MPa)	h_{min} (m)	h_{max} (m)
1	7.7×10^{-4}	21.5	4000	14	4.72	5.66×10^{-4}	5.74×10^{-4}
2	5.0×10^{-4}	10	2000	10	2.39	5.68×10^{-4}	5.71×10^{-4}
3	1.0×10^{-3}	30	6000	18	6.44	5.64×10^{-4}	5.75×10^{-4}

Figures 3.4, 3.5, 3.6, 3.7 and Table 3.2 show that the mean pressure p_{mean} increases proportionally with the discharge pressure p_p, validating the hydraulic consistency of the model. The mean film thickness h_{mean} remains constant across all simulations, $h_{mean} \approx 5.70 \times 10^{-4}$. These results indicate that, within the limited range of operating conditions investigated, the mean film thickness appears to be primarily influenced by geometric configuration and contact correction mechanisms.

From a physical standpoint, this weak dependence of h_{mean} on operating conditions can be explained by several factors. First, the contact correction mechanism imposes a minimum admissible gap h_{crit} that prevents non-physical interpenetration; the solver thus converges toward an equilibrium thickness constrained by this limit. Second, the inclination angle γ and initial central film height H_c geometrically define a baseline profile that dominates the final solution. Third, the model operates in a quasi-static regime, where transient squeeze effects are negligible compared with steady hydrodynamic pressure generation.

As a result, while the local pressure distribution adapts sensitively to load and viscosity, the overall mean film thickness remains locked near its geometric equilibrium value.

Overall, the film thickness variation across all cases confirms that the solver maintains a stable full-film lubrication regime, ensuring the reliability of subsequent stiffness and damping coefficient estimations.

3.3. Extraction of Dynamic Coefficients: Stiffness K and Damping C

This subsection evaluates the dynamic characteristics of the lubricating oil film by estimating its equivalent stiffness and damping coefficients through both analytical and force-based approaches. These coefficients characterize the elastic and viscous behaviour of

the film under small perturbations, directly linking lubrication dynamics to the vibration response of the piston–plate interface.

The force-based approach computes coefficients directly from the pressure induced force amplitude and film thickness variation.

Figures 3.8 and 3.9 illustrate the variation of the hydrodynamic stiffness K and damping coefficient C as functions of the mean film thickness h_{mean}. The analytical relations (blue curves) show the characteristic cubic inverse dependency (K, $C \propto h^{-3}$) [9], while the calibrated results (red curves) and force-based estimations (magenta markers) reveal the limitation of purely theoretical models.

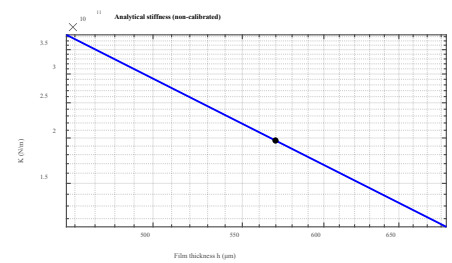

Figure 3.8. Hydrodynamic Stiffness K

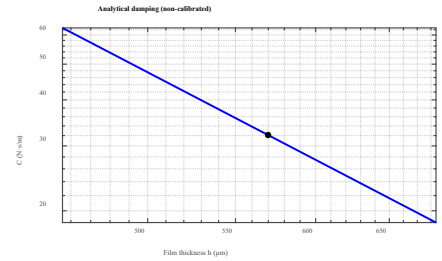

Figure 3.9. Damping coefficient C

Physically, this difference arises from several factors. First, the analytical expressions assume a fully developed hydrodynamic film with uniform pressure over the entire contact area, while the force-based estimation inherently accounts for non-uniform pressure distribution and localized deformation. Then, the contact correction mechanism used in the numerical solver restricts the minimum admissible film thickness, effectively increasing the apparent stiffness of the system. Additionally, the pressure integration in the force-based method tends to overestimate the effective load-bearing area when expressed as **A×p=b**, leading to higher values of K and C.

Table 3.3. Dynamic coefficients extracted for the three simulated operating conditions

Simulation	K_{cal} (N/m)	C_{cal} (N·s/m)	K_{force} (N/m)	C_{force} (N·s/m)
1	1.97×10^{7}	3.21×10^{-3}	4.36×10^{9}	1.13×10^{1}
2	9.97×10^{6}	2.09×10^{-3}	4.22×10^{9}	1.10×10^{1}
3	2.69×10^{7}	4.17×10^{-3}	4.43×10^{9}	1.14×10^{1}

As shown in Table 3.3, the analytical stiffness K_{cal} increases proportionally with discharge pressure, from 9.97×10^6 at 10 MPa to 2.69×10^7 at 30 MPa, following the hydrodynamic load capacity trend. The force-based method yields stiffness values approximately 200 to 400 times higher than the calibrated analytical results, highlighting its sensitivity to local pressure fluctuations and the strong non-linearity of the hydrodynamic field.

The damping coefficients show better consistency, with force-based values clustering around 11 N·s/m across all operating conditions, while analytical values range from 2.09×10^{-3}N/m to 4.17×10^{-3}N/m.

3.4. Vibration Analysis

The dynamic response of the piston-distribution plate system was evaluated using the equivalent stiffness and damping coefficients.

The film behaviour is modeled as a single degree-of-freedom oscillator with equivalent mass M_{eq}=0.0116 kg.

Table 3.4. Vibration parameters for the three different simulations

Simulation	f_n (kHz) *analytical*	f_n (kHz) *force-based*	ζ *analytical*	ζ *force-based*
1	6.56	97.5	0	0.001
2	4.67	96.0	0	0.001
3	7.66	98.4	0	0.001

The Table 3.4. demonstrate physically consistent behaviour: natural frequencies increase with operating pressure ranging from 4.67 kHz to 7.66 kHz. The consistent near-zero damping ratios ($\zeta \approx 0$). across all conditions confirm that the oil film's limited damping capacity is an inherent characteristic rather than an operating-condition dependent phenomenon.

The calibrated analytical approach exhibits distinct resonance peaks that shift with operating parameters as depicted in Figure 3.10.

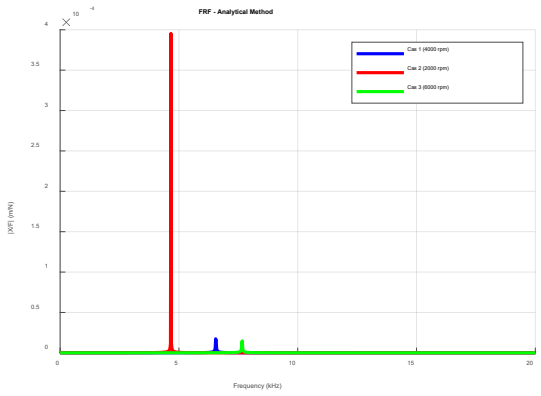

Figure 3.10. Frequency Response Function

The force-based parameters yield fundamentally different behaviour, with no discernible resonance peaks within the 0-20 kHz range. This flat response profile indicates that the excessively high stiffness values dominate the system dynamics, effectively suppressing vibrational motion.

The Free vibration analysis is depicted in Figure 3.11, and reveals critically different damping characteristics between the two methods.

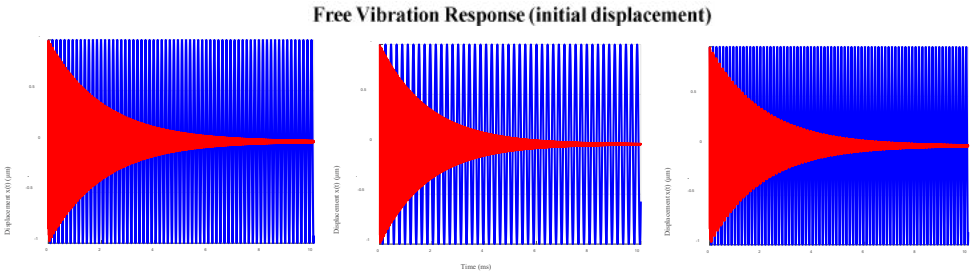

Figure 3.11. Frequency Response Function case 1, 2 and 3 respectively

The analytical solution shows persistent oscillations with negligible amplitude decay over 10 ms, consistent with the near-zero damping ratios calculated for the three cases. The force-base parameters produce immediate decay without oscillations. This quick dissipation contradicts practical observations of piston pump vibrations and underscores the physical inconsistency of the force-based stiffness estimation.

3.5. Physical Interpretation

The dramatic divergence between the two estimation methods provides critical insights for pump design. First, the oil film stiffness dominates dynamics. The analytical results confirm that the oil film provides substantial elastic support, with natural frequencies from 4.67 kHz to 7.66 kHz within typical ranges for piston pump vibrations. This stiffness is essential for maintaining structural integrity but necessitates complementary damping mechanisms.

Then, the persistent oscillations in free vibration response and sharp resonance peaks in forced response demonstrate that the oil film's viscous dissipation is insufficient for vibration control. The calculated damping ratios ($\zeta \leq 0.001$) are orders of magnitude below the critical damping threshold ($\zeta = 1$).

Finally, force-Based Method Limitations: While the force-based damping coefficients ($C \approx 11\text{N}\cdot\text{s/m}$) fall within plausible ranges.

The vibration analysis conclusively demonstrates that while the oil film provides excellent elastic support for the piston-distribution plate interface, its intrinsic damping capacity is fundamentally inadequate for vibration suppression. This finding emphasizes the necessity of integrated damping strategies in the design of high-performance, low-vibration hydraulic piston pumps.

In practical hydraulic piston pumps, measured vibration spectra typically exhibit distinct resonance peaks and sustained oscillations, rather than the flat response predicted by excessively high stiffness values [2,5,7].

4. CONCLUSION

This research successfully developed and validated a integrated model that couples fluid dynamics with structural vibration to analyse the impact of the lubricating oil film on the dynamic behaviour of a hydraulic piston pump. The key findings are summarized as follows:

1) Successful Quantification of Oil Film Dynamics: The Reynolds equation, solved via the FDM, effectively predicted the oil film pressure and thickness distributions under varying operational parameters. The results indicated that the mean film thickness remained stable across simulations, governed primarily by geometric configuration and the contact correction mechanism, confirming operation within a stable full-film lubrication regime

2) Comparative Analysis of Stiffness and Damping: The dynamic coefficients were extracted using both analytical and force-based approaches. The calibrated analytical method provided physically consistent stiffness values, which increased proportionally with discharge pressure. In contrast, the force-based method yielded stiffness estimates orders of magnitude higher, leading to unrealistic vibration response predictions, as shown by the absence of resonance peaks in the frequency response function.

3) The Dual Role of the Oil Film in Vibrations: The vibration analysis clearly delineates the dual role of the oil film. It provides substantial elastic support, resulting in high natural frequencies (4.67 - 7.66 kHz) essential for structural integrity. However, its damping capacity is negligible (damping ratio $\zeta \approx 0$), as evidenced by persistent oscillations in free vibration response and sharp resonance peaks in forced response, proving its inadequacy for vibration suppression.

This study could be further pursued by implementing a more sophisticated time-domain integration scheme, such as the Newmark method, for the vibration analysis. This would allow for the investigation of transient dynamic responses and non-linear phenomena under complex loading conditions. Furthermore, experimental validation of the simulated dynamic coefficients and vibration response is crucial for further model refinement.

The present study does not provide experimental validation. The results are intended to highlight qualitative trends and physical consistency with established lubrication and vibration literature. Experimental validation and advanced coupled fluid–structure models will be addressed in future work.

Abstract.

In the frictional contact of piston pump friction pairs, the formation and evolution of the friction layer are accompanied by significant changes in the grain size, orientation, and distribution within the subsurface region. These grain-level structural characteristics critically influence the friction and wear behaviour of the contact interface. To clarify this process, cross-sectional EBSD (Electron Backscatter Diffraction) is carried out on specimens of port plate material after reciprocating sliding for different times under the same conditions. Changes in grain size, grain boundary misorientation angles, and crystal orientation reveal the rapid formation process of the friction layer. During the first hour of testing, the friction layer changes significantly. Grain size decreases, grain orientation rotation appears, and grain boundaries become pronounced with low-angle grain boundary (LAGB) to dominate. As the sliding continued, the layer thickness kept increasing until it stabilized after 2 h. From 2 h to 16 h, a stable hierarchical structure is established, consisting of an ultrafine-grained surface with persistent {111} alignment, an LAGB-rich transition zone, and the unaffected base material. These findings demonstrate that friction causes time-dependent stratification of microstructure and that the coupled evolution of refinement, boundary character, and orientation selection underpins the stability of the tribolayer, providing a quantitative basis for gradient design of wear-resistant hydraulic components.

1. INTRODUCTION

As a key element of hydraulic systems, axial piston pumps directly influence overall efficiency and reliability through their operational stability and durability. Under long-term high pressure and high-speed sliding, the friction surfaces gradually undergo wear , resulting in increased friction, lubrication deterioration, and leakage. This will reduce efficiency and durability, as well as cause damage to components. Therefore, an in-depth study of the wear mechanisms of key friction parts of piston pumps and their microstructural evolution is of great significance for extending service life and optimising lubrication design. Extensive research has been devoted to improving the tribological behaviour of piston pump components through surface texturing [1], operating-condition control [2], structural optimisation [3], material selection [4], coating design [5].

However, even with such optimisations, friction pairs inevitably experience a run-in stage. During this process, engineered systems transition from the initial state to a stable operating state by removing microscopic asperities via wear or plastic deformation, thereby improving surface conformity and friction stability [6]. R. Ivantysyn, et al analysed the running-in period of axial piston pumps, focusing on clarifying the effects of operating parameters and contact geometry on surface behaviour [7]. Tappeiner, et al. studied the optimisation of the surface roughness of the friction part of piston pumps, emphasising low friction and low wear achieved by matching the appropriate running-in mechanism with roughness parameters [8]. W. Jiao investigated the effects of initial surface roughness, speed and pressure on the tribological properties of axial piston pump port plate pairs under low-pressure conditions with respect to the run-in effect. The results show that higher speed and initial roughness shorten the run-in time, while higher pressure leads to an increase in the fluctuation amplitude of the friction coefficient. The wear mechanism is mainly characterised by abrasive wear [9]. A. Paulus studied the evolution of the friction layer when lead-free copper was used for the piston pair and found that under lubricated sliding contact conditions, both bronze and brass could form a stable boundary lubrication layer, and the formation mechanism was mainly attributed to the friction chemical reaction of tin oxide (SnO/SnO_2) and zinc sulphide (ZnS), which effectively reduced the coefficient of friction and improved the wear resistance [10]. At the contact interface, structural changes in the material can cover a depth range from a few nanometres (e.g., amorphization) to a few microns (e.g., phase transitions, recrystallization), which can lead to significant differences in the properties of the surface material compared to the substrate, including strength, corrosion resistance, lubrication properties, friction behaviour, and wear resistance [11].

Existing studies mainly focus on the macroscopic wear behaviour of the piston pump friction pair during the run-in stage, while there is a lack of systematic research on the microstructure evolution of the material during the run-in process and its influence on the tribological properties, as shown in Figure **1.1**. Especially, the evolution law of the microstructure of the piston pump friction pair still needs to be explored.

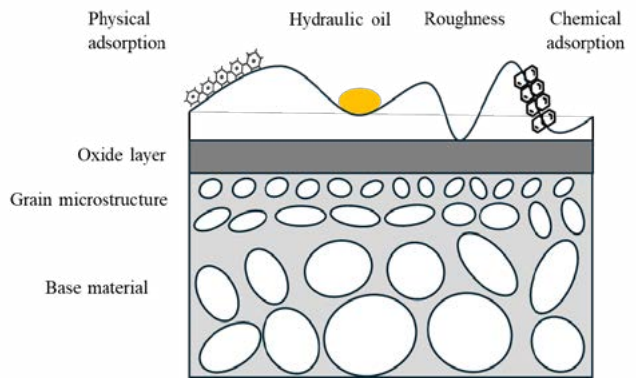

Figure 1.1. Schematic diagram of the microstructure of the friction layer

This study aims to systematically investigate the evolution of microstructure of the friction pairs from the running-in period to the steady state by using microanalysis techniques EBSD, and to analyse the characteristics of the friction layer's thickness, grain refinement, and orientation change in the process of friction, as well as their contribution to the wear resistance, to provide scientific basis for the optimization of the mating piston pump friction pair design.

2. MATERIAL AND METHODS

This section outlines the sample preparation, friction testing, and procedure for analysing the characterisation of friction layers.

2.1. Sample Preparation

Sample Preparation for friction test: the test specimens are the CuZn28Al4Ni3Si alloy, a widely used material for axial piston pump port plates due to its excellent wear resistance and mechanical properties. The specimens were machined into 24 mm × 6.9 mm discs, and surface roughness was controlled to Ra 0.4 μm, ensuring the same as the port plate surface. Before testing, all specimens were cleaned according to DIN 51834 standards, using ethanol and ultrasonic waves for cleaning, followed by drying with compressed air to remove residual contaminants. The other material in the friction pair consists of a QT600 steel pin with a diameter of 10 mm, which was manufactured and heat-treated in the same process as the cylinder block and installed as the upper test specimen.

2.2. Methods

The friction testing is performed on a sliding tribometer (SRV®5) in accordance with DIN 51834 standards. The test configuration consisted of a Pin-on-disc contact under lubricated conditions. The tribological experiments were conducted under the following conditions: frequency: 10 Hz、stroke length: 2 mm, normal load: 400 N, temperature: 50°C (preheating for 5 minutes before testing to ensure thermal stability), lubrication: mineral-based hydraulic oil (ISO VG 46 HLP46), refreshed before each test. Operating conditions

remain constant, only time is varying. Six durations were set: 0.5 h, 1 h, 2 h, 4 h, 8, and 16 h, with three independent specimens per duration (N = 18).

To investigate microstructural evolution and crystallographic orientation, micrographs and orientation maps were obtained using a field-emission SEM (Zeiss Gemini SEM 500) equipped with an EBSD detector (Oxford Instruments Symmetry2). EBSD mapping was performed at an accelerating voltage of 20 kV, with a 120 μm aperture and a step size of 50 nm. After acquisition, the EBSD datasets were indexed and cleaned in Oxford Instruments, and subsequently processed to extract grain size statistics, grain boundary distributions, and grain orientation (inverse pole figure, IPF) by software.

Phase analysis was conducted using X-ray diffraction (XRD) with a Bruker D8 Advance diffractometer, equipped with a Cu-Kα radiation source (λ = 1.5406 Å). measurement conditions, scanning range: 5°–90° (2θ), step size: 0.02°, scan speed: 1°/min. The main purpose is to obtain an unknown phase of the material, which is passed to the EBSD test for phase determination.

2.3. EBSD Sample Preparation

Obtaining a complete subsurface grain-structure is challenging; sectioning and polishing must minimise the removal of tribolayer. Edge rounding caused by cutting, inlaying, or polishing can remove part of the tribolayer, cutting off the layer and making the actual thickness no longer measurable. To preserve the as-formed structure, cross-sections were prepared as follows: The wear-track surface was first sputter-coated with a thin Pt film to protect against local tearing during sectioning. At the centre of the friction zone, vertical to the sliding direction, a low-deformation cutting process is employed. To avoid edge rounding and prevent subsequent disassembly, specimens were inserted into hard conductive resin using a hot-dipping process, enabling direct analysis of the cross-section after insertion. The polishing process involved using SiC sandpaper (grit sizes ranging from 800 to 4000) until scratches were eliminated, followed by final chemical-mechanical polishing: colloidal silica (OPS, approximately 0.04 μm SiO_2) was applied at 50 rpm under low load (10 N) for 5 minutes to remove residual deformation layers. After polishing, the wear zone was re-inspected to confirm that the tribolayer remained continuous and was not polished, and the target region was marked with conductive adhesive. The specimen was then cleaned, dried, and examined by EBSD.

3. RESULTS AND DISCUSSION

This section presents research findings spanning from tribological responses to subsurface mechanisms. Section 3.1 analyses friction-time behaviour, wear cross-sections, and the run-in and steady-state phases. Section 3.2, through X-ray diffraction combined with ICDD-PDF (International Centre for Diffraction Data – Powder Diffraction File) validation, analyses the phase composition of the distributor plate and provides critical background information for EBSD analysis. Section 3.3 employs EBSD techniques to investigate the depth-time distribution of equivalent grain size, grain boundary angle, and grain orientation across cross-sections at different time points.

3.1. Friction Behaviour and Surface Topography

In the study of hydraulic pump friction pairs, the coefficient of friction (COF) and wear are key parameters that characterise tribological performance. Both indicators are influenced by two concurrent mechanisms: material detaches from the surface, and on the other hand, the surface layer undergoes microstructural evolution under high stress and friction. These two mechanisms exist together under sliding lubrication conditions and directly influence the friction response and endurance of the friction pair.[12]

The evolution of the coefficient of friction over time is shown in Figure **3.1**. The results show the trend of the friction coefficient over time, presented as mean ± 1 standard deviation. The shaded areas indicate the standard deviation range with three specimens measured at each time point. During the initial 10 minutes (left figure), all groups showed low and quasi-constant friction coefficients. On a long-term scale (right figure, logarithmic time scale), the variability of the friction coefficient becomes more significant. The coefficient of friction increases between 0.5 h and 2 h. Between 2 h and 5 h, it remained at a high level with moderate fluctuations, before reducing again. Finally, after about 6 h, the coefficient of friction stabilized, with the range of the mean ± 1 standard deviation gradually narrowing, indicating that the system was approaching steady-state. This indicates that time dominates the evolution of friction behaviour. Regardless of the total test duration for individual specimens, results obtained at identical absolute time points remain consistent.

The curves for all specimens exhibit typical running-in characteristics: a rapid increase followed by a peak in the early stage, then a gradual decline toward stability. This closely aligns with Blau's summarised friction transition law, wherein the friction pair initially shows a rapid rise in the coefficient of friction before entering a stable wear phase [13].

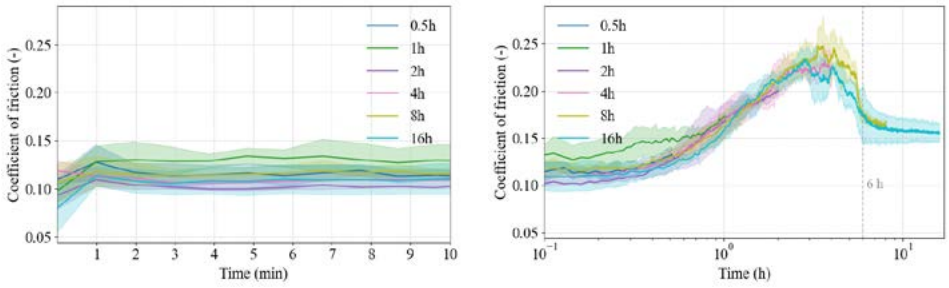

Figure 3.1. Time Evolution of the Coefficient of Friction

Within the first 6 h of measurement, the coefficient of friction changes significantly, indicating that the interface is still undergoing intense adjustment and the surface structure has not yet stabilised. As time progresses, the peak gradually decreases and its decay becomes more gradual, ultimately maintaining a low value and a stable range. This trend can be attributed to friction-induced grain refinement, changes in grain boundary angles and grain orientation [14–16]. The sustained friction process promotes the stabilisation of the surface microstructure, thereby effectively suppressing friction fluctuations.

The cross-sectional profiles of the wear scars (Figure **3.2**) illustrate the temporal evolution of wear depth. At the early stage (0.5 h and 1 h), the wear scars are shallow, and the cross-sections appear relatively smooth, indicating that the material removal is primarily governed by surface plastic deformation accompanied by slight delamination. By 2 h and 4 h, the wear depth increases significantly, and the cross-sections evolve into sharp "V-shaped" grooves. When the sliding time is further extended to 8 h and 16 h, the wear depth reaches its maximum. The good correlation between wear depth and friction coefficient indicates that the system is transitioning from run-in phase to steady-state friction.

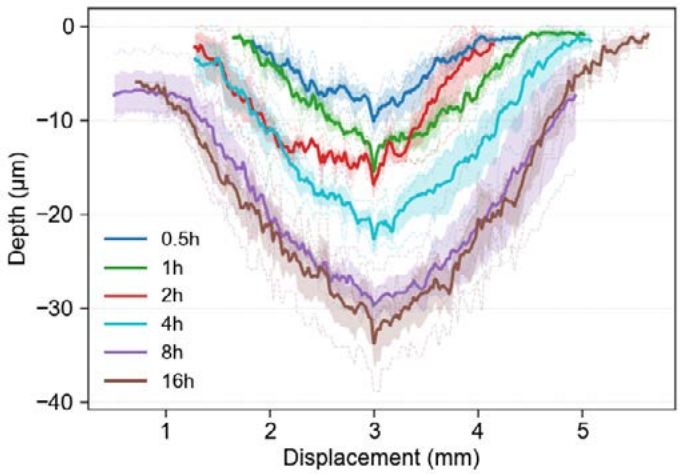

Figure 3.2. Central Groove Profile vs. Time

From a contact mechanics perspective, in the early stages of contact, the interaction is point-to-surface, resulting in extremely high localised stresses that easily lead to strong plastic deformation and ploughing, which increases the friction coefficient. As sliding progresses, the actual contact area increases and becomes more conforming, with the point-to-surface contact gradually transitioning to surface-to-surface contact. The bottom of the wear scar changes from flat to curved, and the contact state tends toward stability [17–19].

However, the above observations primarily reflected friction responses, revealing limited insights into the of the friction layer mechanisms. To uncover this, cross-sectional EBSD was used to construct depth–time maps, tracking grain refinement, orientation selection, and boundary evolution and relating these to friction and wear. This microstructure-to-property linkage clarifies how the tribolayer forms, evolves, and reaches a steady state.

3.2. Phase Identification

The XRD pattern of the port plate material is shown in Figure **3.3**. It displays the XRD diffraction pattern of the end plate material, analysed in conjunction with reference PDF cards for potential constituent phases. The diffraction peaks correspond to three phases: Co_3Ni, CuZn, and $Cu_{0.66}Zn_{0.34}$. Among these, only a faint Co_3Ni diffraction peak was detected, indicating an extremely low content of this phase.

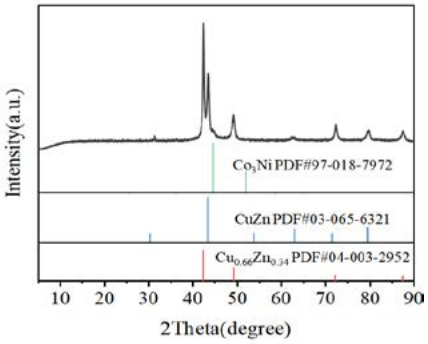

Figure 3.3. The XRD pattern of the port plate material

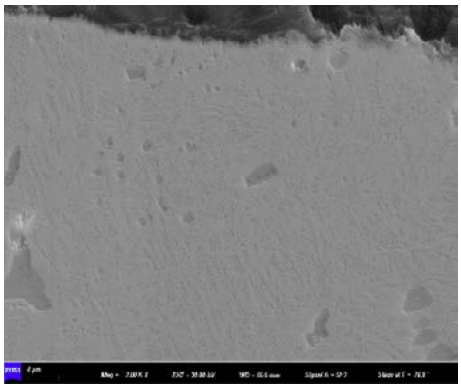
The results show that this phase belongs to the FM3M space group and has a face-centred cubic (FCC) structure. By analysing the diffraction peaks, the crystal structures of each phase were determined, providing fundamental data for the following EBSD testing. This can help deeply understand the microstructural characteristics of the port plate and their impact on material properties.

3.3. Time-dependent evolution of the microstructure of the friction layer

Figure **3.4** shows the SEM cross-section at 8 h: the interface is generally smooth, with no through-peeling observed, nor significant edge rounding, chamfering, or polishing marks, indicating that the sample preparation process preserved the true form of the friction layer.



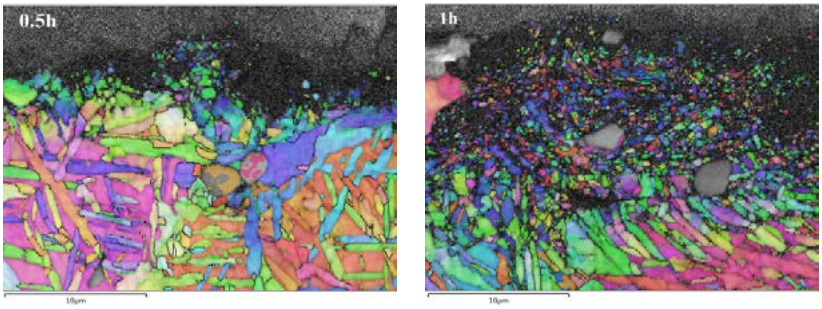


Figure 3.4. Cross-Sectional SEM at 8 h (Wear-Track Centre)

Figure **3.5** shows the EBSD results, with three results for each time point, only one of them is displayed here. All maps are displayed as IPF-ND (normal direction) colourings, with orientations defined by the accompanying inverse pole-figure triangle (red is {001}, green is {110}, blue is {111}). High-angle grain boundaries (HAGB, ⩾15°) are shown in black line; low-angle grain boundaries (LAGB, 2–15°) in green line. Regions affected by severe plastic deformation or delamination, as well as exogenous large particles (third-body debris), were masked and excluded from quantitative statistics. Near-surface nanograins approach the EBSD step-size and pattern-quality limits; values in this range should be regarded as lower-bound estimates.

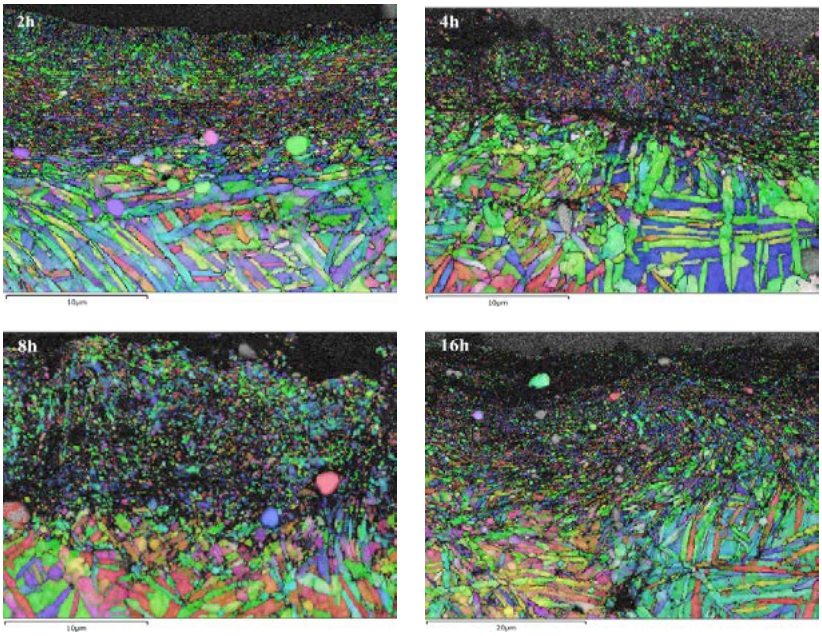

Figure 3.5. Time evolution of the friction layer cross-section at the centre of the grinding mark (0.5 h–16 h)

Grain Size Analysis. EBSD results show that the friction layer at different friction times shows a significant delamination and refinement: surface grains are clearly refined, while base material grains remain large and almost unaffected [20]. At 0.5 h, the friction layer was thinnest, with surface grains appearing refined, indicates that in the early stage, the local high stress and friction were already enough to cause a significant plastic deformation [21]. By 1 h, the fine-grain layer had significantly thickened and expanded, though its grain size remained larger than that at 2 h. Concurrently, EBSD images revealed external grains from the counter-friction material embedded within the copper alloy friction layer, indicative of third-body inclusion during friction [22]. At 2 h, the layer rapidly increases in thickness and reaches a local peak, indicating the intense surface refinement and rapid evolution during the early friction stage. From 2 h to 16 h, the friction layer thickness no longer increased significantly but stabilized at a higher thickness., as shown in Figure **3.6**. The layer thickness is defined as the combined thickness of the ultrafine-grained surface layer and the transition layer, excluding the unaffected base material. The gray dots represent individual sample measurements, while the gray shaded areas denote the mean ± 1 standard deviation for all samples at each time point, the black line as a trend reference.

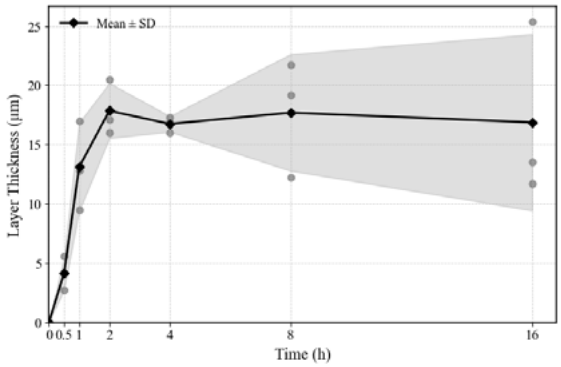

Figure 3.6. Thickness of the Friction-Induced Layer vs. Time

With increasing depth, the grain size increases gradually, with a medium-grain transition layer in the middle and the substrate grains forming the bottom layer. This gradient indicates that friction energy dissipates primarily at the surface and subsurface regions, decreasing with depth [23]. This evolution stems from the competition between grain refinement and surface spalling: on one hand, continuous friction and energy input promote the formation of new fine grains, while on the other, repeated sliding induces localized exfoliation and material removal [24,25].The early rise in COF matches the wear phase dominated by spalling; its decrease and subsequent stabilization match the phase where friction layer refinement/regeneration prevails. As the layer structure stabilizes, COF converges towards a steady state.

Grain Boundary Angle Analysis. Figure **3.7** shows the proportion of LAGB at different time points. At 0.5 h, low-angle grain boundaries appear in the outermost layer. At this stage, grains exhibit slight refinement accompanied by a large number of low-angle grain boundaries. The proportion of surface LAGB significantly increased, far exceeding that of the base phase. However, by 2 h, a distinct further stratification becomes evident: the surface layer consists of fine grains and a small proportion of high-angle grains (27.6%); the subsurface layer contained larger grains than the surface layer but exhibited a high proportion of low-angle grain boundaries (68.4%); the deepest layer comprised the base material (26.8%). During the long-term stage (8 h–16 h), as shown in Figure 3.5, the surface layer kept a low proportion of LAGB, while the subsurface layer maintained a significant proportion.

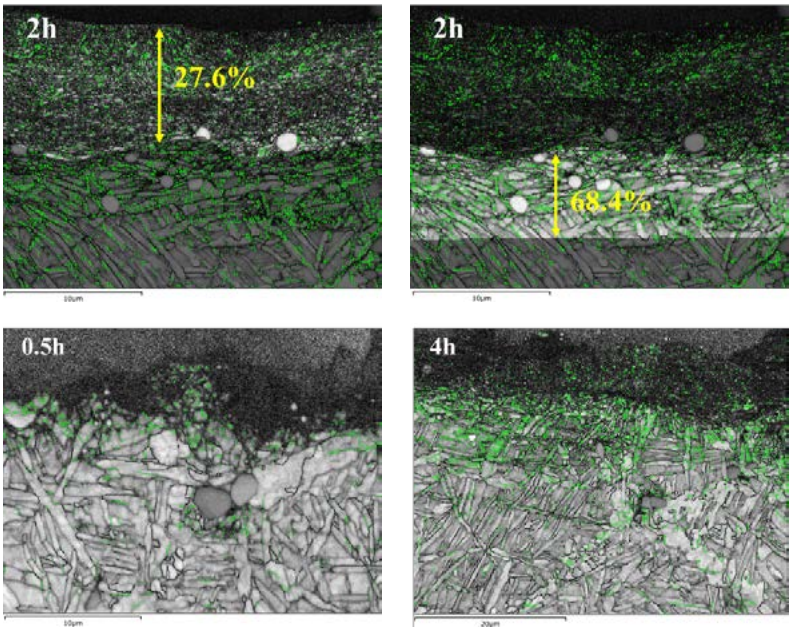

Figure 3.7. Distribution of Low-Angle Grain Boundaries

This indicates that during friction, grains first undergo dislocation or slip, leading to an increase in low-angle grain boundaries and the initiation of grain refinement. As friction persists and energy is continuously input, grain size further refines, and low-angle grain boundaries begin to transform into high-angle grain boundaries.

Before 2 h, the transition zone within the friction layer was not clearly defined. At this stage, the proportion of small-angle grain boundaries in the surface layer initially increased and then decreased. After 2 h, a distinct transition region emerged within the friction layer: grains of moderate size containing a significant number of small-angle grain boundaries. The surface layer and its evolution over time are shown in Figure **3.8**.

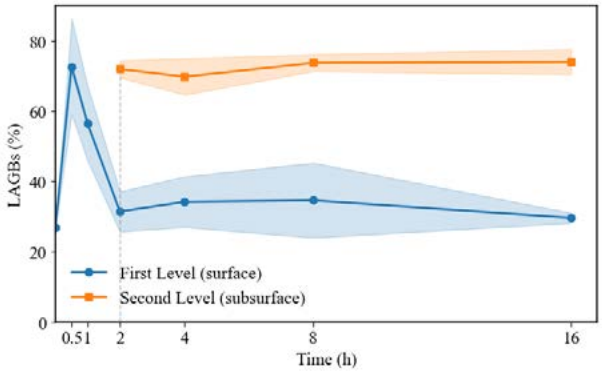

Figure 3.8. Time Evolution of Grain-Boundary Distribution in the Tribolayer

The friction process progressively establishes and maintains a stable delamination structure: fine-grained layers with a high proportion of HAGB surface layers, a large number of LAGB transition zones, and base grain boundaries.

The formation of this stratified structure can be attributed to two mechanisms. First, part of the LAGB in the surface layer gradually undergoes orientation rotation under continuous shear and evolves into HAGB, leading to structural stabilisation. Second, the surface experiences cyclic delamination while former subsurface layer transforms to surface layer. Strain is primarily accommodated in the subsurface, thereby maintaining a high fraction of LAGB in that region [26]. The evolution of microstructure is primarily confined to the friction layer and transition area, with the deeper base material remaining largely unaffected by this process and keeping its original grain boundary characteristics.

Grain Orientation Analysis. To quantify the temporal evolution of crystallographic orientation, the surface normal direction (ND) was taken as the reference for EBSD-based IPF analysis. In the base material, due to the properties inherent to casting and processing conditions, grain orientation remains essentially random. After sliding, however, the surface layer of most specimens consistently exhibits a pronounced {111} texture, while the subsurface retains a more random orientation distribution. This trend is evident in both short-term (0.5 h) and long-term (16 h) specimens, as shown in Figure **3.9**.

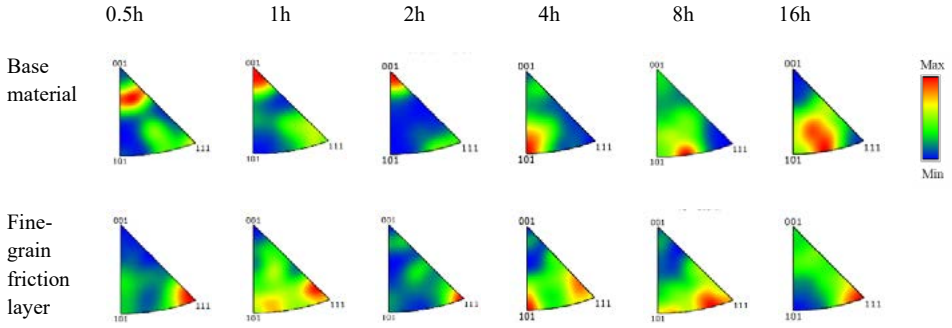

Figure 3.9. Time-Dependent Evolution of Grain Orientation

The evolution of grain orientation toward {111} can be explained by two mechanisms. First, during repeated sliding, surface grains are subjected simultaneously to tangential shear stress and normal contact stress, which induce progressive grain rotation. The rotation path is mainly governed by the sliding direction (SD), transverse direction (TD), and the initial orientation of each grain [16,27]. For FCC copper alloys, the combined shear and normal stresses during friction drive grains to rotate until their orientations align with the most easily activated and mechanically stable slip system. In this case, the favourable orientation is {111}, resulting in the predominance of {111}-oriented grains at the surface. The second mechanism is orientation selection: grains with less wear-resistant orientations are more prone to removal during sliding, leaving behind grains with the more stable and wear-resistant {111} orientation.

4. CONCLUSIONS

1) Under boundary lubrication, a friction layer forms on the planar distributor plate within around 0.5 h; surface grains are rapidly refined, with a significant {111} orientation and a higher proportion of LAGB grains.

2) The thickness of the tribological layer increases over time; after 2 hours, it shows a fluctuation pattern with a cycle of "formation-detachment-reformation," and the peak thickness no longer increases monotonically.

3) After 2 h, the LAGB proportion decreases and the friction layer enters a stable delamination state: the surface layer consists of ultrafine grains of {111} with less LAGB; the subsurface layer beneath is oriented and dispersed, enriched with LAGB, and has slightly larger grains; the base layer extends further downward.

4) The friction layer stabilisation and friction coefficient decrease occur concurrently, showing that grain-scale micro-evolution directly influences macro-scale tribological properties.

5. SUMMARY AND OUTLOOK

5.1. Summary

This study demonstrates that the friction layer of the distributor undergoes systematic evolution with increasing friction duration. Within a short timeframe, surface grain refinement occurs, LAGB increases, and preferred orientation develops. As friction time increases, ultrafine grains form in the surface layer, exhibiting preferred orientation and an increased proportion of HAGB; the subsurface layer contains numerous LAGB with larger grain sizes than the surface layer and random grain orientation. The stable emergence of this friction layer coincides with the oscillatory decrease in the coefficient of friction, indicating that the evolution of the friction layer governs the friction and wear of the distributor plate. This provides a basis for designing wear-resistant port plates.

5.2. Outlook

Although this study has clarified the time series evolution and formation mechanism of the friction layer, two questions still require answers. The specific effects of variable load pressures and shear stresses on grain-level microstructural evolution, along with their direct correlation to wear resistance, have not been quantitatively established. Furthermore, the structural evolution processes at finer scales before observable changes in grain size and orientation require further clarification. On this basis, effective stabilisation mechanisms for the friction-induced layer can be developed, providing a route to significantly enhance the wear resistance and operating efficiency of hydraulic pump friction pairs.

Yuhan Song received bachelor's degree in Mechanical Design, Manufacturing and Automation from Taiyuan University of Science and Technology in 2015, the master's degree in Engineering Mechanics from Taiyuan University of Science and Technology in 2018. His professional experience includes serving as a Hydraulic Component Development Engineer at Linde Hydraulic China (August 2018-June 2021), a Component Simulation Engineer at Linde Hydraulic Germany (July 2021-June 2023), and currently as a Hydraulic Component Development Engineer at Weichai Power European Science & Technology Innovation Center (July 2023-present). His primary research focus encompasses the development and simulation of hydraulic components, including pumps, motors, and valves.

Dr. Julian Angerhausen received his bachelor's degree (2012), master's degree (2014), and PhD (2020) in mechanical engineering from RWTH Aachen University. Since 2020, he has been with the Weichai Power European Science & Technology Innovation Center in Aachen, Germany, where he currently serves as Chief Engineer and Head of Hydraulic Component Technology. His research interests include tribology, hydraulic components (valves, pumps, motors), and hydraulic systems for off-road machinery.

Prof. Katharina Schmitz studied mechanical and chemical engineering at RWTH Aachen University and Carnegie Mellon University, Pittsburgh (USA) and graduated 2015 as Dr.-Ing. at RWTH Aachen University. Since 2018, she is full professor at RWTH Aachen University and director of the Institute for Fluid Power Drives and Systems (ifas). In addition, she is Vice Dean of the Faculty for Mechanical Engineering at RWTH Aachen, a position she holds since 2020. Prof. Schmitz's awards and honors include several best paper awards and 2023 IMechE Joseph Bramah Medal award.

Physics-Informed Neural Network-Based Prediction of Mixed Lubrication Characteristics on Cylinder Block/Valve Plate Interfaces via Mechanism-Data Integration

Abstract.

Aerospace electro-hydrostatic modules (EHMs) play a critical role in precision actuation for flight control systems. The cylinder block/valve plate (CB/VP) interfaces of EHMs are subject to extreme lubrication failure under high-frequency alternating conditions. Typical failures include fluid starvation caused by the gate effect at ultra-high speeds, as well as accelerated wear resulting from boundary friction spikes during low-speed reversals. These issues pose great challenge to conventional analysis, as the high computational cost and inherent instability of high-fidelity simulations present a critical barrier to developing reliable EHM systems. To address these challenges, this study developed a physics-informed neural network (PINN) framework that integrates physical principles with data-driven deep learning. By conducting experiments on the CB/VP interface thermal characteristics under specified operational conditions, the acquired dataset served as the basis for developing a mapping model that correlates operational parameters (rotational speed and pressure) with interface temperature. This established relationship was subsequently integrated into a mixed lubrication model, yielding a thermo-elasto-hydrodynamic (TEHD) coupling simulation framework incorporated into the PINN architecture. Experimental validation demonstrated that the PINN-based model achieved significantly better agreement with measured outputs compared to conventional theoretical predictions, The implemented deep learning methodology enabled precise prediction of mixed lubrication characteristics, maintaining physical consistency while achieving data-driven accuracy. The proposed PINN framework will be extended to investigate rotor dynamics and vibrational behavior in future studies. This work provides enhanced insights into interfacial lubrication mechanisms and establishes an innovative paradigm for analyzing high-performance aerospace servo systems.

Keywords. electro-hydrostatic actuator, deep learning, thermo-elasto-hydrodynamic coupling, tribo-pair.

1. INTRODUCTION

Aerospace Electro-Hydrostatic Module (EHM) work as the critical power components for precision applications such as thrust-vector control and flight-surface actuation, operate under extreme high-frequency quadrant-altering conditions [1–3]. The integrated EHM architecture induces significant rotor vibrations that critically destabilize the lubrication regime at the cylinder block/valve plate (CB/VP) interface [4,5]. This dynamic environment generates two distinct failure modes unobserved in conventional hydraulic systems. The first is gate effect-induced self-priming suppression: At ultra-high speeds [6], transient flow barriers cause lubricant starvation. While near zero-speed zones, frequent reversals provoke friction spikes that intensify adhesive wear and can lead to catastrophic seizure [7,8]. These phenomena constitute fundamental limitations for achieving reliable lubrication in aerospace EHMs.

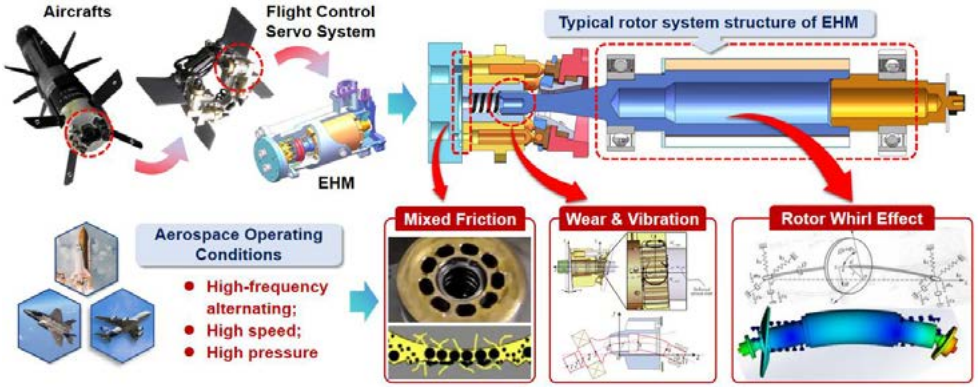

Figure 1.1. Challenges of aerospace highly-compact EHM

Traditional theoretical and numerical methods exhibit significant limitations: high-fidelity models suffer from convergence difficulties [9–12] while predictions consistently deviate from experimental friction torque measurements. System instability has been identified as the root cause [2], and rotor dynamics modelling has revealed critical speed behavior [13]. Although DLC-CrN coatings demonstrate wear resistance [6–8], these methods fail to accurately characterize friction transitions under transient conditions, reflect dynamic oil film rupture/reconstruction processes, or establish wear-vibration coupling frameworks. While artificial neural networks (ANN) show strong function approximation capabilities, purely data-driven approaches face substantial limitations.

To address these challenges, Physics-Informed Neural Networks (PINNs) embed governing equations into neural architectures, achieving synergistic integration of physical principles and data features [14,15]. Faras et al. [16] validated PINNs as effective solvers for elastohydrodynamic lubrication problems, and further demonstrated their versatility in handling both hydrodynamic and EHD regimes [17]. Addressing computational cost, they achieved significant acceleration in contact analysis compared to traditional methods [18]. Moreover, hard-constraint formulations [19] were introduced to strictly enforce physical boundaries, while Ahmed et al. [20] successfully integrated these surrogate models into digital twins for real-time monitoring of lubricated systems. And Yin et al. [21] established a coupled framework resolving cross-scale challenges in seawater-lubricated friction pairs.

This study integrates PINNs into a thermo-elasto-hydrodynamic (TEHD) coupling framework, enabling precise prediction of mixed lubrication characteristics and providing innovative research directions for characterizing complex dynamic behaviors of servo motor pump cylinder block/valve plate pairs under typical power spectra.

To overcome the limitations of conventional methods in analyzing the lubrication performance, this study developed a mechanism-data fused PINN model for the CB/VP interface. The research established a mixed lubrication numerical model, constructed the PINN framework, and validated its predictive accuracy against experimental data. The results demonstrate the efficacy of the proposed data-mechanism integration approach.

2. MIXED LUBRICATION NUMERICAL MODEL OF CB/VP INTERFACE

To analyze the tribological interface between the CB/VP tribo-pair, mathematical and numerical models are employed to simulate its mixed lubrication regime, characterized by partial fluid film and partial asperity contact. These models serve as traditional tools for performance prediction, design optimization, and service life extension [13,22].

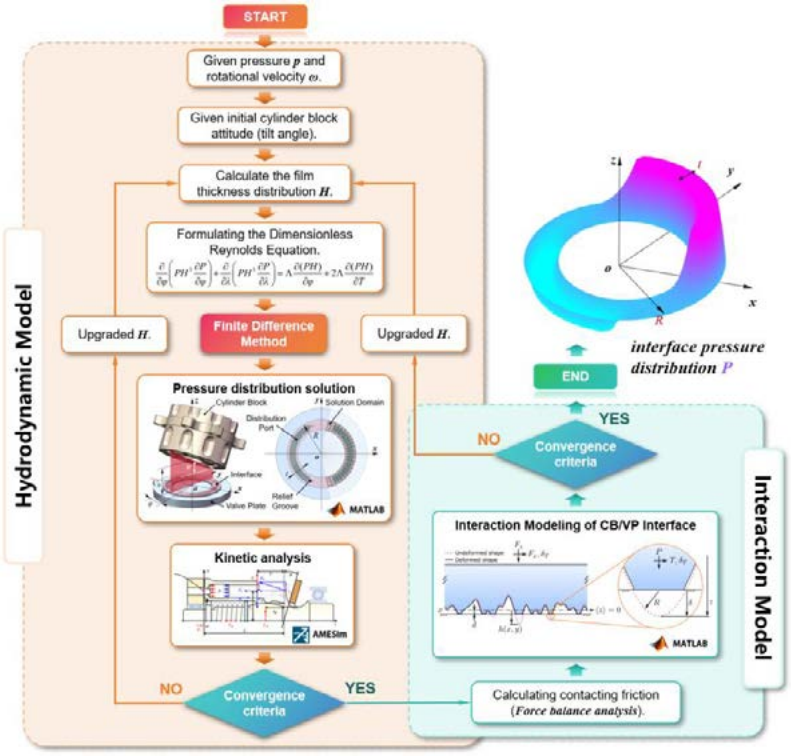

Figure 2.1. Elasto-hydrodynamic numerical modelling framework

2.1. EHD Coupling Modelling Framework

Based on the elasto-hydrodynamic (EHD) model that integrates geometric, lubrication, and contact performance analyses, the procedure for determining the optimal tolerance of the CB/VP interface is structured as follows: Initially, geometric tolerances, including

cylindricity error and dimensional deviations of the piston and cylinder, are characterized [9,10,23]. Subsequently, the fluid pressure distribution at the interface is solved by coupling fluid dynamics with the mechanical equilibrium of the cylinder assembly. This pressure distribution is then input into a contact mechanics model (the Greenwood-Williamson contact model, G-W model [24]) to achieve fluid-solid domain coupling. Finally, the resulting film thickness and pressure distributions are used to compute key performance parameters such as friction losses and leakage rates.

a) *Hydrodynamic Model*

The CB/VP interface represents a critical tribo-pair that integrates sealing, bearing, and lubricating functions [6]. As the contact interface with the largest surface area in EHM systems, it serves as the primary site for cavitation, leakage, and wear failures, thereby fundamentally constraining the performance ceiling of the entire system. The dynamically engaged region highlighted in red in Fig. 2.2(a) constitutes the core area of lubrication analysis.

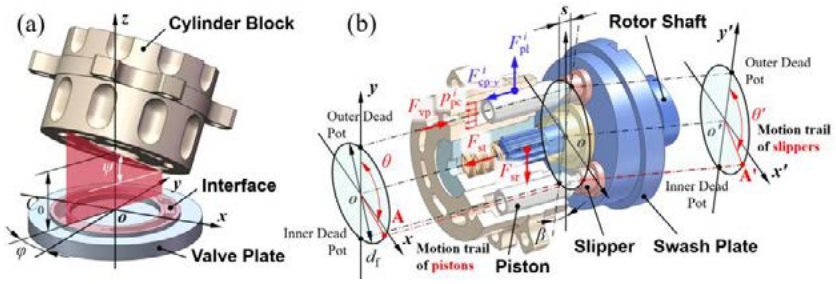

Figure 2.2. Geometric relationship of cylinder block/valve plate interface [22]

To characterize its hydrodynamic behavior, the dimensionless Reynolds equation is employed in this study. The pressure field is normalized using the contact zone's mid-radius (radial direction) and the nominal film thickness (normal direction) as characteristic length scales [13]. This approach ensures numerical stability and eliminates potential errors induced by dimensional inconsistencies during the computational process. Based on this framework, the following equation is established:

$$\frac{\partial}{\partial\varphi}\left(\rho H^3\frac{\partial P}{\partial\varphi}\right)+\frac{\partial}{\partial\lambda}\left(\rho H^3\frac{\partial P}{\partial\lambda}\right)=\Lambda\frac{\partial(\rho H)}{\partial\varphi}+2\Lambda\frac{\partial(\rho H)}{\partial T} \quad (2.1)$$

$$\Lambda=\frac{6\mu\omega}{P_a}\left(\frac{R}{C_0}\right)^2 \quad (2.2)$$

Where φ and λ denote the dimensionless circumferential and radial coordinates, respectively. T is the dimensionless operating time. P and H represent the dimensionless oil pressure and oil film thickness, respectively. ρ denotes the density of the hydraulic working medium. Λ denotes the scaling factor, and it is defined by the mid-radius of the interface R, rotational velocity ω, hydraulic medium viscosity η, nominal clearance C_0, and standard atmospheric pressure P_a.

Fig. 2.2(b) depicts the dynamic equilibrium of the cylinder block assembly. A lumped-parameter model representing the integrated cylinder block-piston-slipper-swash plate system was established in AMESim to characterize the multi-body dynamics. Detailed

modelling methodology is provided in Ref [25]. And tilting angle ψ of the cylinder block are incorporated into the characterization of H, as can be shown below.

$$H = \frac{C_0 + R\sin\psi\cos(\varphi + \varphi_0)}{R} \tag{2.3}$$

b) *Interaction Model*

The G-W model is a classical theory in contact mechanics, specifically employed to calculate elastic contact between rough surfaces. The core of this model lies in idealizing a rough surface as a series of elastic hemispheres with varying heights, and deriving the overall contact behavior by superposing the contact solutions of individual hemispheres. By quantifying the contact laws governing rough surfaces, this model provides a crucial theoretical framework for subsequent research in the field [24].

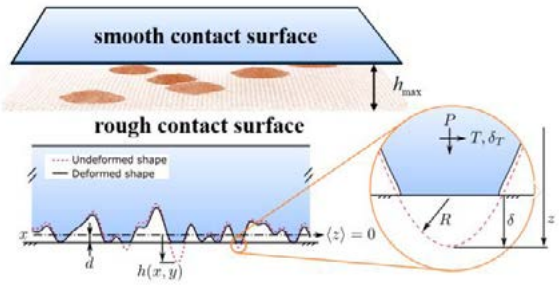

Figure 2.3. The Greenwood-Williamson contact mechanics model [24]

In this model, one of the rough surfaces is assumed to consist of an infinite number of independent hemispheres with identical radii, and the heights of these hemispheres follow a Gaussian distribution. The formula for the probability density function $f(h)$ is given as follows:

$$f(h) = \frac{1}{\sigma\sqrt{2\pi}} exp\left(-\frac{(h-\mu)^2}{2\sigma^2}\right) \tag{2.4}$$

Where h is the height coordinate of an individual asperity, σ is the standard deviation of asperity height distribution, μ is the mean value of asperity height distribution.
Whereas the other surface is assumed to be perfectly smooth. Meanwhile, it is postulated that the contact between each individual hemisphere and the rigid plane is an independent event; the total contact force and contact area are thus the sum of contributions from all hemispheres that come into contact. The formula for the total contact force F is shown as follows:

$$F = \frac{4}{3} E * R^{\frac{1}{2}} n_0 \int_{h_c}^{\infty} (\partial + h - h_c)^{\frac{3}{2}} f(h)\,dh \tag{2.5}$$

Where E is the equivalent elastic modulus, R is the equivalent radius of asperities, n_0 is the asperity density, δ is the normal displacement, h_c is the contact threshold height.

2.2. Numerical Solution Methodology

The pressure distribution is solved using a circumferential difference scheme combined with an elliptic partial differential equation iterative configuration. The circumferential difference

equations ensure continuity of pressure and film thickness in the annular solution domain, while the elliptic formulation enables rapid convergence of the nonlinear fluid governing equations. This approach facilitates subsequent contact mechanics calculations. For specific implementation details, refer to [13].

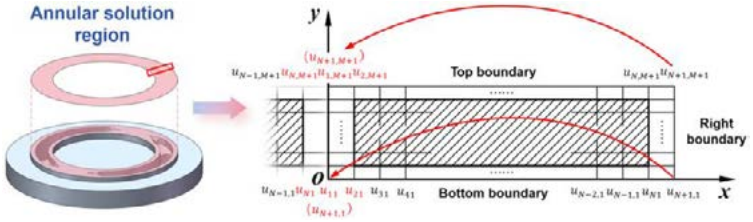

Figure 2.4. Circumferential finite difference discretization of the CB/VP Interface [13]

3. PINN Prediction Model via Mechanism-Data Integration

This study introduces a novel dual-domain nested PINN framework. Its loss function is innovatively constructed by integrating experimental data from EHM characteristic tests with multi-physics governing equations.

3.1. Deep Learning Prediction Framework

A dual-layer nested neural network architecture with mechanism-data fusion is developed in this research. The inner-layer network employs data-driven ANNs, which are trained on thermal characteristic test data from the CB/VP interface to predict its thermal characteristics. The trained ANN model is subsequently embedded to constitute a TEHD model. The outer-layer PINN framework incorporates TEHD governing equations and experimental data into its loss function, enabling accurate prediction of mixed friction characteristics at the CB/VP interface, as shown in Fig 3.1.

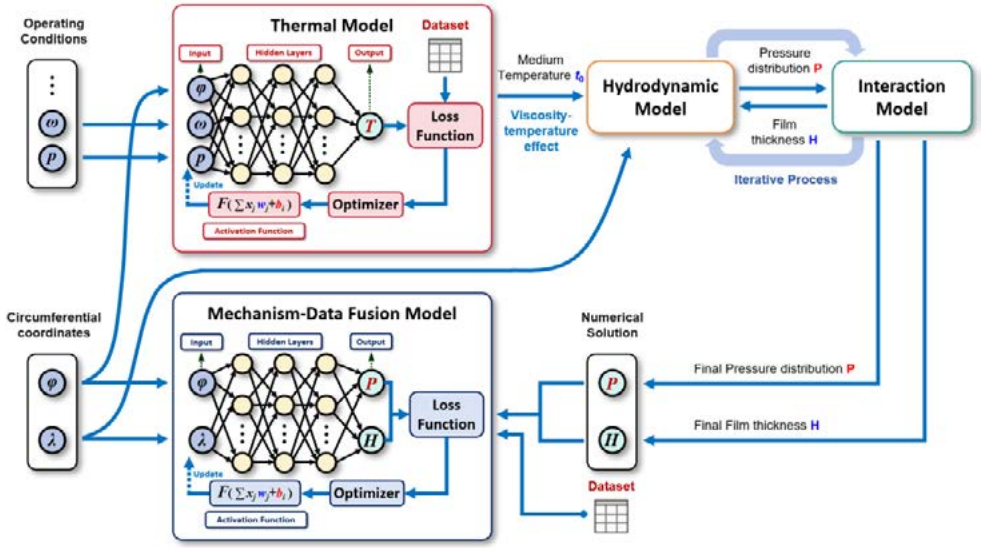

Figure 3.1. Mechanism-data fusion-based PINN prediction framework

Based on the EHD model for the CB/VP pair described in Section 2., where the fluid viscosity μ is initially a constant, an ANN-based temperature prediction model is now nested. Under specified outlet pressure and rotational speed boundary conditions, the ANN first computes the temperature distribution T across the CB/VP interface. This predicted temperature field is subsequently used to determine the spatially varying fluid viscosity μ_d via a temperature-viscosity effect. The updated, non-uniform viscosity field is then fed into the subsequent hydrodynamic and contact mechanics calculations, enabling a fully coupled TEHD simulation. Due to the fast computational speed of the ANN model, the overall computation time of this TEHD model remains comparable to the EHD model.

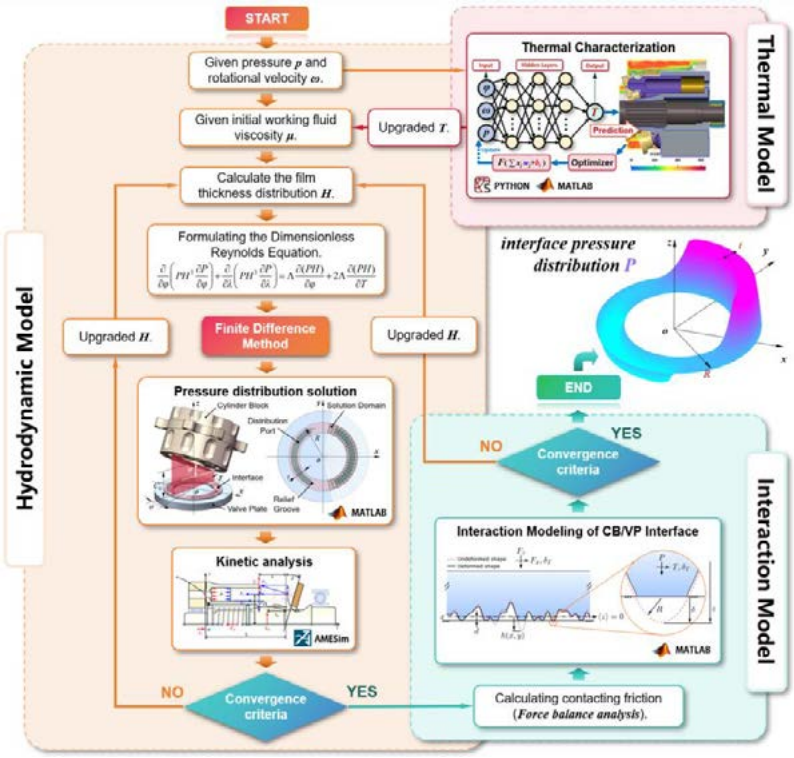

Figure 3.2. Thermal-elasto-hydrodynamic model based on PINN thermal prediction

3.2. Loss Function

The loss functions for the two nested neural networks are respectively defined, broadly categorized into theoretical loss and data loss.

a) *Implementation of Mechanism-Data Integration*

In the dual-layer nested architecture of this study, the neural networks in both the inner and outer layers share an identical internal structure. The distinction lies solely in the composition of their loss functions and the number of parameters in the input and output layers, as illustrated in Fig 3.3. and Fig 3.4. As depicted in Fig 3.3., the loss function directly computes the difference between the training set values and the predicted outputs, subsequently optimized by adjusting biases and weights through a solver.

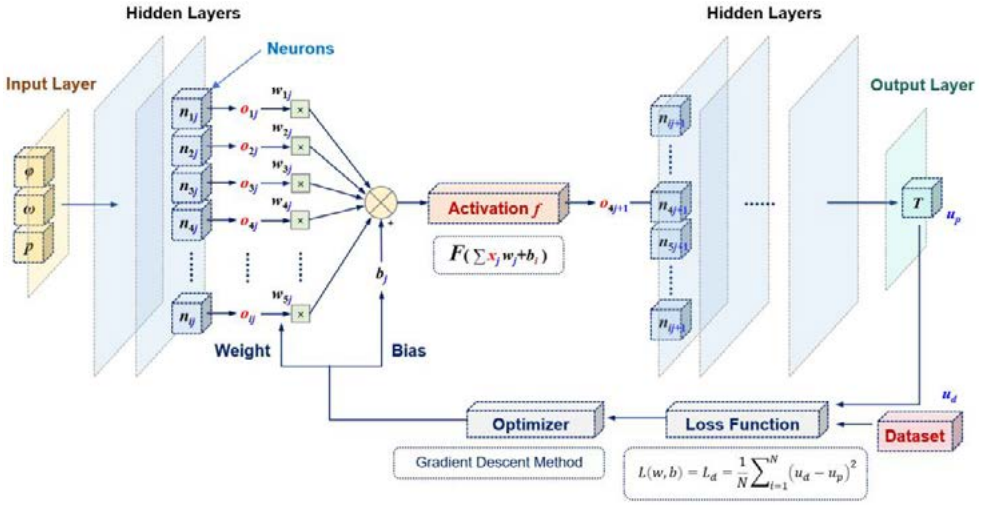

Figure 3.3. Training process of interface thermal prediction

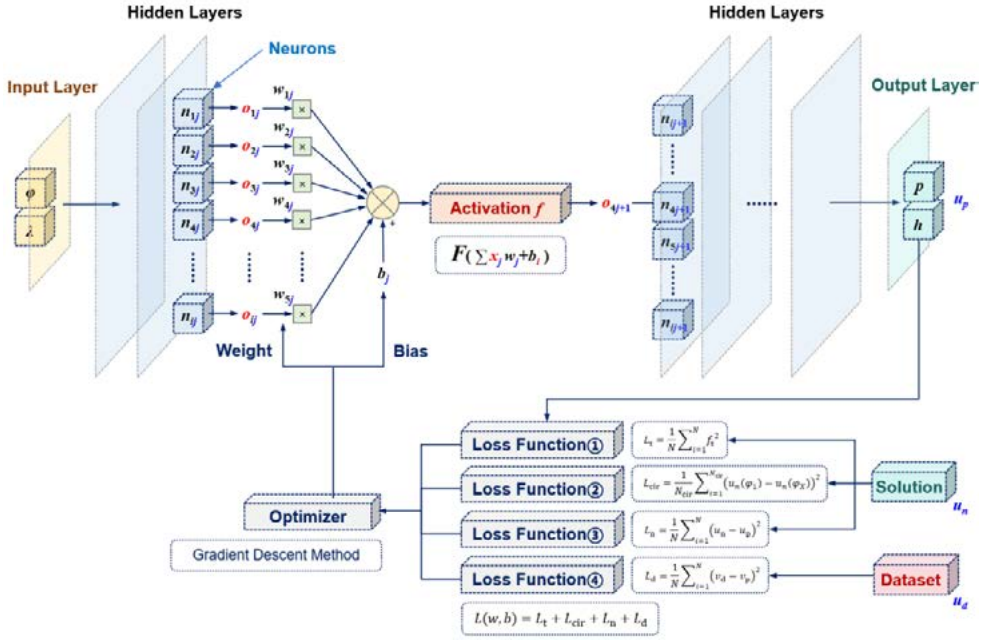

Figure 3.4. Training process of mixed lubrication prediction

In contrast, the loss function in the outer PINN framework shown in Fig 3.4. is considerably more complex. It incorporates the theoretical loss derived from the governing equations and data loss from numerical solutions. A key advantage of PINN architecture lies in its flexibility: unlike traditional equation systems that may suffer from over-constraint issues, the loss components in PINN can be seamlessly integrated without such limitations. However, it is important to note that simply stacking excessive loss terms does not necessarily enhance training accuracy and efficiency.

b) *Theoretical Loss*

In the nested architecture employed in this work, the theoretical error resides solely within the outer PINN framework and arises from the following three distinct sources, where u_{nn} denotes the prediction value. N denotes all types of collocation points (interior points set, boundary condition set, and circumferential boundary set):

1) the first component originates from physical equations, constructed by substituting the PINN outputs for dynamic pressure distribution P and film thickness distribution H into Eq. (2.1) and (2.5), then calculating the mean squared error between the left-hand and right-hand sides of these governing equations.

$$L_{t1} = \frac{1}{N_{in}} \sum_{i=1}^{N_{in}} \left(f_l(u_{nn}) - f_r(u_{nn}) \right)^2 \tag{3.1}$$

2) Second, the boundary condition error encompasses four segments: the inner and outer boundaries of the CB/VP interface, along with both kidney-shaped groove boundaries. The pressure values at the two kidney-shaped grooves are set to the high- and low-pressure zone values respectively, while the interface boundaries are assigned the chamber pressure.

$$L_{t2} = \frac{1}{N_b} \sum_{i=1}^{N_b} \left(u_{nn}(\varphi_{b1}, \lambda_{b1}) - P_b \right)^2 \tag{3.2}$$

3) Third, the circumferential continuity error arises from the annular solution domain of the CB/VP interface as mentioned in Section 2.2. This requires the nodal values, first-order partial derivatives, and second-order partial derivatives at the left and right boundaries of the nodal matrix to be consistent, ensuring periodicity across the computational domain.

$$L_{t2} = \frac{1}{N_c} \sum_{i=1}^{N_c} \left(u_{nn}(\varphi_{b1}, :) - u_{nn}(\varphi_{br}, :) \right)^2 \tag{3.3}$$

$$L_{t2}' = \frac{1}{N_c} \sum_{i=1}^{N_c} \left(\frac{\partial u_{nn}(\varphi_{b1}, :)}{\partial \varphi} - \frac{\partial u_{nn}(\varphi_{br}, :)}{\partial \varphi} \right)^2 \tag{3.4}$$

$$L_{t2}'' = \frac{1}{N_c} \sum_{i=1}^{N_c} \left(\frac{\partial^2 u_{nn}(\varphi_{b1}, :)}{\partial \varphi \partial \lambda} - \frac{\partial^2 u_{nn}(\varphi_{br}, :)}{\partial \varphi \partial \lambda} \right)^2 \tag{3.5}$$

c) *Data Loss*

Under this nested architecture, the two neural networks exhibit distinct data loss: 1) The data for the inner ANN model is entirely derived from EHM thermal tests, with its training set constructed from measured data. 2) The two output quantities of the outer PINN model (dynamic pressure distribution P and film thickness distribution H) have no direct correlation with temperature parameters. Consequently, measured temperature data cannot be directly used to build its training set. Instead, numerical solutions obtained from the TEHD model embedded with the ANN are employed as training data, which integrates thermal test data with mechanistic modelling. Nevertheless, both neural networks adopt identical loss function expressions, as shown below:

$$L_d = \frac{1}{N_t} \sum_{i=1}^{N_t} \left(u_{nn} - u_d \right)^2 \tag{3.6}$$

where u_d denotes the data value at a specific collocation point. Nt denotes all collocation points. The term L_d directly computes the mean squared error between the deep learning predicted values and the data values across all collocation points in the training set.

3.3. Network Training Configuration

Hyperparameter selection for neural networks remains predominantly experience-dependent, as these choices critically govern the model's convergence behavior, predictive accuracy, and computational overhead [14].

a) *Network Architecture*

Based on established research [26], the mesh configurations for the dual nested networks have been defined and are presented in Table 3.1. Notably, the ANN training set comprises 10 Operating Points (OPs) × 5 Measuring Points (MPs), whereas the PINN training set is constituted by 20% of the available numerical solution nodes.

Table 3.1. Parameter settings for network training

Networks	Hidden layers	Neurons	Training set size
1) Thermal prediction ANNs	4	20	10 OPs × 5 MPs = 50
2) Lubrication prediction PINNs	4	50	20% of numerical nodes

b) *Activation Function and Optimizer*

The Multilayer Perceptron (MLP) is constructed with 'Tanh' activation functions and trained using the 'Adam' optimizer, minimizing a mean squared error (MSE) loss that integrates numerical data with governing equations.

4. EXPERIMENTAL VALIDATION

This section details the experimental rig's modular architecture. A multi-level temperature monitoring system with distributed armoured thermocouples at the CB/VP interface enables automated data acquisition. The collected dataset is used to develop a PINN prediction model.

4.1. Overall Performance Test Platform of EHM

The experimental platform comprises three main modules. The first module is a high-frequency variable-condition motor-pump load simulation module, integrating a load simulation system, external control system for simulated loads, oil replenishment system for the tested servo pump, circulation filtration system, cooling system, residual oil recovery system, and hydraulic signal acquisition module. The second module is a human-machine interaction interface consisting of quick-connect components, safety monitoring systems, and display/control panels. The third module is an electronic control multi-dimensional real-time perception system incorporating signal acquisition and control units, with the physical setup shown in Fig 4.1.

Through coordinated operation of its modular systems, the platform performs essential functions including basic parameter testing, load simulation, system pressurization, oil temperature control, and data storage. A multi-level temperature monitoring system was established on the CB/VP interface using armored thermocouples. As shown in Fig. 4.2, a set of sensors were circumferentially arranged near the valve plate and embedded through radial drilling. The thermal testing module can automatically acquire temperature signals in real time and stored them in a database for the PINN training process.

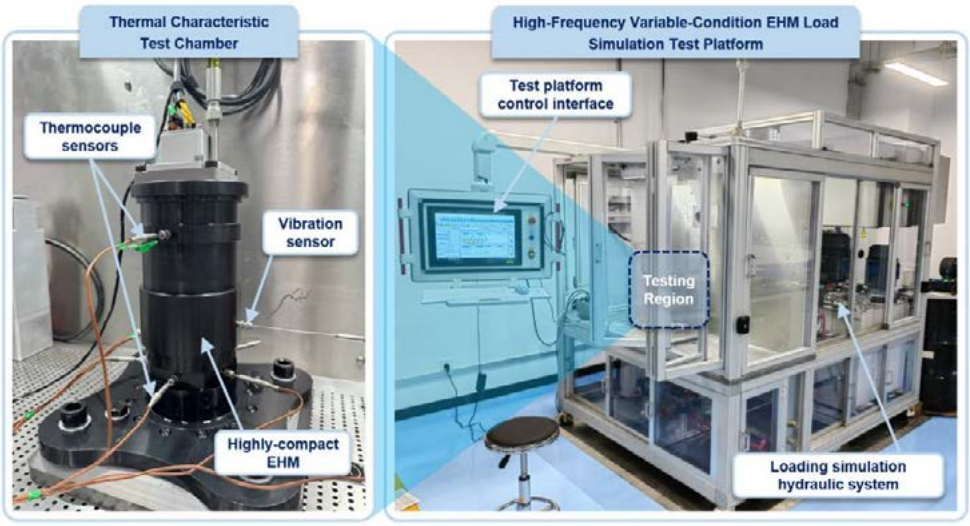

Figure 4.1. The overall performance test platform of EHM

4.2. Dataset Acquisition: Thermal Characteristic Test of CB/VP Interface

The dataset was constructed through the following three-step procedure: 1) First, temperature data were collected from all monitoring points during operation from initial startup to steady-state conditions at each designated working point. 2) Next, a mapping array was constructed using rotational speed ω, outlet pressure P, and initial temperature T_0 as inputs, with the corresponding steady-state temperatures as outputs. 3) And then, neural network architecture described in Section 3.2 was employed to train a temperature prediction model for the CB/VP interface using the developed dataset. 4) At last, the PINN prediction model of thermal characteristics was integrated into the TEHD framework. The curves shown in Fig 4.2. were measured under constant conditions of 14 MPa and 4000 r/min.

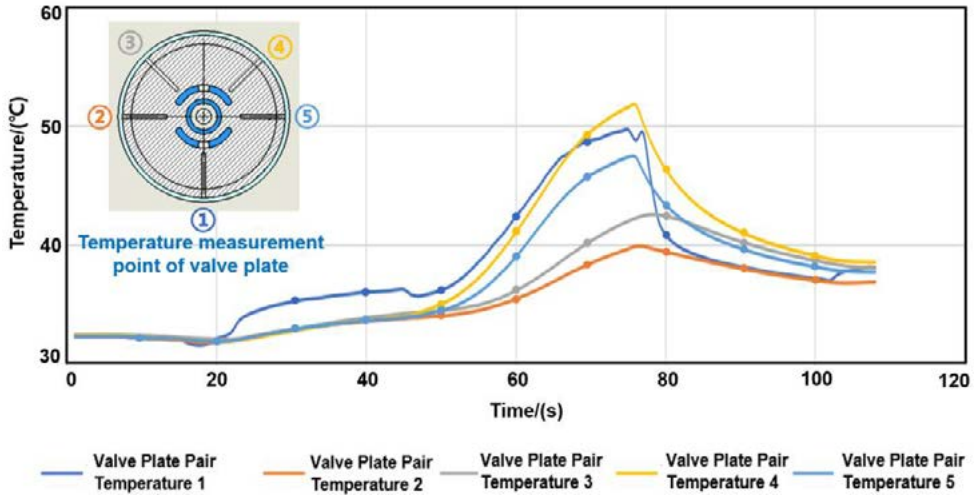

Figure 4.2. Thermal characteristic testing of EHM

5. RESULTS AND DISCUSSION

Model accuracy was assessed by comparing experimental data with EHD and PINN simulations. The influence of training epochs was then systematically analyzed to validate the model's precision. Ultimately, the PINN prediction on lubrication was finished.

5.1. Prediction Accuracy Comparison

As depicted in Figure 5.1, the leakage data and predictions are compared with experimental measurements across four operating points. The vertical axes denote the output pressure and rotational speed (represented by blue and red polylines), and the horizontal axis lists the operating points. The actual leakage, along with the predictions from both models, are visualized using bar clusters, with respective values detailed in Table 5.1.

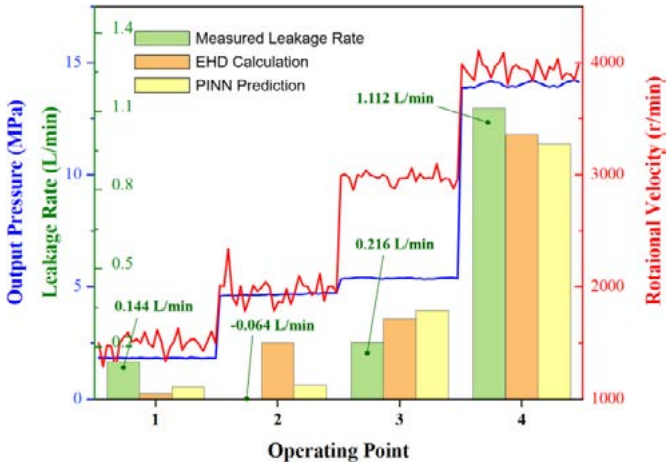

Figure 5.1. Comparisons of measured and predicted leakage rates

A comparative analysis of the relative errors shows a vastly wider distribution for the EHD model (13.9% to 332.8%) than for the PINN model (32.5% to 156.6%). The EHD model showed significant deviations, especially at Operating Points 2 and 3, whereas the PINN model yielded lower errors at all points except one. The significantly lower mean error of the PINN model confirms its superiority, indicating not only higher average precision but also better adaptability to different operating conditions and enhanced robustness.

Table 5.1. Operating point setting and leakage values

Operating Conditions	**Operating Points**			
	I	**II**	**III**	**IV**
Outlet Pressure (MPa)	1.842	4.679	5.390	14.03
Rotational Velocity (r/min)	1496	1968	2972	3938
Measured Leakage (L/min)	0.1438	-0.06440	0.2161	1.112
EHD Calculation (L/min)	0.02004	0.2143	0.3068	1.012
PINN Prediction (L/min)	0.04677	0.05293	0.3383	0.9748

The PINN model's training progress was analyzed by tracking its predictive accuracy across epochs. Detailed outputs, including numerical results and contour plots, were examined at eight key nodes. As shown in Fig. 5.2, the prediction error converged significantly from 1596.1% to 4.08%. This improvement was not entirely uniform, as a noticeable error rebound occurred at 40000 iterations.

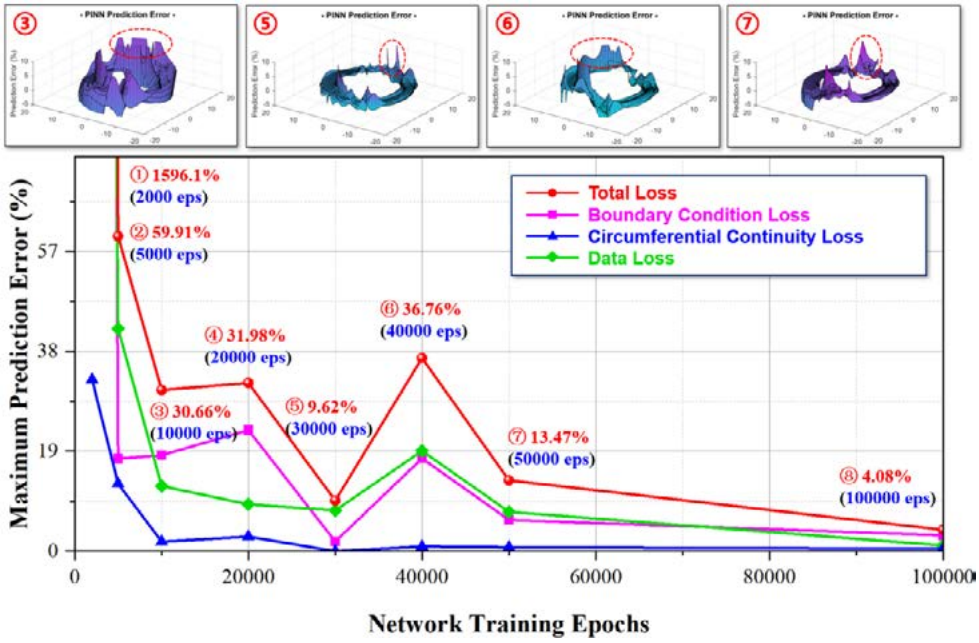

Figure 5.2. PINN prediction accuracy across various training epochs

By comparing the boundary loss, data loss, and circumferential continuity loss separately, it can be further observed that across different training epochs, the locations of maximum error consistently lie on the inner and outer boundaries of the solution domain, rather than at circumferential discontinuities. The influence of circumferential continuity loss is minimal, with errors being primarily driven by boundary loss and data loss. As the number of training epochs increases, the boundary loss shows a clear oscillatory decline, while the data loss fluctuates more irregularly. Additionally, errors near the two dead zones are larger than in other regions, with the locations of maximum error predominantly concentrated in these areas.

5.2. Mechanism-Data Fusion-Driven Prediction of Lubrication Characteristics

The PINN model demonstrates a decisive computational advantage by performing complete simulations and generating detailed contour plots within milliseconds. This stands in stark contrast to the conventional EHD model, which requires approximately 10 minutes to solve due to its inherent computational bottlenecks, a limitation that is further exacerbated by longer solve times and convergence challenges in its more complex TEHD formulation. The remarkable efficiency of the PINN approach enabled the extensive simulation of the interface's mixed lubrication state across a wide spectrum of operating conditions, as comprehensively detailed in Figure 5.3.

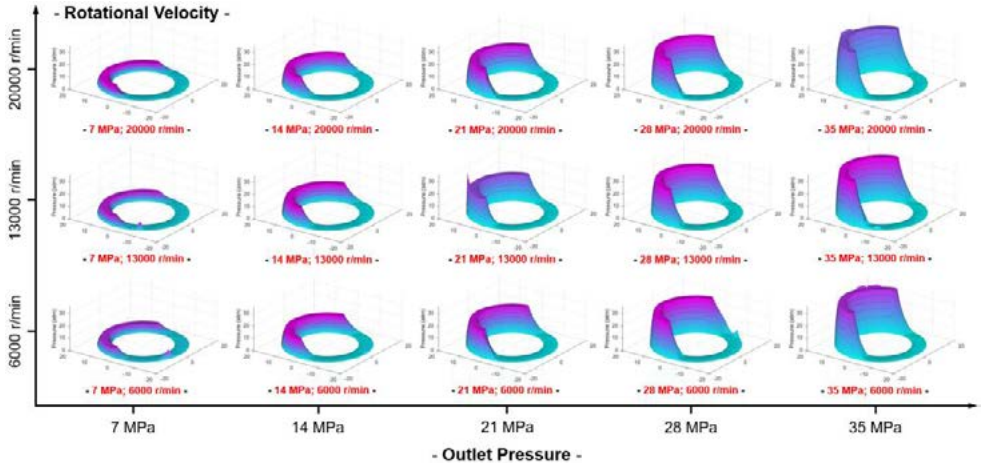

Figure 5.3. PINN prediction of mixed lubrication under various operating conditions

The pronounced growth of oil film thickness in the high-pressure zone under increasing load, at a constant speed, underscores the critical role of pressure in governing film formation. Meanwhile, variations in rotational velocity under a constant pressure condition exhibit minimal impact on the pressure profiles within critical areas such as the dead zone and kidney port, thereby maintaining the overall pressure landscape largely unchanged. Furthermore, the inherent operational tilt of the cylinder block is confirmed to generate an asymmetric oil film distribution, which sporadically triggers intense local pressure concentrations, manifesting as isolated, sharply defined peaks within the contour plots.

6. CONCLUSION

This study pioneers a mechanism-data fused PINN prediction method for analyzing the lubrication regime in aerospace EHM's CB/VP interface. The framework synergizes thermal experiments with EHD modelling, achieving unprecedented predictive accuracy over conventional methods. It significantly enhances the prediction accuracy and efficiency of mixed lubrication parameters while rigorously preserving physical consistency. The principal findings include:

- The PINN model demonstrates superior predictive accuracy over the conventional EHD approach, with a substantially narrower relative error range (32.5%-156.6% vs 13.9%-332.8%) and significantly lower mean error across four operating conditions.
- Training iterations critically influence model convergence, reducing prediction error from 1596.1% to 4.08%. The temporary error resurgence at 40,000 iterations represents a natural optimization phenomenon, while the overall downward trend confirms the value of extended training. Meanwhile, PINN enables millisecond-level simulations versus 10 minutes for EHD.
- The key lubrication mechanisms are revealed: pressure-dominated film formation, minimal speed impact on pressure profiles, and tilt-induced asymmetric film distribution with localized pressure peaks.

Abstract.

Gerotor pumps have been successfully used in low pressure systems (< 50 bar) such as in automotive and in charge systems, owing to their low cost, low acoustic noise, and high filling capability. These positive features make gerotor still attractive in modern applications that require higher energy efficiency or reduced spatial claim. Therefore there is still an interest in studying alternative geometries with respect to the conventional ones. This paper takes into consideration a gerotor morphology referred to as Kfloid, which is not well studied in literature, and compare its performance with respect to a reference industry design. The approach of study is based on a parametric numerical optimization of this morphology, where the objective functions relate to specific displacement of the unit, sealing capabilities, flow non-uniformity and mechanical stress and wear. To allow such analysis, a numerical model for the generation and the processing of Kfloid profile is presented, and then used in an optimization workflow. Results include Pareto fronts highlighting trade-offs between the considered objective functions. To highlight the potential of the optimized Kfloid profile, comparison with a design previously optimized by the research team, and based on a cycloidal morphology are presented.

Keywords. Pumps, Gerotors, Optimization

1. INTRODUCTION

A gerotor gearset consists of an internally toothed gear and a conjugate externally toothed pinion of one tooth difference and features continuous contact between the rotors. The name was coined by its inventor by the combination of the two words "generated" and "rotor" [1]. Gaps between the teeth are sealed by the contact points and create control volumes that increase and decrease in size throughout a revolution, which enables a pumping action in the axial direction. An example of a typical gerotor pump is shown in Figure 1.

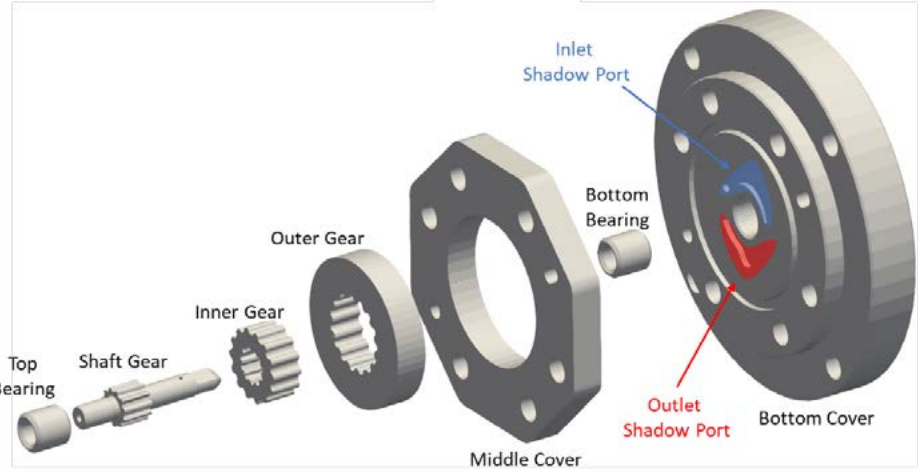

Figure 1: Typical Gerotor Assembly

Gerotor pumps are commonly employed in low-pressure applications such as oil, fuel, automatic transmission, and charge systems. They operate on a simple and elegant principle, requiring only a few components, which contributes to their robustness and cost-effectiveness. Their compact construction and suitability for powder metallurgy make them highly economical to manufacture. The most critical design consideration for a gerotor pump lies in the macro-geometry of its gears, as this directly influences the pump's displacement, flow ripple, efficiency, wear characteristics, and overall dimensions. Furthermore, the gears must maintain an appropriate drive relationship to ensure that the inner and outer rotors engage smoothly without the need for additional synchronization mechanisms.

In theory, for creating a gerotor profile any curve can be selected to form either the inner or outer gear, and a matching conjugate curve can be generated by applying the law of gearing [2]. An infinite number of possible profile families exist, each with an infinite number of profiles belonging to the family. This leads to the question, which is the best possible profile geometry? This is one of the main motivations behind undertaking this research for developing and understanding different profiles.

Much work has been done on multi-objective optimization of cycloidal gerotor profiles [5, 6, 12] and asymmetric profiles [11] has been done, but in these papers the main focus on the displacement, flow ripple and contact characteristics of the gerotor. The exploration of different composite profiles has been done by combining cycloidal and elliptical segments [13], cycloidal and circular arc curves [7], cycloidal and involute curves [8] and cycloidal curves with straight lines [3] has been conducted so far. But none of these works have tried to find an optimum pump geometry for high pressures at which the tip leakages become a very important consideration.

This work is motivated by the need to realize gerotor designs that operate reliably at higher pressures and speeds than conventional applications which in this study are considered to be 100 bars and 4000 RPM. A fast gear-generation algorithm is made and run within modeFRONTIER [16] to compute a Pareto set of candidate geometries. The paper first describes the gear-profile parameterization and generation procedure, then details the

optimization framework in modeFRONTIER and the objective functions (OFs). The resulting designs are compared against an a few industry standard pumps that were available, and a subsequent stage of optimization is performed to refine the porting span for each Pareto-optimal geometry. The optimal design is selected from the Pareto front through additional analytical screening of candidate geometries, with primary emphasis on leakage performance. The best-performing design is then subjected to a lumped-parameter analysis to optimize the port geometry while accounting for operating pressure and speed.

2. PROFILE DESCRIPTION

The mixed profile named taken as reference in this work is the kfloid profile morphology illustrated in the work by Liu et al [3] where the author shows that the kfloid morphology performs better at higher pressure in terms of volumetric efficiency. A kfloid half-tooth section can be very simply defined by three sections which are two shifted cycloidal sections connected by a straight line of length L which is by definition a common tangent to the two end points of the shifted cycloids as shown in figure 2.

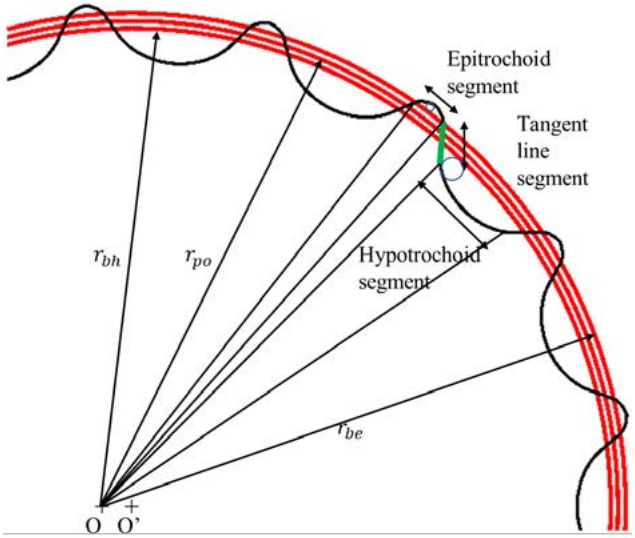

Figure 2: Geometric definition of quantities in a Kfloid profile, adapted from [3]

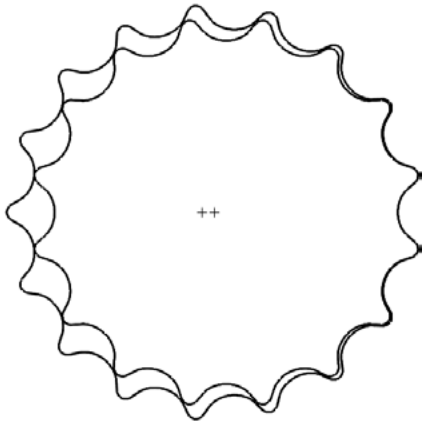

Figure 3: Example of a Kfloid gearset

The parametrization of the profile is done with the sets of uniquely defined parameters mentioned in table 1. This parametrization can be used to define either of the inner or outer gears.

In theory with the application of the law of gearing the generated Kfloid gear can be considered an inner or outer gear, but in this study the generated gear is defined as the outer gear and using the law of gearing the inner gear is generated from the defined outer gear. A resulting Kfloid inner and outer gearset is shown below in figure 3.

Parameter	**Value**	**Unit**
Number of Teeth	17	-
Eccentricity	3.190	mm
d	2.241	mm

$\Delta\theta_2$.	287.965	deg

Table 1: Parametrization used to uniquely define the Kfloid gear in figure 3.

3. GEOMETRY CODE

The geometry code implements a numerical procedure for discretizing the pump domain into displacement chambers (DCs) by identifying minimum-distance segments between the inner and outer rotors that uniquely bound each chamber and preserve continuity of the

enclosed fluid volume over a full revolution. This method is based on the approach of Pelligri et al. [14], with targeted modifications to achieve smoother chamber evolution in the vicinity of the dead-volume region. In particular, the minimum-gap criterion is selectively deactivated over a small angular interval, and the DC boundaries are interpolated to provide a continuous and physically consistent transition through this region. The parameters extracted from the geometry code are summarized in Table 2, while Figures 5(a) and 5(b) illustrate the evolution of the DC near the dead volume at shaft angles of 320° and 340°, where the modified interpolation procedure replaces the standard minimum-distance algorithm to ensure a smoother transition.

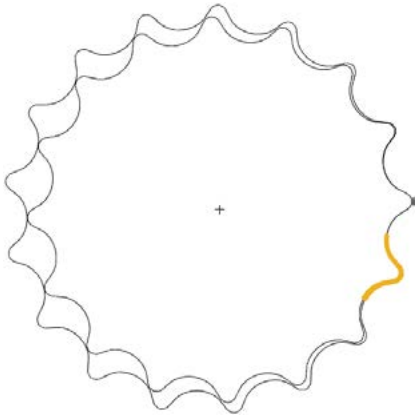

Figure 5 (b): DC definition at an angle of 340^{o} of the outer rotor rotation

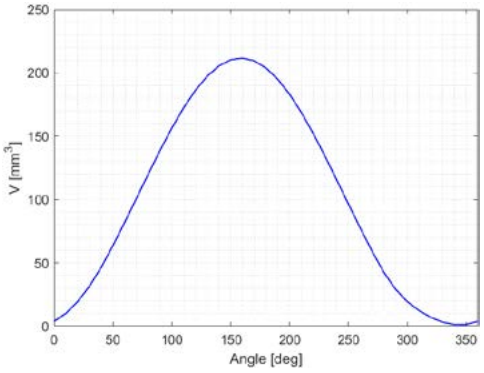

Figure 6: Resulting volume variation with the variation in outer rotor shaft angle

Parameter	Description
V	Displacement Chamber Volume (DCV) [mm^3]
h_t	Clearance gap height [mm]
Ω	DCV projected area [mm^2]
$\frac{dV}{d\theta}$	Rate of change of volume w.r.t rotation [mm^3/deg]
R_{eq}	Equivalent radius of curvature at contact point [mm]
$\hat{n}$	Contact point normal vector
v_x	Contact point velocity [m/s]

Table 2: Parameters obtained from the numerical geometry code

4. OPTIMIZATION METHODOLOGY

The gear generation and optimization framework uses the MOGA-II algorithm [17], which was selected for its suitability in handling multi-objective optimization problems through Pareto-based ranking rather than objective scalarization. This approach provides a broader understanding of the trade-offs between design parameters and helps identify an optimal family of solutions rather than a single design point. The first step of the design optimization was executed for a total of 350 generations, with the initial Design of Experiments (DOE) populated using a constraint-satisfaction sampling method to ensure that only geometrically feasible configurations were evaluated, the DOE table was populated by 100 designs in total. A numerical algorithm is used to numerically discretize the pump domain into isolated displacement chambers by drawing segments along the regions of minimum gap height, allowing for continuous variation in the computed chamber volume V(θ) along with other geometric properties of interest such as the tooth-tip gap height, the projected areas of the DCs and the curvatures of the gears in contact of the DC throughout the rotation for different rotational orientations.

Input Parameter	Min. Value	Max. Value	Unit
Number of Teeth	5	20	-
Eccentricity	0.5	5	mm
d	0.5	4.5	mm

Parameter	Constraint	Value	Unit
Gear Root Radius	Lesser than	45	mm
Connecting Segment Length	Greater than	0	mm
Gear Intersection Area	Lesser than or equal to	0	mm^2
Minimum Chamber Volume	Equal to	10^{-9}	mm^3

Table 4: Constraints applied to each generated gear design for the analytical optimization

The algorithm selects geometric parameters which are described in table 3 within the prescribed design space and scales the pump dimensions to achieve the specified displacement of 3.365 cc/rev, which is maintained constant across all configurations for consistent comparison. The variables in table 3 describes the rolling circle parameters for the inner and outer cycloids namely as the rolling circle radius, base circle shift and angle of rotation for the inner circle as b, $s_{hypo,}$ and $\Delta\theta_1$ as well as the outer circle parameters d, $s_{epi,}$ and $\Delta\theta_2$ and the outer rotor root circle radius is r_{po}. Additional constraints are imposed on the maximum allowable radius and leakage rate to prevent unrealistic or non-physical designs in the analytical optimization along with a minimum chamber volume, these constrains are described in table 4. The optimization proceeds in two stages which are described in more detail further in section 4. The first stage involves analytical screening and ranking of designs based on leakage and stress performance described in the objective functions in section 4.1, while the second stage refines the selected candidate designs using a lumped-parameter simulation of the porting system to maximize both volumetric and hydromechanical efficiencies. Designs violating any geometric constraints described in table 4 are automatically discarded, and the MOGA-II evolutionary operators iteratively evolve the feasible population toward the Pareto-optimal front. This framework is flexible and can accommodate additional objective functions such as minimizing wear or stress

concentrations within the same multi-objective optimization procedure as described later in section 4.

5. OBJECTIVE FUNCTIONS

5.1. Analytical Design optimization

The objective of this optimization is to analytically identify the top-ranked gerotor designs with minimal leakage, so they can be selected from the Pareto front and advanced to the second optimization stage. Figure 7 gives a good overview of the complete optimization procedure. The feasibility of the geometry is obtained based on the constraints in table 4 and the design evaluation is performed by the numerical geometry code which extracts the parameters listed in table 2 in order to calculate the objective functions.

5.1.1. Gerotor sizing

$$OF1: minimize\ r_o \qquad (4.1)$$

For this project the expected delivery flow from the gerotor was fixed as per the requirements of the sponsor along with the width of the pump, a scaling algorithm for the gear radius was applied to ensure that the gerotor displacement is within the specification while the radius of the pump outer rotor r_o is minimized as per the objective function given in equation (4.1) and additionally a constraint on the outer radius was applied to ensure the sizing limits of the pump. The radius is defined as the distance of the farthest point on the outer rotor from the centre of the outer rotor.

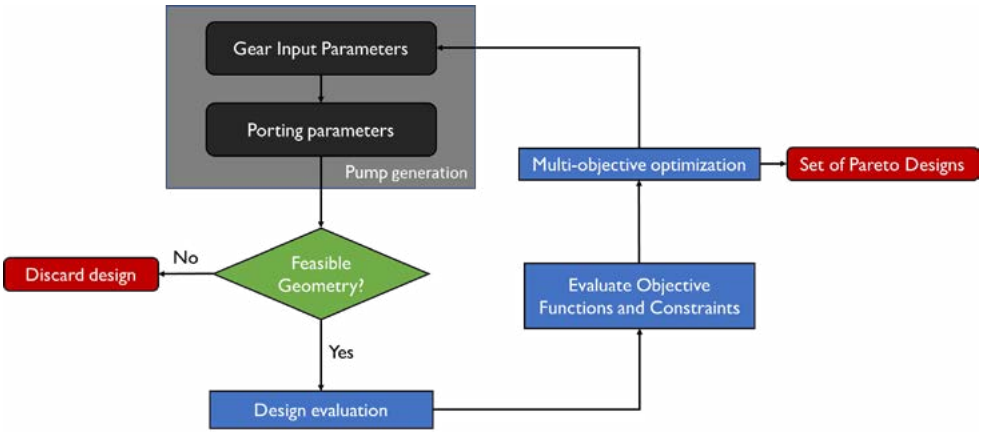

Figure 7: Algorithm for the first analytical step of the optimization

5.1.2. Flow ripple

The kinematic flow of the gerotor is defined as the sum of the outlet flows from all the DC, equations (4.2) and (4.3) describe the delivery flow rate from each DC which is defined as q_i for the ith DC. Whenever any DC is closing the negative of the volume change of the DC is defined as the kinematic delivery flow rate and when the DC is opening the delivery from the chamber is zero. The total kinematic flow (Q) is the sum of the delivery from each DC

as shown in equation (4.2) and the calculation is done assuming an incompressible fluid and no internal leakages within the pump geometry.

$$Q = \sum_i q_i \tag{4.2}$$

$$q_i = \begin{cases} -\frac{dV_i}{d\theta_i} & \frac{dV_i}{d\theta_i} < 0 \\ 0 & \frac{dV_i}{d\theta_i} > 0 \end{cases} \tag{4.3}$$

The flow pulsation and flow power are calculated and used as objectives to be minimized in the optimization, to improve flow pulsation performance and they are calculated as per equations (4.4), (4.5) and (4.6)

$$\bar{Q} = \frac{1}{N}\sum_{i=1}^{N} Q_i \tag{4.4}$$

$$Q_{peak} = \frac{Q_{max} - Q_{min}}{\bar{Q}} \tag{4.5}$$

$$OF2: minimize\ Q_{peak} \tag{4.6}$$

5.1.3. Tooth tip leakage

Tooth tip leakages are the most significant source of pump volumetric losses especially in this case where they dominate the leakage loss. To quantify the tooth-tip leakage for each design the tooth-tip leakage is calculated using the correlation provided by Rituraj et al [4] with the geometrical values obtained from the numerical discretization of the gearset. Here h is the tooth tip gap height and κ is the curvature of the tooth where the displacement chamber leakages are calculated.

$$Q_{tip} = \frac{m}{4\pi}\int_{\theta=\pi-\frac{2\pi}{m}}^{\theta=\pi+\frac{2\pi}{m}} h^{2.5}\kappa^{0.5} d\theta \tag{4.7}$$

$$OF3: minimize\ Q_{tip} \tag{4.8}$$

5.1.4. Adhesive wear

Due to the constant sliding contact that happens between gerotor teeth, quantification of wear experienced by the gerotor and optimizing the design for improved wear resisting performance is something that is important while designing a new gerotor profile. In this study the classical Archard wear model, expressed in Eq. (4.9), which states that the volume of worn material, W is proportional to the frictional work, where F is the contact force, S is the sliding distance, H is the material hardness, and K is an empirical wear coefficient. This model can be normalized with respect to operating pressure, face width, and material properties to yield a dimensionless wear rate as given in Eq. (4.10), where $\bar{F}$ and $\bar{S}$ represent normalized contact force and sliding speed, respectively, p is the operating pressure, and ω_i is the inner gear rotational speed. The normalized sliding speed can also be expressed in terms of the instantaneous velocities of the inner and outer gear contact points, v_i and v_o, and the unit tangent vector $\hat{t}$, as shown in Eq. (4.12) and the outer gear rotation speed ω_o is used to normalize the sliding velocity. The purpose of using the non-dimensional wear equation (4.10) is to express the tendency of wear irrespective of the material that is to be

used for the pump. Equation (4.11) describes the formulation of the force with is calculated using the pressure difference and the projected areas of the gear teeth and is normalized with the pressure difference and gear width. This objective function aims to minimize the maximum normalized wear rate over one full rotation, as defined in Eq. (4.13). A more detailed formulation and discussion is present in previous work of Robison et al [5-6].

$$W = \frac{KFS}{H} \tag{4.9}$$

$$\bar{W} = \bar{F}\bar{S} \tag{4.10}$$

$$\bar{F} = \frac{F}{\Delta p h} = \frac{\Delta p \sqrt{\Omega_x^2 + \Omega_y^2}}{\Delta p h} \tag{4.11}$$

$$\bar{S} = \frac{|v_i \cdot \hat{t} - v_o \cdot \hat{t}|}{\omega_o} \tag{4.12}$$

$$OF4: minimize \left\{ max\, \bar{W}(\theta_i),\ 0 \le \theta_i < \pi - \frac{2\pi}{m-1} \right\} \tag{4.13}$$

5.1.5. Contact stress

When force is transmitted between two curved surfaces, local elastic deformation occurs as the load is distributed over a finite contact region. This deformation generates both normal and shear stresses within the material, collectively referred to as contact stress. The maximum shear stress typically develops below the surface and alternates in sign across the contact plane, which may result in fatigue-induced surface damage such as pitting under repeated relative motion. In the case of a gerotor mechanism, the meshing teeth can be idealized using Hertzian contact theory as two cylinders in contact, with their radii corresponding to the local radii of curvature of the inner and outer gear flanks. The resulting peak contact pressure, p_0, is a key indicator of mechanical durability and can be normalized with respect to material properties and operating pressure as expressed in Eq. (4.14). In this formulation, E^* represents the combined modulus of elasticity defined in Eq. (4.15) as per [15], while κ_i and κ_o denote the curvatures of the inner and outer gear profiles at the point of contact. The Poisson's ratios of the respective gears, ν_i and ν_o, together with their elastic moduli E_i and E_o, determine E^*. The maximum value of p_0 observed over a full revolution is used as the objective function Eq. (4.16), further discussion can be found in earlier studies by Robison et al [5, 6].

$$\overline{p_0} = p_0 \sqrt{\frac{\pi}{E^* \Delta p}} = \sqrt{\bar{F} |\kappa_i + \kappa_o|} \tag{4.14}$$

$$\frac{1}{E^*} = \frac{1-\nu_i^2}{E_i} + \frac{1-\nu_o^2}{E_o} \tag{4.15}$$

$$OF5: minimize \left\{ max\, \overline{p_0}(\theta_i),\ 0 \le \theta_i < 2\pi + \frac{2\pi}{m-1} \right\} \tag{4.16}$$

5.1.6. Lateral gap leakage

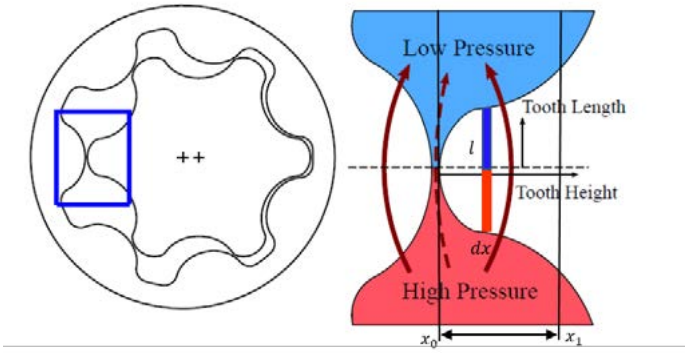
Lateral gap leakages in gerotor pumps arise through the thin clearances between the rotor side faces and the pump casing or endplates. Each differential section of a tooth along its axial height can be modelled as a Poiseuille flow between parallel plates, where the pressure

difference acts laterally across the tooth width as is illustrated in figure 8. Assuming constant gap height, viscosity, and pressure difference, the leakage flow can be obtained by integrating the Poiseuille equation over the lateral direction of the tooth for each of the inner and outer gears, leading to a total leakage for each tooth as per equation (4.17), a more detailed description of the equation can be found in [6].

$$\overline{Q_L} = \frac{3Q_L\mu}{2h_z^3\Delta p} = \int_{x_0}^{x_1} \frac{1}{l} dx \qquad (4.17)$$

Where h_z is the lateral gap height, μ is the fluid viscosity, and l is the lateral flow length at a particular section. This expression can be normalized by the pressure difference to emphasize the geometric and fluid property dependencies, showing that longer, narrower teeth permit greater lateral leakage, whereas higher viscosity or improved axial sealing reduces it. Thus, while lateral leakages can theoretically contribute to volumetric losses, they remain negligible in well-sealed pumps with appropriately controlled axial clearances.

$$OF6: minimize\ \overline{Q_{L,i}} + \overline{Q_{L,o}} \qquad (4.18)$$



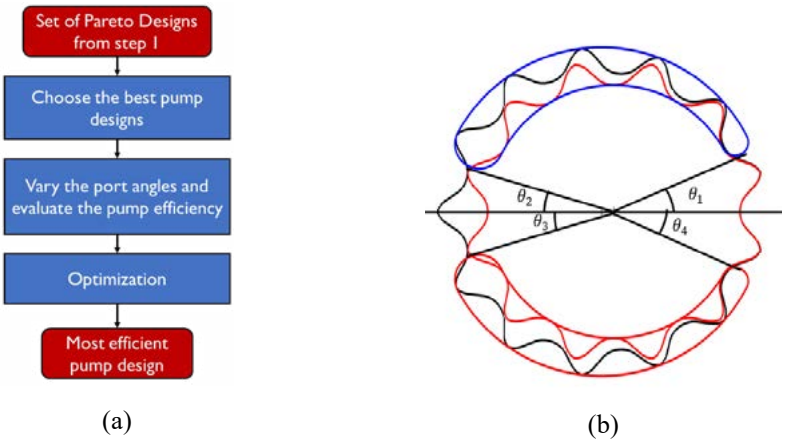


Figure 8: Representation of lateral gap leakage losses

5.2. Porting optimization

The porting optimization only has the objective to maximize the volumetric efficiency for every port angle of the design obtained from the multiple objective analytical optimization, multiple simulations were run where a lumped parameter based method was used to optimize the angular span of the porting considering the efficiency to be maximized in a manner similar to what is shown in figure 9 (a). The angular span of the porting geometry was parametrized as shown in figure 9 (b). To ensure the symmetric geometry for bidirectional operation of the pump the values of the four porting angles can be expressed with the parameters $\hat{\theta}_1$ and $\hat{\theta}_2$ as equations (4.19) and (4.20), while the volumetric efficiency was evaluated using equation (4.21) where Q_{sim} is the outflow predicted from the simulation in one revolution and V_{max}, V_{min} are the maximum and minimum values of the DCV that is predicted. For this study the parameters $\hat{\theta}_1$ and $\hat{\theta}_2$ were set to the range $\in [1, 2]$, while a 2D heat map could have been used to illustrate the performance variation of the pump with porting angle variation an optimizer which seeks the best combination was

considered to be a better alternative. Also, all the simulations for the optimization are performed at a high pressure difference Δp of 100 bar and a shaft speed of 4000 RPM.

(a) (b)

Figure 9: (a) Algorithm for the second step of the optimization and (b) Representation of the angular parametrization of the porting.

$$\theta_1 = \theta_4 = \hat{\theta}_1 \cdot \frac{180}{m} \quad (4.19)$$

$$\theta_2 = \theta_3 = \hat{\theta}_2 \cdot \frac{180}{m} \quad (4.20)$$

$$\eta_{vol} = \frac{Q_{sim}}{mN \cdot (V_{max} - V_{min})} \quad (4.21)$$

6. RESULTS

For the first step optimization, a total of greater than 35000 designs were evaluated out of which there were around 2700 pareto designs. The resulting pareto fronts are plotted as shown in figure 10 and an industry pump whose specification are provided by the sponsor is used as a reference for the comparison of the performance, here the reference pump is represented as a red dot with a black outline to highlight it. In the pareto fronts shown in figure 10 while the pumps with the best leakage performance are chosen from the leakage pareto front. The leakage performance of the new profile is seen to be within the range of the reference profile, but this profile can be seen to have a big advantage particularly when it comes to the wear performance in which the chosen pareto designs have almost an order of magnitude better performance in comparison to the reference cycloidal design. Additionally, design clusters can be observed with respect to the leakage performance which can be attributed to the clusters of similar geometrical designs with small variations in parameters, the designs shown in figures 11 (a) and (b) are two such best performing designs from design clusters having low leakages.

The figure 11 (a) and (b) show the geometry of the pumps chosen with the best leakage characteristics while (c) and (d) shows the maps of the efficiency plotted against the angular span of the ports. While table 5 describes the geometric parameters chosen for each gear design. The best performing design out of which has an efficiency (η_{vol}) of 97.5%.

7. CONCLUSIONS

A gear generation algorithm was developed to fully define the geometry, size, and other key parameters of a Kfloid-type gerotor pump. The Kfloid profile was subsequently optimized using modeFRONTIER in conjunction with Multics through a two-stage process aimed at maximizing volumetric efficiency for a specified delivery and pump size. A distinct Pareto front was established, and the optimized designs were compared with a reference industrial cycloidal type pump. The results indicate a modest improvement in volumetric efficiency, while the predicted trends suggest significantly better wear resistance and reduced flow ripple for the optimized Kfloid profiles. On comparing the resulting designs from the clusters that were formed as mentioned in section 6 we can see that design (a) has better lateral leakage performance compared to (b) due to the longer tooth geometry and on comparing the stress performance (b) performs better than (a) since geometry (b) has lower curvatures thus resulting in better stress performance.

Future work can focus on exploring mixed gerotor configurations with thinner teeth, similar to the Parafloid, Megafloid, and Geocloid profiles [6,7], with particular attention to hybrid geometries employing involute driving flanks due to their favourable drive characteristics [8].

8. ACKNOWLEDGEMENTS

The authors gratefully acknowledge ESTECO for providing access to the modeFRONTIER multi-objective optimization platform, which was used in this work to perform the numerical optimization studies.

Abstract.

Recent advancements in electric drive technology are enabling new applications in hydraulics, particularly in valve actuation. New electric actuators based on stepper or BLDC motors offer higher forces and virtually unlimited stroke lengths, making them viable alternatives to conventional solenoids, especially for large hydraulic valves that have traditionally required hydraulic pilot systems. These actuators have already been successfully utilized in mobile machinery, where they enable the direct actuation of large valves, resulting in a simplified system architecture and improved efficiency. However, in stationary hydraulics, direct electromechanical actuation nowadays is limited to valves of NS10 due to the high forces required. Whereby the flow and spring forces constitute the most significant share of the total actuation force. This work investigates strategies for reducing flow forces to enable direct actuation of NS16 proportional valves with the actuators mentioned before, based on electric motors. Based on theoretical analysis, design modifications on the spool and housing/sleeve for flow force reduction are identified and evaluated using CFD simulations and measurements. The resulting optimized valve design significantly reduces actuation force requirements, providing a feasible pathway for direct electromechanical actuation of larger industrial valves and eliminating the need for pilot stages.

Keywords. Pilot Controlled Valves, Direct Valve Actuation, Flow Force Reduction, Experimental, CFD-Simulation

1. INTRODUCTION

The use of stepper motors for controlling hydraulic valves in mobile machinery has been explored since the 1990s. Started when the hydraulic pilot control of a tractor's lift valve was replaced by an electromechanical actuator based on a stepper motor back in 1995 [1]. Followed by the direct actuation of the front loader valve in 2000 [2]. One of the key motivations for this research was the potential to simplify the overall system by eliminating the separate pilot-control circuit that had been necessary up to that point [2]. Additionally, other significant advantages of stepper motor-based valve actuators were emphasized, including their high rigidity and force capabilities, as well as their ability to achieve stable and precise positioning [1].

All Open Access articles are peer-reviewed, distributed under the Creative Commons Attribution-Non Commercial 4.0 International

While the application of stepper motors was reported only sporadically in the 1990s and subsequent years, there has been a notable increase in activity over the last ten years regarding stepper motor-based electromechanical valve actuators. These developments have primarily been driven by the company SONCEBOZ, which has been publishing articles on the subject since 2014, presenting the latest research findings on their S42 and S40 actuators. That this research addresses market demands is evident, as Sonceboz is not the only company active in this field. For example, there was another actuator based on an electric motor presented by THOMAS MAGNETE at the 9th IFK. Both actuators the S40 by SONCEBOZ and the EMA by THOMAS MAGNETE are shown in **Figure 1**. [3]–[8]

Figure 1: S40 Actuator by Sonceboz [4], [9] and EMA-Actuator by Thomas Magnete [8]

Although the discussion about motor-based valve actuators is primarily led by individual companies that are active in the field of electromechanical actuation, while focusing their research on their specific actuators to enhance performance and extend their limits further, there has also been a growing momentum in university research in recent years. In contrast to the aforementioned company-led research, university studies focus on decreasing the necessary actuation forces [10]–[17] or fundamental analyses of pilot-controlled valves aiming to optimize their performance [18]–[20].

Overall, it is evident that direct control of large valves has been increasingly discussed in research and application for about a decade, and the first market-ready actuators are now available [4]–[6]. Compared to solenoid magnets, they are characterized by higher forces and a significantly longer stroke. Performance data of these actuators can be looked up at the individual homepages or in [8]. However, current in-field applications are mostly limited to the field of mobile machinery, where they have already been introduced in some product series on the market to directly control valves with flow rates of up to 100 l/min, see e.g. the LCV from Bucher Hydraulics [5]. In this case the actuators are used in combination with a pressure balance valve, which means that the differential pressure across the valve is always constant, limiting the maximum flow rate to the nominal flow rate chosen during the design process.

Even though the disadvantages of hydraulic pilot control, such as the sensitivity of the position regulation quality of pilot-operated valves to pressure fluctuations, contamination, and low temperatures, are particularly significant in the field of mobile machinery, it seems obvious to use these actuators also in industrial hydraulics to push the limits of direct pilot control above NS10. In contrast to applications with pressure balancing valves commonly

used in the field of mobile machinery, the flow rates in industrial valves can be much greater than the nominal flow rate, as a pressure balancing valve does not control the pressure difference over the valve. While valves of NS10 in the standard market range have a minimum nominal flow rate of around 30 l/min and a maximum flow rate of 75 l/min (see **Figure 2**), the flow rate increases to around 100 l/min and 460 l/min, respectively, for the next larger NS16 valves (see **Figure 3**). Consequently, the flow rates controlled by NS10 valves are smaller compared to those already achieved in known mobile applications. For NS16 valves, on the other hand, although the nominal flow rates remain comparable, the maximum flow rate can exceed 100 l/min by four times.

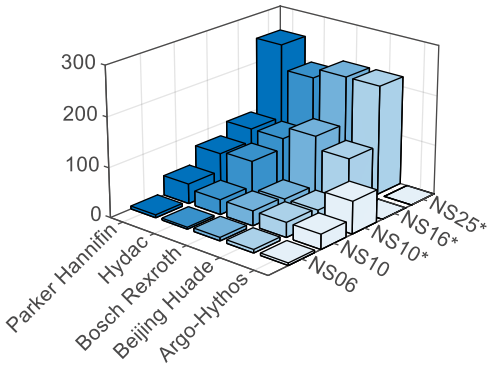

Figure 2: Nominal flow rate of proportional valves of different nominal sizes and manufacturers

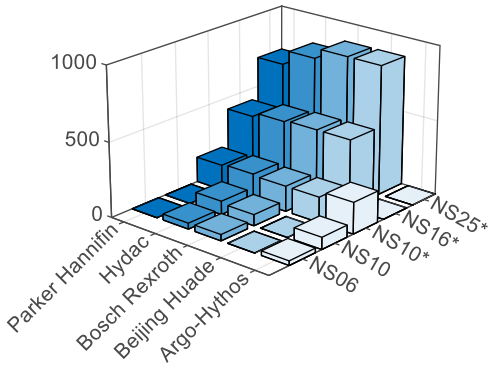

Figure 3: Maximum flow rate of proportional valves of different nominal sizes and manufacturers

In most cases, an increase in flow rate and valve size results in higher stroke and actuating force, unless the valve design has been specifically optimized to counteract these effects. For valves NS16, this typically results in forces and strokes that exceed the capabilities of conventional solenoids, which is why they are generally pilot-operated. Together with its industrial partner KMS Stoßdämpfer GmbH, ifas is currently working to demonstrate that the availability of previously presented actuators based on stepper or BLDC motors has opened up further potential for the direct control of larger valves in the field of industrial hydraulics. This is the first step towards shifting the application limit for direct control from NS10 to NS16 and making corresponding valves available on the market, thereby unlocking the associated potential for system optimization and performance enhancement.

This contribution not only aims to develop the initial step towards a directly controlled NS16 industrial valve but also employs systematic analysis to demonstrate how flow forces on spool valves can be reduced through appropriate geometric optimization. These findings can be applied to other valves from various manufacturers and in different sizes, facilitating a general evaluation of the feasibility of direct electromechanical control for larger valves using actuators based on stepper or BLDC motors.

2. NEW DIRECT DRIVEN PROPORTIONAL VALVE NS16

A central aspect of the project was the development of an optimized NS16 hydraulic main stage, characterized by low operating forces. To this end, the first step was to develop a functional hydraulic main stage with a nominal flow rate of 125 l/min and a maximum flow

rate of 400 l/min achieved at a pressure difference of max 70 bar over the metering notch. To keep the radial flow forces as low as possible and at the same time enable easy adjustment of the internal geometry, the valve was designed as a sleeve valve. This allows systematic investigation of different geometries for the spool and sleeve to demonstrate the potential for reducing flow forces. A cross-sectional view of the prototype is shown in **Figure 4**.

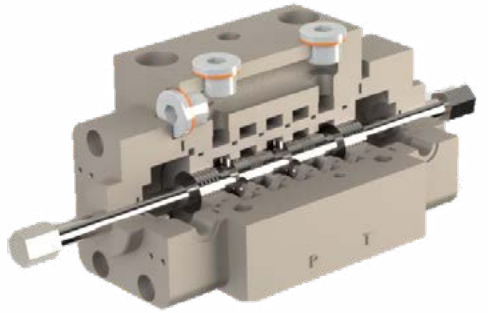

Figure 4: CAD of the developed direct driven main stage

2.1. Force Requirements

Since the valve cannot be actuated if the generable forces are insufficient, achieving an appropriate actuating force is a fundamental requirement for the implementation of direct electromechanical actuation. To determine the necessary actuating force, all forces acting on the spool must be analyzed. **Figure 5** shows a corresponding spool with all the forces acting on it. These are usually the spring forces F_C, friction forces F_R, flow forces F_{Flow}, and the actuating force F_{Act}.

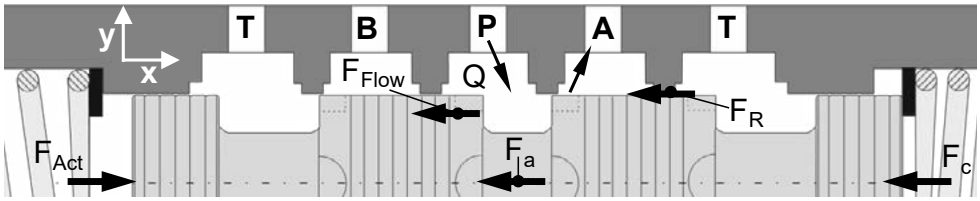

Figure 5: Forces acting on the slide of a globe valve according to [21]–[23]

Within the illustration, the spool is assumed to be deflected in the positive x-direction, with positive velocity and acceleration. Friction (F_R), inertial forces (F_a) and spring forces (F_C) therefore act in the negative x-direction, and the actuating force (F_{Act}) exceeds the sum of all these opposing forces. Since this is a standard design without any flow force compensation geometries, it can be assumed that the flow forces (F_{Flow}) act in the closing direction and thus in the negative x-direction. In this case, the force balance on the spool can be formulated according to **Equation 2.1**.

$$F_{Act} = F_a + F_C + F_R + F_{Flow} \tag{2.1}$$

To keep the required force as low as possible, all opposing forces must be minimized. However, each one can only be reduced to a limited extent due to their causes or functions.

2.2. Inertia Forces

Since inertial forces are defined by mass m and acceleration $\ddot{x}$ for a given acceleration profile, they can only be reduced by decreasing the mass. However, this is only possible to a limited extent, as both the shape and material of the spool cannot be chosen arbitrarily. For the valve considered in this contribution, the inertia force was estimated assuming that the spool must travel the full stroke of 7.5 mm within 50 ms, accelerating until the midpoint of the stroke followed by a subsequent constant deceleration. With a mass of 300 g this leads to an inertia force of 18 N.

2.3. Frictional Forces

In the context of pilot-operated valves, friction forces typically refer to those forces acting between the spool and the housing or sleeve. According to common models, these forces consist of a Newtonian and a Coulombian component. They always oppose the direction of movement and thus have a damping effect on the valve spool motion. The choice of material, the fit between the spool and the sleeve, and the radial flow forces influences friction. A careful trade-off must be made in terms of this fit. It must be tight enough to prevent excessive leakage but not so tight that frictional forces become too large.

2.4. Flow Forces

Flow forces are generally defined as the sum of the forces caused by the flow of fluid. These are usually forces resulting from uneven pressure distribution, viscous friction forces, and inertia and acceleration forces of the fluid [24], [25]. The law of conservation of momentum is usually used to derive a usable equation**.** Thereby, a control volume defined in the flow area between the spool, and the housing is used to calculate the flow force, see **Figure 6**. At the selected control volume, the flow Q enters the control volume at the P port at a velocity $\vec{v}_1$ at an angle of ε_1 and leaves the system at a velocity $\vec{v}_2$ at an angle of ε_2 at port A.

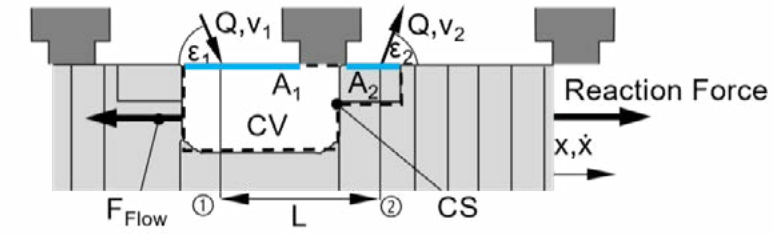

Figure 6: Derivation F_{Flow} using the law of conservation of momentum [22], [26]–[29]

Using Reynolds' transport theorem, the equation for the flow forces can be written according to **Equation 2.2**.

$$\sum \vec{F} = \frac{d}{dt}\left(\int_{CV} (\rho \cdot \vec{v}) dV\right) + \int_{CS} \rho \cdot \vec{v}(\vec{v} \cdot \vec{n}) dA \qquad (2.2)$$

The flow forces are derived analytically from the temporal derivative of the integral of density ρ and the velocity vector $\vec{v}$ over the volume V of the control volume CV, added to the integral of the product of density ρ, velocity vector $\vec{v}$ and the scalar product of velocity vector $\vec{v}$ with direction vector $\vec{n}$ integrated over the area A of the whole control surface (CS). The first part of the equation describes the unsteady flow force and thus forces related to the

inertia and acceleration of the fluid, while the second term describes the steady state flow forces. While steady state axial flow forces have been well researched today, the number of studies dealing with the unsteady flow force is considerably lower. However, these studies show that the unsteady flow force for slow and moderately switching valves is considerably lower than the steady state flow forces. The assumption of quasi-steady state that is usually made, therefore, can generally be considered valid [30].

2.4.1. Axial Flow Forces

Using the orifice equation and assuming constant fluid density, ideal rotational symmetry, sharp metering edges, and a negligible clearance between the spool and the sleeve, the equation for the steady-state axial flow force for one metering edge can be expressed as follows [27], [31].

$$F_{Flow,\mathrm{axial,stat}} = 2\alpha_D^2 \cdot \pi \cdot d \cdot x \cdot \Delta p \cdot \frac{\cos(\varepsilon_1)}{\sin(\varepsilon_1)} \tag{2.3}$$

While measuring the axial flow forces, frictional forces typically superimpose on them. As a result, plotting the measured force against position usually produces a hysteresis loop (see **Figure 7**).

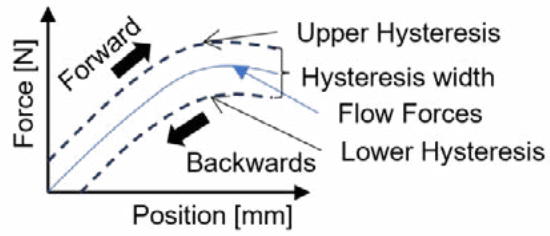

Figure 7: Illustration of measured forces: Hysteresis and flow forces

Assuming the frictional forces are equal in both the opening and closing directions, the axial flow forces are centered within the hysteresis, with half the width of the hysteresis corresponding to the frictional force. [21], [22], [27], [32]

2.4.2. Radial Flow Forces

For the radial flow forces, Equation 2.2 must be integrated over the circumference of the spool. With an ideally rotationally symmetrical geometry and an ideally rotationally symmetrical flow, these forces would completely compensate each other, resulting in a total net force of 0 N. In reality, however, perfect rotational symmetry of geometry and flow profile is rarely achieved, so that radial flow forces usually still occur. An increase in the nominal forces acting on the spool results in higher Coulomb friction forces; consequently, variations in the hysteresis width may reflect changes in the radial flow force [32].

2.4.3. Spring Forces

For 4/3-way valves, the rest position defined by the springs can be either one of the two switched positions (A or B) or the center position (0). In Figure 5, a valve with a blocked center position is shown, in which both springs push the spool into the center position. Since

a secure rest position must always be ensured and reached within a specified time, the springs must be designed accordingly. In the case of pilot-controlled valves, the required actuating force usually does not need to be considered, as forces in the kN range can typically be achieved. Therefore, in proportional valves, springs are chosen to have high stiffness in order to achieve high accuracy within the control loop [33].

However, stepper motors are inherently capable of moving to a defined position. Even when operated in a closed-loop position control system via the motor controller to improve accuracy, spring stiffness has only a minor influence on position control. Given the limited forces available from electromechanical actuators, it is therefore advisable to design the spring with the lowest possible stiffness while selecting the highest possible preload force. Selecting a suitable spring within the available installation space presents a separate optimization problem. Nevertheless, to achieve the highest possible spring force and thus minimize return time while considering the limited actuation forces, all other opposing forces must be kept as low as possible, which is why flow forces need to be reduced.

3. PRINCIPLES FOR FLOW FORCE REDUCTION

The reduction of flow forces by optimizing spool geometries is a widely researched topic and is regularly discussed in the technical literature [10], [13], [15]–[17], [34]–[38]. However, most studies focus on servovalves, with optimizations that are difficult to adapt to proportional valves with metering notches. Therefore, this contribution investigates geometric optimization methods for reducing flow forces that can be applied to proportional valves with metering notches. Based on theoretical, analytical, and literature-based considerations [11], [12], [14], [16], [35], [37], [39]–[41], possible geometric optimizations for the spool and sleeve were identified. Their potential to enable direct actuation by electromechanical actuators through the reduction of flow forces is investigated in a systematic study on the NS16 main stage developed as part of this work. For the evaluation of this potential, a non-optimized proportional valve, shown in **Figure 8**, serves as the reference. The geometric optimizations investigated are illustrated in **Figure 9**.

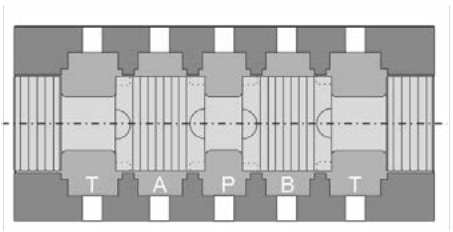

Figure 8: Spool without features

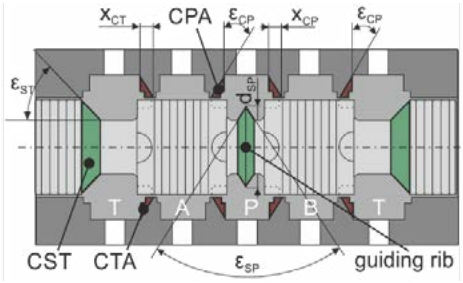

Figure 9: Spool with features

Compared to the non-optimized geometry, Figure 9 shows areas in green where additional material needs to be added, and areas in orange where material must be removed. For the sleeve, adding a chamfer to the partition between the valve chambers was identified as a

promising way to achieve sufficient flow guidance and thereby reduce flow forces. Two geometric parameters are required to fully define this chamfer the angle ε and the chamfer length x. At the Port P, it is referred to as chamfer CPA and defined by the parameters x_{CP} and ε_{CP}. At the Port T, it is referred to as chamfer CTA and is defined by x_{CT} and ε_{CT}. For the spool, a centrally located guiding rib at the geometric center and an additional chamfer at the outer shoulder of the T-Port were identified as possible optimizations for reducing flow forces. The guiding rib can be fully described by d_{SP} and ε_{SP}, while the chamfer CST is characterized by the angle ε_{ST}. Whereas the guiding rib and chamfer CST are established features used in prior studies and industrial applications to reduce flow forces (see [11], [12], [14], [16], [35], [37], [40], [41]), the sleeve chamfers represent an optimization derived from theoretical considerations.

In order to achieve the most efficient reduction in flow forces based on the reference geometry, the influence of the geometric features was analyzed in a three-step process consisting of two simulation steps carried out with ANSYS Fluent CFD-Software and one experimental step. The first step involved a statistical analysis whereby a parameterized CAD model was imported into the simulation software, and simulation points were generated and solved using an optimally space-filling design. Response surfaces were then derived from these simulations to assess the influence of each feature. Subsequently, each feature was simulated individually to determine suitable parameters. As a result, four valve geometries incorporating the identified measures were manufactured and tested experimentally.

To keep the simulation effort manageable, it was important to minimize the computational domain in the CFD simulations. Therefore, the valve was divided into two separate models, each examined individually. The first model, system P, includes the P-port and one working port (A), allowing investigation of flow from P to A. The second model, system T, includes the other working port (B) and the T-port, enabling analysis of flow from B to T. This division made it possible to specifically study both flow scenarios and to investigate the features separately, while also reducing computational complexity.

3.1. Validation of CFD Simulation

To validate the CFD simulations, the reference geometry was first manufactured and measured. The ifas has a measuring device and a test bench available for this purpose. The measuring device consists out of a stepper motor, whose rotational motion is converted into linear motion via a threaded rod and nut assembly with a pitch of 3 mm. A force sensor is integrated into the connection between the actuation unit and the spool to measure the forces which are acting on the spool. To minimize the influence of transverse forces on the measurement, a combination of clevis and head joints was implemented. Additionally, prior to the measurement, the device was carefully aligned with the valve spool. Therefore, the actuation mechanism was moved over the full stroke to ensure that resulting friction forces were as low as possible. Additionally, a position sensor was incorporated to monitor the position of the spool. A similar actuation device also designed by ifas has been described in [42].

The circuit diagram of the test rig can be found in [43]–[45]. While this configuration enables measurement of the forces acting on the spool during flow from the pressure port

(P) to either of the working ports (A or B), as well as during overall flow through the valve (PABT/PBAT), it does not permit individual measurement of flow from either working port (A or B) to the tank port (T). Consequently, separate analysis of the return flow paths (AT or BT) is not possible.

For the reference geometry, the target flow rate of 400 l/min was achieved at a pressure difference of 60 bar, while at a pressure difference of 5 bar, a flow rate of 125 l/min was achieved. In line with theoretical expectations, an increase in pressure difference resulted in a corresponding increase in flow force. Consequently, operation at a pressure difference of 60 bar led to the highest observed flow forces within the pressure range (5 – 60 bar). The results of the simulations and measurements for a pressure difference of 60 bar for the system P (Flow from P to A) of the reference geometry are shown in **Figure 10**. Within the simulation the mesh consists of around 13 Mio Cells with local refinement within relevant areas like the metering notches or the inlet and outlet. The average orthogonality was 0.9662 and the skewness 0.03381.

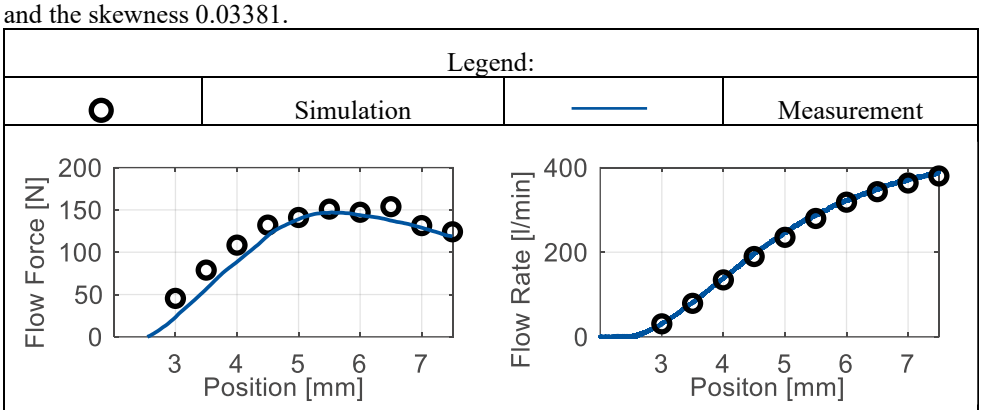

Figure 10: Comparison Simulation Measurement for Flow Rate and Flow Force

As can be seen in the graphs, the simulation results correspond very well with the measurement data. The CFD simulation can therefore be used to generate reliable results in terms of both flow rate and flow forces for the considered system P of the reference geometry.

3.2. Statistical Evaluation of Principles (CFD-Simulation)

The following **Figure 11** to Figure 14 show examples of the response surfaces for the guiding rib feature, illustrating the influence of the parameters diameter d_{SP} and angle ε_{SP}. Since both the flow force and the flow rate must be considered over the entire range of spool positions x, the visualizations are presented as three-dimensional characteristic maps. The resulting flow force F_{Flow} and flow rate Q are plotted on the Z-axis, spool position x on the Y-axis, and the value of each geometric feature under investigation (e.g., d_{SP} and ε_{SP}) on the X-axis. This form of representation enables a detailed analysis of how spool position and geometric features interact to affect flow force and flow rate.

As shown in **Figure 11**, the guiding rib is particularly effective for large valve openings (X) and large diameters (d_{SP}). For diameters greater than 20 mm, even negative forces are achievable, which means that the system is overcompensated and the flow force is acting in opening direction. However, selecting a large diameter d_{SP}, may negatively affect the flow

rate characteristic curve. This can be seen in **Figure 12**, where the flow rate drops for diameters larger than 20 mm. By appropriately selecting the diameter d_{SP}, it is possible to reduce the flow force without adversely impacting the flow rate characteristic for example with diameters of maximum 20 mm. **Figure 13** and Figure 14 show the response surfaces for the angle ε_{SP} of the guiding rib. As can be seen the angle ε_{SP} of the guiding rib has a relatively minor influence on the flow force. Angles around 100° result in a maximum flow force, whereas both smaller and larger angles have a slightly positive effect by reducing the flow force. At the same time, the impact of angle ε_{SP} on the flow rate characteristics is very small.

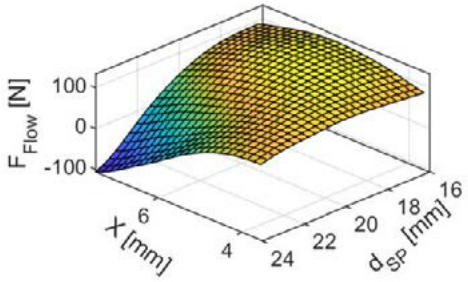

Figure 11:Response Surface F_{Flow}-X-d_{SP}

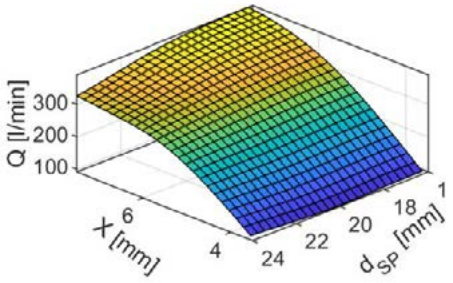

Figure 12: Response Surface Q-X-d_{SP}

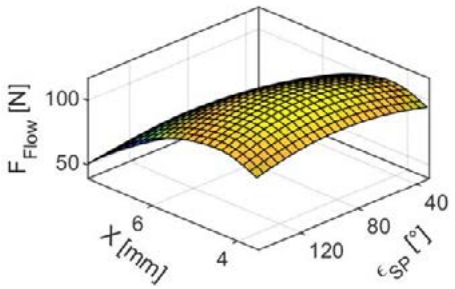

Figure 13: Response Surface F_{Flow}-X-ε_{SP}

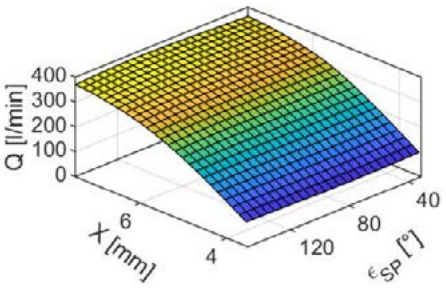

Figure 14: Response Surface Q-X-ε_{SP}

3.3. Simulation of the various concepts

In statistical analysis, the influence of individual features can be evaluated quickly and efficiently. However, assessing combined effects is significantly more complex. After it was proven that all features can have a positive effect, their influence was systematically analyzed in a second step to identify optimal design parameters. As the key objective of this investigation was to identify the potential of each individual design feature for reducing flow forces, a targeted exploration of the design features was preferred over deriving a statistical model in the following. This approach enables a direct and transparent assessment of each feature's contribution to flow force reduction. Initial parameters for each feature were selected based on the prior results, and then individual parameters were systematically varied to identify suitable values for each feature.

From the results, two promising configurations for both the spool and the sleeve were selected, each with and without optimization features. This allowed four different valve

configurations to be formed. $Spool_{Ref}$-$Sleeve_{Ref}$ without any feature, $Spool_{Opt}$-$Sleeve_{Ref}$ with features in the spool, $Spool_{Ref}$-$Sleeve_{Opt}$ with features in the sleeve and $Spool_{Opt}$-$Sleeve_{Opt}$ with features applied to both the spool and the sleeve. By the different combinations, the effectiveness of each feature could be examined separately and in combination. The selected geometric values were as follows. The angles ε_{SP}, ε_{ST}, ε_{CP} and ε_{CT} were set to 45°, the removal depths $X_{CP\ and}$ X_{CT} to 5 mm and the diameter d_{SP} to 22 mm.

Simulation results for these geometries at a pressure level of 60 bar are presented in **Figure 15** and **Figure 16** (system P) and **Figure 17** and **Figure 18** (system T). The simulation results of system P show that all features are effective in reducing flow forces. However, the guiding rib feature can negatively affect the flow rate characteristic, as the flow rate decreases for strokes greater than 5 mm. This negative effect can be avoided when the guiding rib is combined with the chamfer in the sleeve.

For the system T, it can also be concluded that all features have a positive effect, with no negative impact on the flow rate characteristic curve. Notably, in the $Spool_{Opt}$-$Sleeve_{Ref}$ and $Spool_{Opt}$-$Sleeve_{Opt}$ configurations, the chamfer at the spool leads to an opposing flow force for strokes greater than 4 mm respectively 6.5 mm, resulting in overcompensation.

Figure 17: Simulation Results Flow Forces System P

Figure 18: Simulation Results Flow Forces System T

4. EXPERIMENTAL EVALUATION OF COMBINED PRINCIPLES

Once the effectiveness of the features had been identified through simulations, all versions were evaluated experimentally. To this end, the two spool and sleeve variants were manufactured and measured in their respective combinations. Measurements were conducted for system P, where flow occurs from P to A, as well as for the combined system PT, where flow occurs from P to B and from A to T, using the available test bench. Unfortunately, it was not possible to measure system T separately due to limitations of the existing test rig. Therefore, only the simulations result of system A can directly be compared with measurement data. The simulations result of system T can only be analyzed using the measurements of system P and PT, as by comparison between both systems the effectiveness of the features of system T can be identified. The measurement results are shown in **Figure 19** to **Figure 22.**

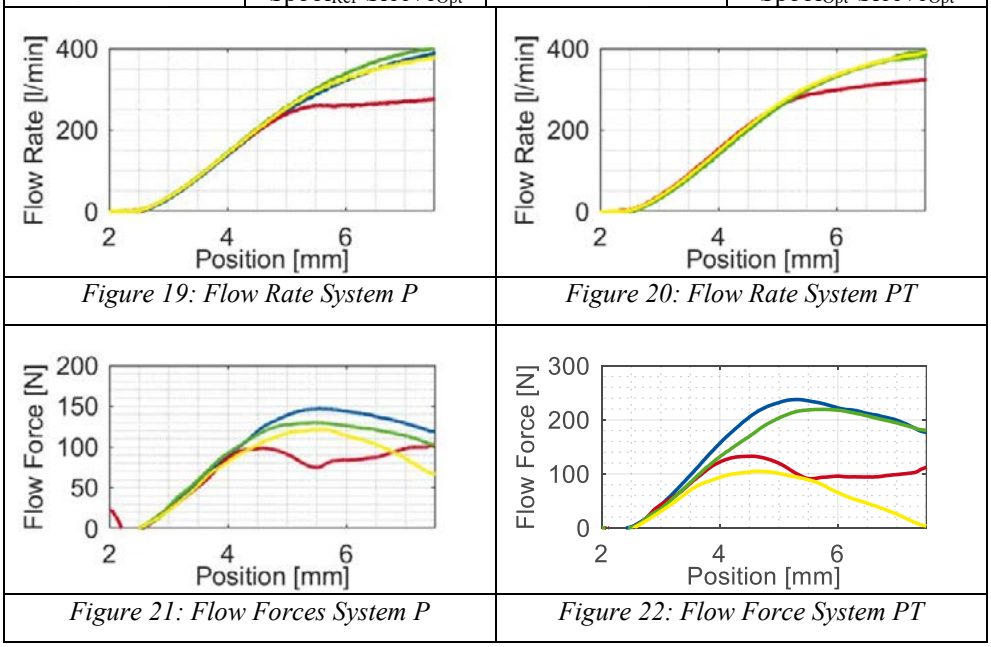

Figure 19: Flow Rate System P

Figure 20: Flow Rate System PT

Figure 21: Flow Forces System P

Figure 22: Flow Force System PT

The measurement data show that the configuration without optimization features exhibits the highest flow forces, and that applying the features produces the expected effects, as anticipated from the CFD simulations. Implementing the features on the spool alone leads to a reduction in flow force; however, this is accompanied by a decrease in flow rate, as assumed from the simulation whereby the impact is underestimated within the simulation. Within simulations conducted at a pressure difference of 70 bar, the effect was considerably more pronounced. It remains questionable whether the observed reduction in flow force is genuinely due to the optimization or simply a result of the lower flow rate. Optimizations to the sleeve show a positive effect, with a reduction of 12 %, although this is significantly less

than predicted by simulation. The same applies to the combination of both measures. In this case, flow forces were reduced by 18 %, indicating a clear positive effect but still falling short of the optimistic simulation results. When only the system P is flowed through, the proposed features lead to a reduction in flow force of 18 %. When both PB and AT are evenly flowed through, an even greater reduction of 65 % is achieved.

Since simulations appear to overestimate the potential of sleeve optimization, further analysis is required to determine the reason for this discrepancy and improve the simulation models. In this study, CFD was employed as a design tool to efficiently investigate the effects of various geometric features on flow forces. By systematically screening a large number of design variants through simulation, it was possible to identify promising designs for experimental validation without having to manufacture each individual parameter set. This approach allowed for a significant reduction in the number of required measurements and enabled efficient identification of improved geometries. Consequently, further refinement of the simulation models be desirable for future valve improvements, however such optimization of the simulation model lies beyond the scope of this contribution

5. SUMMARY AND OUTLOOK

Over the past ten years, new actuators based on stepper and BLDC motors have been tested for use in mobile hydraulics and have also been introduced to the market in some products. Compared to conventional solenoids, these actuators are characterized by higher forces and strokes, making them a viable alternative to hydraulic pilot control. Direct control offers several advantages over hydraulic pilot control, especially in mobile machines where highly fluctuating loads, operation with cold fluid during startup, and heavy fluid contamination are common conditions. Due to their increased forces and strokes, these actuators also have potential applications in stationary hydraulics. In this context, they could help shift the system limit for direct control from NS10 to NS16.

However, the maximum possible flow rates in stationary hydraulics are considerably greater than those in mobile applications, which increases demands on the actuator. While spring forces should be minimized overall, maximizing them within the limits of the actuator's maximum capacity helps to minimize reset times and enhance system safety. Therefore, reducing flow forces is essential.

Within the scope of this contribution, various flow force compensation design features that can be implemented on conventional proportional spools and sleeves/housings were identified, analyzed and investigated by simulations and measurements for their potential to reduce flow forces. Overall, flow forces could be reduced by 18 % percent compared to a reference spool without optimization measures. In particular, the chamfer in the sleeve (ε_{CP}, x_{CP}) and the additional angle ε_{ST} on the spool demonstrated high potential for reducing flow forces while having only a minor impact on the flow rate characteristic curve. The addition of a guiding rib also resulted in a reduction in flow forces, however, if not correctly designed, it can negatively affect the flow rate characteristic curve.

The reduction in flow forces achieved helps to keep the total required actuating force as low as possible. Depending on the selected spring, the necessary actuating forces may be matched to the maximum output of modern actuators. Therefore, reducing flow force is a decisive step toward enabling direct electromechanical control of large valves.

Abstract.

Initial cleanliness of hydraulic components is vital for system reliability and longevity. Existing on-line oil condition monitoring technologies, though advanced, cannot verify baseline cleanliness before assembly. To address this limitation, a novel device was developed that combines component flushing and cleanliness evaluation in a single process. The system features a dual-pump configuration: one pump performs high-flow flushing and sampling, while the other circulates and filters a glycol-water fluid. Flow is controlled through valves, and contaminants are collected under vacuum onto membrane filters for microscopic evaluation per ISO 4407 and rated using ISO 4406. A key innovation is vibration-assisted flushing, which effectively dislodges embedded particles. Tests showed cleanliness improvements of 3–5 ISO codes within five minutes. The device provides a practical, repeatable, and ISO-compliant solution for verifying initial hydraulic cleanliness, with planned developments including automated particle analysis and integration into digital quality management systems.

Keywords. Cleanliness, membrane filters, IS0 4406, ISO 4407, filtration, particles.

2. INTRODUCTION

Ensuring the cleanliness of hydraulic components prior to assembly is crucial for system reliability, wear prevention, and extended operational life. Contaminants such as metal particles, dust, or residues from manufacturing can cause premature wear, clog valves, and reduce the efficiency of hydraulic systems, making initial cleanliness a key determinant of long-term performance.

Particles that are in the fluid can cause abrasive wear [1,2] and cause damage to surfaces. For instance degradation of hydraulic gear pump is shown in increase of microparticles in the fluid, which causes a decrease in the quality of the fluid, which is a class that does not meet the prescribed standards. Solid particles cause specific wear mechanisms of the contact surfaces (abrasion, erosion, material fatigue, etc.) [3,4]. Karanović et al. [3] describe the influence of solid particle impurities in the radial gap between the control piston and the

All Open Access articles are peer-reviewed, distributed under the Creative Commons Attribution-Non Commercial 4.0 International

directional valve housing: due to three-body abrasion, they carry away material and increase the gap. As the gap increases, the flow through the gap also increases (internal leakage), which causes even more particles to travel through the gap. This further increases friction and stimulates the wear process. Pressure losses in the gaps and friction of the particles cause local heating. Optimal fluid cleanliness is required to reduce the intensity of wear. Jung-Hun et al. [5] studied the influence of particle composition and particle quantity. It is proven that size distribution also have an impact on damaging the surfaces because that are so-called "critical size" particles [6,7], that come between two surfaces, causing three body abrasion. This phenomenon is also shown in tribological studies in micro-scale abrasive tests [8].

Fiber filtration technology is used due to its versatility, adaptability and superior filtration efficiency [9]. Multilayer nonwoven fiber filter media has superior flirtation efficiency, lower pressure drop and higher dust holding capacity [10,11]. The filtration velocity and fiber diameter along with surface energy determines the pressure drop through filter material [9].

Although real-time, on-line oil condition monitoring has seen rapid advances in recent years—supported by sensor fusion, microfluidic technologies, and inductive-resistive detection systems [12–14] —these systems are inherently limited in their ability to assess the initial cleanliness of hydraulic assemblies. On-line particle counters are most effective during early system operation but quickly lose relevance as contaminants either settle or disperse. This limitation makes it particularly difficult to verify the baseline cleanliness of components immediately after manufacturing, creating a gap in quality assurance processes.

Current standard practices for cleanliness assessment rely heavily on manual sampling and laboratory analysis, which can be time-consuming, subjective, and insufficiently integrated with the cleaning process. Furthermore, complex geometries within hydraulic assemblies often trap particles in hard-to-reach areas, reducing the effectiveness of traditional flushing or filtration methods. To address these challenges, there is a need for a methodology that combines efficient cleaning with objective, reproducible measurement of particulate contamination. Integrating vibration-assisted flushing with ISO-compliant membrane filtration and microscopic particle counting for measuring cleanliness offers a promising approach to overcome these limitations. The purpose of this paper is to critically evaluate such a methodology for cleaning hydraulic pipe assemblies and to demonstrate its effectiveness in achieving the required cleanliness standards, providing a reliable and repeatable workflow for pre-assembly quality assurance.

3. MATERIALS AND METHODS

The objective of the developed device is to provide a repeatable procedure for achieving and verifying the required cleanliness level of pipe assemblies (PA) prior to their integration into hydraulic systems. To reach this goal, the device combines controlled flushing, vibration-assisted particle excitation, and standardized cleanliness measurement within a single workflow. Cleanliness verification is performed by sampling contaminants onto membrane filters using a vacuum filtration unit, followed by microscopic analysis in accordance with ISO 4407 [15] and cleanliness classification according to ISO 4406 [16]. This approach enables both effective removal of contaminants and reliable assessment of the resulting cleanliness level.

The working principle of the device is based on two hydraulically separated but functionally complementary circuits, driven by two electric motors and centrifugal pumps. The first circuit is dedicated to flushing and cleanliness measurement of the PA, while the second circuit continuously filters the working fluid to maintain a stable and low background contamination level. A glycol–water mixture (DOWFROST™ LC 25) is used as the flushing medium due to its suitable viscosity, corrosion protection, and thermal stability.

3.1. Flushing function and performing cleanliness measurements

The device consists of a centrifugal pump (MovitecV 006/11) which pushes the liquid through the throttle, further along the flexible pipe to the upper ball valve and further to the pipe assembly. The liquid flows through the lower ball, through the coarse filter (25 µm) and the fine filter (3 µm) into the tank. The flow rate is determined by the centrifugal pump characteristics and the overall pressure drop of the system. A throttle valve was used to modify the system resistance (control the pressure) and thus flow rate. At full throttle opening, the pump outlet pressure was 6.7 bar and the flow rate was 150 L/min, whereas at an outlet pressure of 9.2 bar (with semi-closed throttle) the flow rate decreased to 50 L/min. Pressure was measured at the pump outlet and therefore does not directly represent the pressure drop across the pipe assemblies, which remains constant for a fixed configuration and is governed by pipe dimensions and quick couplings. Pump maximum pressure is 11 bar. In case of higher pressure-resistance pump will not provide flow because of the limitations of centrifugal pump. The viscosity decrease due to the increase of temperature is negligible.

In the case of performing cleanliness measurements, the upper ball valve is bypassed, so that the vent filter is in function. The liquid passes through the quick coupling to the PA via the bypassed lower ball valve and the measuring tube to the measuring ball valve and the vacuum device for separating particles on the membrane. The measuring ball valve supplies the appropriate volume of liquid (100 ml) to the upper container of the vacuum device for separating particles on the membrane, which must be provided for the cleanliness measurement.

3.2. Liquid filtration function and heating

The second circuit also contains a centrifugal pump, which sucks the liquid from the bottom of the tank and pushes the liquid through flexible pipes via a fine filter (3 µm) into the tank. This circuit is intended exclusively for filtration and maintaining a high level of liquid cleanliness.

A heater is located in the tank, for heating the liquid in the tank. The temperature switch and the level switch constitute a safety module that switches off the entire device if the liquid has a higher temperature than that set on the temperature switch or if the liquid level is lower than the minimum permissible level (determined by the float mounted on the level switch in the tank). The vibration motor (Netter Vibration NEG 5050 Electric-vibrator, external 400V, 3000 rpm) is important in vibrating the pipe assembly during the flushing function and is controlled by a frequency regulator mounted in the electrical cabinet. Vibration is defined as the applied mechanical oscillation of the system, quantified by its frequency (Hz). The frequency converter may regulate the frequency between 20 and 60 Hz at a constant torque load (linear volt-hertz-curve). It was set to 40 Hz (stage 7 out of 14 on frequency potentiometer control rolling button).

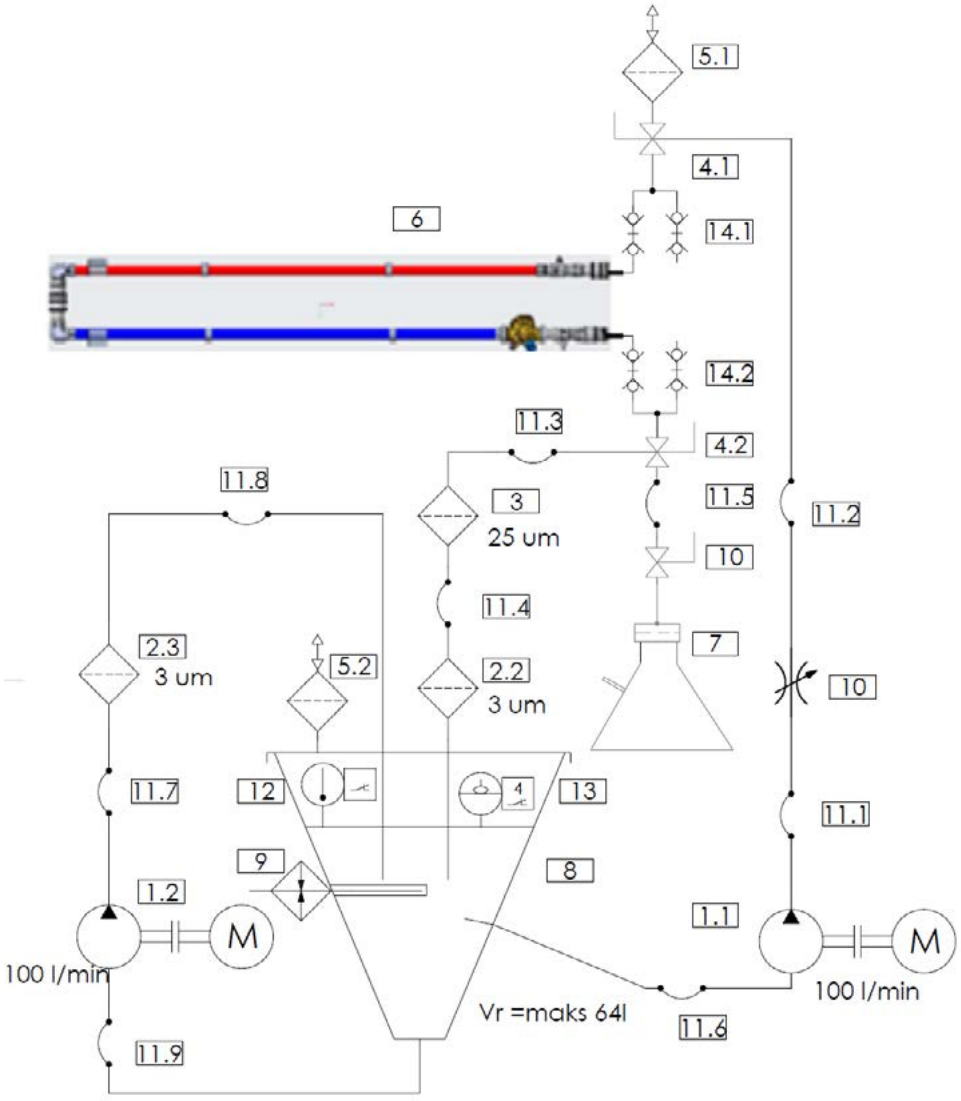

Figure 2. Hydraulic scheme of cleaning device for PAs

3.3. Procedure for flushing and measuring cleanliness

The cleaning and cleanliness assessment of pipe assemblies (PAs) were performed using a dedicated device integrating controlled fluid flow, vibration excitation, and membrane filtration. Prior to measurement, the hydraulic connections were configured so that the lower 3/2 ball valve established a link between the PA and the measuring tube, while the upper 3/2 valve connected the supply line to the PA. The assembly was mounted using quick couplings to ensure a sealed, contamination-free connection.

To define the initial liquid volume, the pump was actuated intermittently, introducing approximately 1600 ml of glycol–water mixture into the PA. A one-minute vibration cycle was applied to release loosely bound contaminants. The flow path was then redirected toward the vent filter to enable sampling. Cleanliness evaluation was conducted by vacuum-filtering 100 ml of the working fluid through a membrane, capturing suspended particles for microscopic examination according to ISO 4407. Multiple samples were taken to ensure statistical reliability.

Following the initial measurements, the rinsing/flushing phase start by redirecting the flow between the PA, inlet, and outlet lines. The rinsing pump was operated for approximately five minutes, accompanied by vibration excitation to enhance particle removal from internal surfaces. After rinsing, the flow configuration was restored for sampling, and the cleanliness measurement was repeated under identical conditions.

Upon completion, the PA could be disconnected either filled with fluid or vented, depending on subsequent handling requirements. This procedure provides a repeatable method for both cleaning and ISO-compliant cleanliness verification of hydraulic pipe assemblies, enabling a quantitative assessment of contamination removal efficiency.

Test coolant DOWFROST LC 25 with fluorescent yellow-green colour was used. It can be diluted with water. The liquid also supports bio-oxidative degradation at concentration between 15 % and 25 % glycol volume. Viscosity of fluid is 2.5 mm^2/s at 20 °C and 1.5 mm^2/s at 50 °C. In Table 2 there are given characteristics of the liquid [17].

Table 2. Characteristics of DOWFROST LC 25 [17]

Component	Concentration
Water	65.0 – < 75.0 %*
Propylene glycol	> 25.0 – < 26.0 %
Dipotassium hydrogen phosphate	1.0 – < 5.0 %*
Sodium tolyltriazole	≥ 0.1 – < 0.25 %*

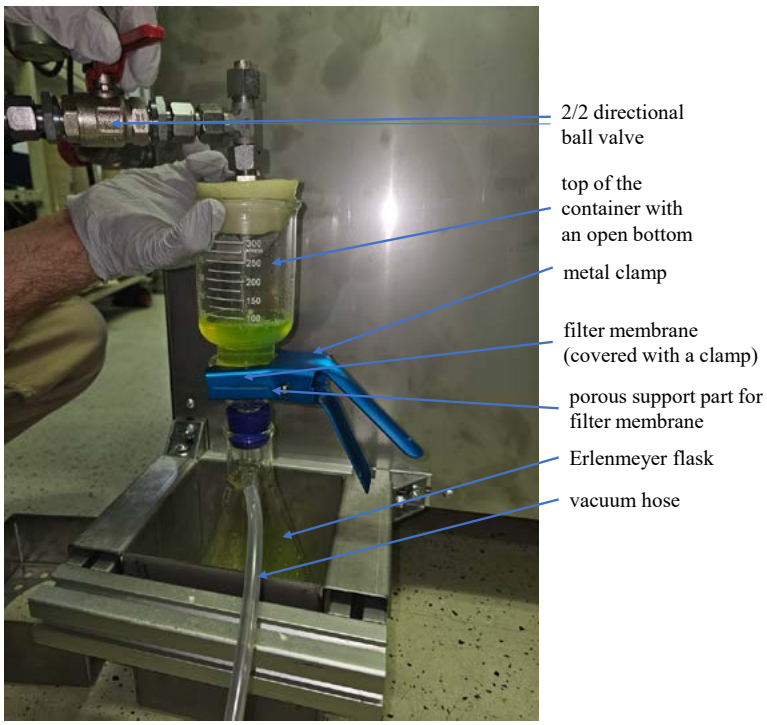
Initial cleanliness, measured from the plastic container was 14/14/12. Temperature was varying from room temperature due to the insufficient cooling system and at times reached temperature up to 100 °C.

3.4. Measurements according to ISO 4407

Solid particle contamination in hydraulic fluids was quantified following ISO 4407, which specifies a standardized microscopic counting procedure for determining fluid cleanliness. Maintaining low particulate levels is critical for the operational reliability of hydraulic systems. Although the method was once constrained by manual counting and slow analysis, recent progress in automated microscopy and digital imaging has re-established it as an efficient and accurate technique for contamination assessment.

For all cleanliness evaluations, 100 ml of DOWFROST LC 25 working fluid was vacuum-filtered through a membrane to collect particulate contaminants released from the pipe assembly (PA). The initial cleanliness, referred to as pouring, was determined by introducing

clean fluid into the PA through short pump cycles, followed by one minute of vibration excitation. The resulting 100 ml sample was withdrawn and filtered through a membrane. Subsequent measurements were performed after different flushing periods, where highest cleanliness improvements were observed. During filtration, the membrane filter was carefully positioned on the vacuum apparatus to prevent airborne contamination (figure 3). The upper container was secured with metal clips, clamping the membrane between the container and the porous support.



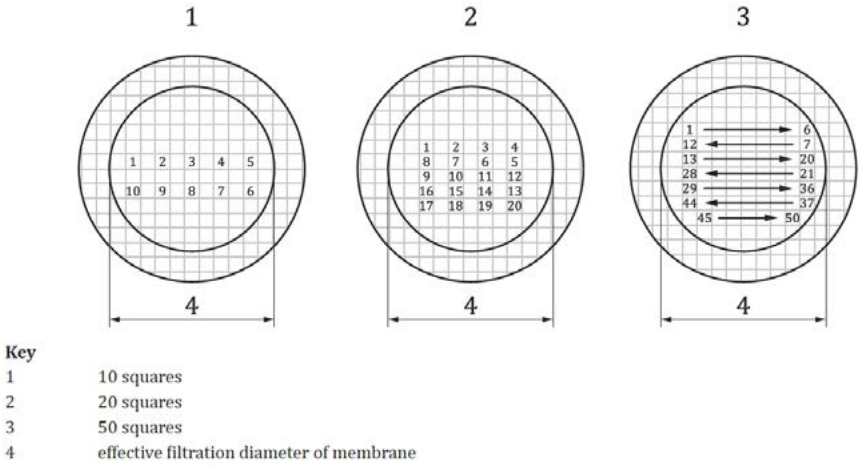


Figure 3. Taking a sample of the cleanliness of the liquid on a vacuum device for membrane filtration

A 100 ml fluid sample was introduced through the measuring tube and filtered under vacuum. After filtration, the membrane was removed with its holder and prepared for analysis. Samples were then placed in an oven at 50–60 °C for two hours to ensure uniform drying without thermal damage. The dried membranes were subsequently examined under a microscope to determine particle count and size distribution in accordance with ISO 4407.

In Figure 4, the number 4 indicates the effective diameter through which the liquid is filtered. The filter membranes are Φ47 mm in size. The first set of filters was made of mixed cellulose (MCE) material with 0.45 µm pores and 2.69 mm x 2.69 mm squares etched into the membrane. The second set of membranes was made of the same material with 1.2 µm pores without squares.

Key

1	10 squares
2	20 squares
3	50 squares
4	effective filtration diameter of membrane

Figure 4. Particle counting in 10 area squares using method 1 according to ISO 4407 [15]

The number of particles was determined in 100 ml of liquid according to the ISO 4407 standard using the equation (2.1) [15]:

$$N = \frac{A \cdot n \cdot 10^5}{f \cdot L \cdot W \cdot V} \quad \text{in 100 ml} \qquad (2.1)$$

where:

A [mm^2] effective filtration area

n [/] number of counted particles larger than the selected size

f [/] number of counted squares

L [mm] length of the observed rectangle, or mesh size

W [µm] width of the observed rectangle,

V [mL] volume of filtered liquid

After drying the membranes, the particles were examined under a Nikon Eclipse Ti-U microscope (Japan) equipped with an IDS u-Eye camera for classical transmitted light technique. It allows for combination with an EMCCD Andor Ixon 888 Ultra camera, a Carin Optosplit III image splitter system and a CoolLed pE-4000 illumination source for epifluorescence microscopy. Only classical transmitted light technique with an E Plan 10X/0.25 objective and WD 7.0 was used.

Since an area of 1 mm x 1 mm was imaged due to magnification and the standard states that the entire square area is analysed, it was necessary to take several images and then combine them in the Image J program and appropriately determine the particle analysis field [18]. This was followed by determining the particle detection intensity threshold, since the analysis works on the bitmap principle and the program counts automatically. The program allows for measurement of the Feret length, which is described in more detail in the article by Walton [19]. Count and classification were done for the Feret particle lengths in Excel into size categories specified by ISO 4406. The oil cleanliness rating consists of three

numbers, the first indicating the class of particles greater than 4 µm, the second the class of particles greater than 6 µm, and the third the class of particles greater than 14 µm per milliliter of liquid.

4. RESULTS AND DISCUSSION

The fluid cleanliness was measured based on the filtration of 100 ml of DOWFROST LC 25. The results were divided into 3 sets. The first set presents the cleanliness measurements of the flow pipe assembly (blue) labelled PA1F and the return pipe assembly (red) labelled PA1R at the beginning before rinsing (pouring) and after different flushing time intervals.

The second set presents the measurements of the combined flow-return pipe assembly labelled PA2FR and determines the cleanliness for both pipe assemblies simultaneously. The cleanliness results are presented at the beginning before rinsing (pouring) and after different flushing time intervals. The last set presents the results of the combined flow-return pipe assembly sets labelled PA5FR and PA6FR using the same procedure with slight changes in regard to vibrations and flow.

4.1. Determining cleanliness measurement from particle counting method

The procedure for determining cleanliness measurement by microscopic particle counting and translation to ISO 4406 is shown using the example of a PA1F pipe assembly. Figure 5 shows the beginning (pouring) before rinsing. First, an image is obtained from the microscope. Figure 6 shows the threshold setting for automatic particle detection software [20]. All red zones are recognized as particles that are determined according to the threshold, as can be seen in the box in Figure 6.

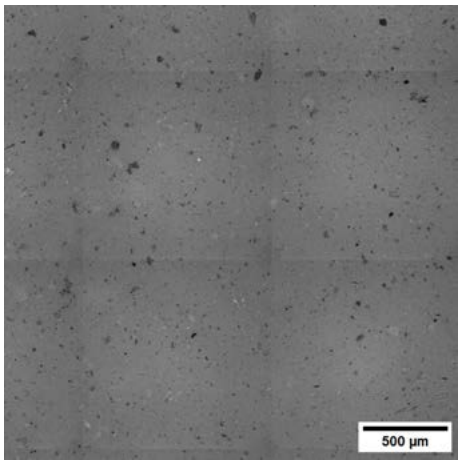

Figure 5: Particles in one particle analysis square for sample PA1F at the beginning (pouring) before rinsing

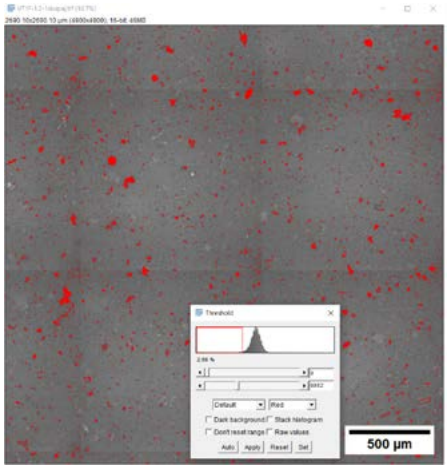

Figure 6: Determination of the particle detection threshold for the PA1F sample at the beginning (pouring) before rinsing

When a threshold is selected, the program automatically converts the image into a 2-bit image (Black and White) (Figure 7). Then it is analysed with the Analyse Particles function in Image J. In this function, it is possible to specify the values that are measured in the image [20]. The size of the particle is measured according to Feret diameter [21].

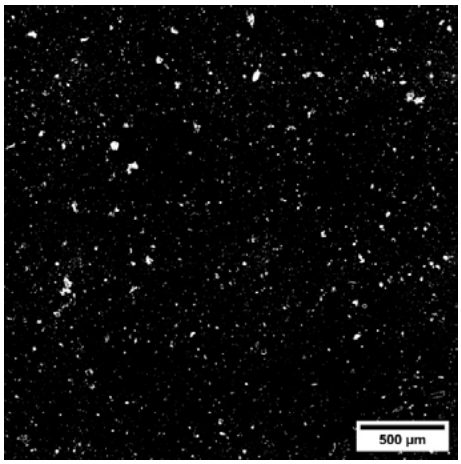

Figure 7. Bitmap for PA1F particle count analysis at the beginning (pouring) before rinsing

4.2. Cleanliness measurements

The first set of measurements served as a preliminary evaluation of the cleanliness of the hydraulic fluid itself, without the influence of any specialized cleaning procedures or treatments. For this purpose, samples from the flow pipe assembly PA1F (blue) and the return pipe assembly PA1R (red) were analysed separately. Microscopic images were

obtained using MCE membranes with 0.45 µm pores, and a grid of drawn squares on the membrane facilitated systematic particle counting. This approach allowed for a detailed "blank" test, establishing a baseline of particulate contamination present in the fluid prior to any flushing. The results, summarized in Table 3, provide the largest particle detected in each of the five analysed squares, along with the corresponding number of particles per millilitre, calculated according to ISO 4406 standards. This initial assessment was essential for establishing reference values, against which the effectiveness of subsequent flushing and vibration-assisted cleaning could be quantitatively evaluated. It also allowed identification of inherent variability in particle distribution across the membrane, ensuring that later measurements would be both reliable and statistically meaningful.

Table 3: Cleanliness measurements on 5 different squares (areas) of a membrane filter of 100 ml of clean liquid (from the packaging container)

Internal	>4µm	>6µm	>14µm
0-1	28	20	2
0-2	29	22	4
0-3	98	69	15
0-4	121	91	28
0-5	71	54	33
	>4µm	>6µm	>14µm
Measured particle count 1 ml	127	93	30
ISO 4406	**14**	**14**	**12**

On PA1F measurements were performed at the beginning (pouring) and after 10 min, 20 min and 30 min of rinsing. Results after 20 min of rinsing showed high cleanliness (14/14/13) (Table 4).

Table 4: Collected together for sample PA1F according to ISO 4406

	>4µm	>6µm	>14µm	Largest particle, µm
PA1F-pouring (start)	**20**	**19**	**17**	128
PA1F-10 min	**16**	**15**	**13**	130
PA1F-20 min	**14**	**14**	**13**	87
PA1F-30 min	**14**	**13**	**11**	60

In the pipe assembly sample PA2FR, the total cleanliness of the joined "flow" and "return" pipe assemblies with quick couplings were measured at the same time. 4 repetitions of cleanliness measurements (cleanliness removal on the membrane) before rinsing (pouring

(start)) and after 1 min, 2 min, 3 min, 4 min, 5 min and 27 min of rinsing (Table 5) were made (together 28 measurements). The speed of improvement of cleanliness in terms of determining the optimal time of cleaning the pipe assembly . For greater clarity, only the cleanliness according to the ISO 4406 standard is given.

Table 5: Total collected for the PA2FR sample according to ISO 4406

	>4µm	>6µm	>14µm	Largest particle, µm
PA2FR-pouring (start)	**19**	**18**	**16**	299
PA2FR-1min	**17**	**17**	**15**	295
PA2FR-2min	**16**	**15**	**11**	64
PA2FR-3min	**16**	**15**	**13**	508
PA2FR-4min	**15**	**14**	**12**	252
PA2FR-5min	**14**	**14**	**12**	113
PA2FR-27min	**14**	**13**	**11**	117

For the other samples (PA5FR pipe assembly), vibration was activated during rinsing and at the beginning, but during the actual collection of the liquid for the cleanliness measurement, the tube assembly was not vibrated. From initial cleanliness 18/17/16 the particles were reduced due to 5 min filtration to cleanliness 15/14/12. The last PA6FR pipe assembly was measured with a reduced flow rate of 50 L/min and a pressure of 9.2 bar. This measurement was made to observe the influence of the different flow rates to cleanliness and it is concluded that higher flow rates have slightly higher cleaning capabilities. The other pipe assemblies were measured with a flow rate of 150 L/min and a pressure of 6.7 bar upstream of the pump. Cleanliness went from 17/16/15 to 14/13/11 after 5 min filtration.

4.3. Examination of particles

Particles retained on the membrane from sample PA1F-pouring (start) were examined using a Hirox HRX1 optical microscope with the objective of demonstrating the capability of the proposed method to classify particle types and potential contamination sources following standardized membrane filtration. In Figure 7, an elongated red fibre was identified and measured, with a length of approximately 950 µm and a width of 20 µm. Similar fibrous particles (black, dark blue, and light blue) were repeatedly detected, indicating a systematic contamination mechanism rather than an isolated occurrence, most likely associated with tube handling or mechanical damage. Such fibres were classified as low-hardness contaminants and are therefore expected to have limited abrasive impact on hydraulic components.

A golden-yellow particle with a reflective surface was observed in Figure 8. Based on its optical appearance, this particle was categorized as a metallic fragment, potentially originating from copper-based alloys such as brass. In contrast, angular particles with dimensions of approximately 52 µm, morphologically similar to standardized test dust, were also detected. These particles were classified as potentially critical due to their sharp edges and higher likelihood of causing abrasive wear. Their presence is indicative of either

airborne dust ingress, insufficient removal of sediments from the working fluid, or residual particles introduced during manufacturing processes, such as sawing or cutting operations. The identification and differentiation of these particle classes demonstrate that the examination serves not to document random particles, but to validate the method's ability to systematically detect, size, and interpret contamination relevant to hydraulic reliability.

5. CONCLUSIONS

This study proposes a method for assessing and improving the initial cleanliness of hydraulic pipe assemblies that complements, rather than replaces, existing standard procedures. Conventional approaches—such as flushing and filtering with parallel use of on-line particle counters or post-flush oil sampling followed by ISO 4407 analysis—are well established and effective during system commissioning or operation. However, these methods provide limited insight into the true baseline cleanliness of newly manufactured components, as

particle counters are sensitive to transient contamination and oil samples are often taken after particles have already settled or been partially removed.

The primary benefit of the proposed method lies in its systematic integration of cleaning and standardized cleanliness verification into a single, controlled workflow. By coupling defined flushing conditions with immediate, ISO-compliant membrane filtration, the method ensures that contaminants released during cleaning are directly captured and quantified. This eliminates uncertainties associated with delayed sampling, fluid dilution, or background contamination that can affect conventional flushing-and-measurement strategies.

All cleanliness evaluations are performed according to ISO 4407 and ISO 4406, ensuring full comparability with established standards. The novelty of the approach does not lie in the measurement principle itself, but in the methodological arrangement that enables reproducible, pre-assembly cleanliness verification under laboratory-like conditions. Optional mechanical excitation was introduced as an auxiliary means to enhance particle release in complex geometries; however, the core advantage of the method remains the controlled flushing and immediate, standardized assessment rather than the excitation mechanism itself.

Furthermore, the use of image-based microscopic analysis improves traceability and repeatability compared to purely manual particle evaluation, while remaining fully compliant with ISO requirements. Overall, the proposed method provides a practical and scientifically justified extension of standard cleanliness procedures, specifically targeted at the manufacturing stage. It enables manufacturers to verify and document initial component cleanliness prior to assembly, thereby closing a critical gap between production and operational monitoring. The methodology is readily transferable to other hydraulic components and can be integrated into existing quality assurance frameworks.

Nejc Novak received the PhD in Mechanical Engineering from University of Ljubljana in 2025. He is currently working as researcher at the Department of Tribology and maintenance systems, Laboratory for Fluid Power and Controls, Faculty of Mechanical Engineering, University of Ljubljana. His research areas include analyses of hydraulic components wear mechanisms and lifetime, hydraulic fluid properties and filtration.

Ana Trajkovski received the PhD in Mechanical Engineering from University of Ljubljana in 2015. She is currently working as teaching assistant at the Department of Tribology and maintenance systems, Laboratory for Fluid Power and Controls, Faculty of Mechanical Engineering, University of Ljubljana. Her research areas include inovative materials and lubricants for sustainable hydraulics, smart control design and optimization of hydraulic components, water hydraulics. She has written many scientific papers and collaborated in many national and international conferences and research projects.

Jan Pustavrh received the M.Sc. in Mechanical Engineering from University of Ljubljana in 2022. He is currently working as researcher at the Department of Tribology and maintenance systems, Laboratory for Fluid Power and Controls, Faculty of Mechanical Engineering, University of Ljubljana. His research areas include design and control of multi-axis servo hydraulic systems, smart control and design of hydraulic components.

Mitjan Kalin is full professor and the head of the Department of Tribology and maintenance systems, at the Faculty of Mechanical Engineering, University of Ljubljana. He has written more than 200 international peer-review papers, gave more than 80 invited lectures at international conferences and is project leader of more than 50 major projects. His main research areas are in wear and friction mechanisms of advanced materials, green lubrication technologies and nanoscale interface phenomena. In particular, he is recognised in academia and industry as a pioneer in boundary lubrication and tribochemistry of diamond-like carbon (DLC) coatings. Prof. Dr. Kalin was elected as a member of Slovenian Academy of Engineering, a Member of the International Academy of Engineering, and in 2024 to European academy of science and arts. He received a 2025 ASME Mayo D. Hersey Award, one of the highest academic recognitions in tribology.

Franc Majdič received the PhD in Mechanical Engineering from University of Ljubljana in 2010. Hi is currently working as assoc. professor at the Department of Tribology and maintenance systems, at the Faculty of Mechanical Engineering, University of Ljubljana and is the head of the Laboratory of Fluid power and controls. His research areas include water hydraulics, hydraulic components development and testing. He has written many scientific papers and collaborated in many international conferences. He is a project leader of more than 50 industrial and research projects and collaborated in several industrial patents.

Automated Processing of FMEA-Induced Fault-Injection Simulation for Safety Functions in Dangerous Machinery

Dipl.-Ing. Christa Düsing, Dipl.-Ing. Benjamin Erzberger

Authors affiliation, duesing@xcmg-erc.com, benjamin.erzberger@fluidon.com

Abstract.

Safety-critical and hazardous mobile machines must not only be technically safe, but also require a validation process with increasing demands on process quality, traceability, and reproducibility as the required safety level rises. Since safety functions (SF) often operate close to safety limits, validation by physical testing is associated with high effort and late availability; therefore, systematic simulation-based testing is considered as an early, safe and repeatable alternative. This paper presents a systematic simulation-based validation approach using a digital model that represents the aspects of machine structure and kinematics, drive and control subsystems, and safety-related software algorithms within a physics-based simulation environment. The method is derived from a Safety Function-FMEA (Failure Modes & Effects Analysis) [4, 10] in combination with Failure Modes, Effects & Diagnostic Analysis (FMEDA) [3, 10] to define relevant failure modes, test conditions, and diagnostic expectations. These failures are implemented in the digital model as targeted fault injections via virtual sensors and manipulators, enabling controlled and adjustable experiments for machine-level assessment of system response, failure detection, and diagnostic performance. The implementation is carried out using a digital model [1, 14] in DSHplus® [1, 2] (1D simulation of hydraulics, mechanics and controls) By integrating the digital model into the Cube® platform [1,2], the simulation environment is extended to a digital twin, enabling automated parameter management, test execution, and result evaluation in a reproducible workflow according to established definitions. In addition to verifying logic and algorithms, the approach is aligned with relevant functional safety requirements and processes such as ISO 13849 [8], ISO 19014 [7] and ISO 26262-8, Clause 11 [9], supported by tool assessment and complemented by model validation and plausibility checks. The approach is demonstrated using the safety function for working range limitation of an excavator and shows how digital-twin-based fault injection testing can provide traceable evidence for early, standard-compliant validation before physical prototypes are available or dangerous tests have to be carried out.

1. INTRODUCTION

The development of safety-related parts of control systems (SRP/CS) [8] in mobile machinery with increasing levels of automation requires a systematic evaluation of safety functions to ensure reliable operation in the event of failures. Functional safety is not only a regulatory requirement defined by standards such as ISO 13849 [8], ISO 19014 [7], but also a key contributor to the operational performance and acceptance of automated and (semi-) autonomous mobile machines. With increasing automation, safety functions are required to operate close to physical and functional limits, which significantly increases the complexity of their development and validation. In conventional development processes, the validation of safety functions is often time-consuming, labour-intensive, and usually only feasible in late development stages. This late availability delays the detection of safety-relevant design weaknesses and increases development effort and costs, particularly when design iterations become necessary. At the same time, safety standards demand traceable and reproducible evidence that safety functions meet the required Performance Level (PL) [8], which further increases the pressure on high-quality development and validation processes, especially for highly dangerous machines according to new machinery directive in which notified bodies have to be involved along with the development. In current industrial practice, these challenges are primarily addressed through extensive hardware-based testing and analytical safety assessments such as FMEA [4,10] and FMEDA [3, 10], which are however largely limited to late development stages and component-level evaluation. To address these challenges, automated and simulation-based validation methods are increasingly considered as a means to enable early, repeatable, and cost-efficient testing of safety functions. In addition, such methods must not only reproduce nominal machine behaviour, but also allow systematic investigation of failure conditions in order to support functional safety validation. In this context, safety functions are distributed across multiple technical domains, including machine structure and kinematics, hydraulic or electric actuators, electronic hardware such as sensor, controllers and software algorithms. Ensuring functional consistency across these domains requires validation methods that operate at machine level rather than at isolated subsystem or component level. The approach presented in this paper follows a structured validation process in which Safety Function-FMEA [4, 10] and FMEDA [3, 10] results are transferred into a physical-based digital model of the machine. This digital model is used to execute systematic fault-injection simulations, enabling automated evaluation of safety function behaviour at machine level. By embedding the simulation model into an automated workflow environment, parameter variations, test execution, and result evaluation can be managed in a traceable and reproducible manner. Figure 1-1. illustrates the structured validation process followed in this work.

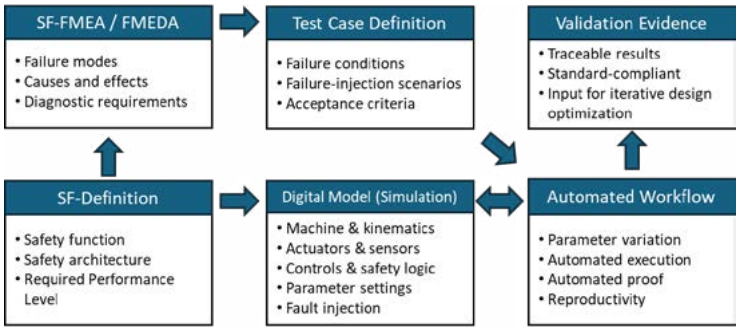

Figure 1-1. Process Flow of the proposed Simulation-based Validation approach for SF

2. EXCAVATOR USE CASE AND SAFETY FUNCTION SCENARIO

The proposed approach is applied to a representative use case of a (semi-)autonomous excavator equipped with the safety function *"Avoid bucket collision with detected obstacle"* for a hydraulic excavator. This function ensures that the bucket movement is automatically stopped before a potential impact occurs and requires a performance level PL = d. The presented simulation model represents the safety-relevant machine behaviour and includes the subsystems kinematics, the hydraulic system, sensors and the control algorithms required to analyse the selected safety function. Figure 2-1 shows in the top the excavator test without failure injections. The sequence illustrates the excavator bucket approaching the obstacle (a), detecting it (b), and stopping automatically before contact (c). This test verifies the correct operation of the implemented safety function under nominal conditions.

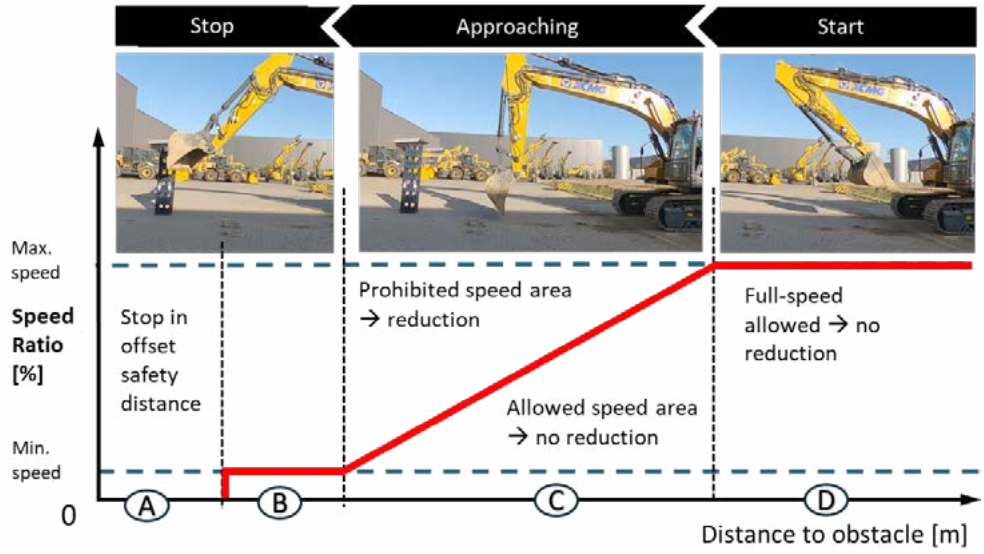

Figure 2-1. Excavator movement limit function: (c) Bucket approaching, (b) entering critical Obstacle Distance, (a) Bucket stopped [11, 12]

The bottom area of Figure 2-1 illustrates the determination of the speed scaling factor for the movement limiter. The speed scale on Y-axis is tracked against the distance to the obstacle on the X-axis. The red line shows the maximum speed curve for each distance. In section D, full speed is allowed and now speed reduction is applied. In the section C, set speed is limited along the red line. Values above the red line are reduced accordingly, values below the red line pass without reduction. Minimum speed is applied in the section B to approach obstacle slowly until safe stop is achieved in a safe offset distance to the obstacle in section A. Based on the operator-defined boundary limits, potential collision points of the work equipment are identified and extended by circular safety offsets this way. The maximum and minimum x- and z-position of these points are assigned to the corresponding boundaries. If multiple boundaries are active, the smallest scaling factor is applied to all drives of the excavator. The resulting scaling factor is multiplied with the set speed input and transmitted to the valve solenoid via the main PLC.

2.1. Possible Failures and Effects

During approach of an obstacle, various failure conditions can affect the safe execution of the movement limiter function. The following failure modes are typical examples derived from the Safety Function-FMEA [4, 10] and do not constitute a complete list:

(A.) **Sensor drift or sensor offset,** i.e. a gradual or constant deviation of the sensor signal from the actual value, can delay obstacle detection, increase the stopping distance or cause a collision;

(B.) **Hydraulic valve malfunction**, e.g. a stuck spool, can prevent the actuator from stopping even when the stop command is issued;

(C.) **Signal loss or signal degradation,** i.e. a temporary or intermittent reduction in signal quality (e.g. noise, dropouts or reduced resolution), can lead to incorrect interpretation of the machine status and uncontrolled movements of the actuator;

These effects directly influence the reliability of the stop function and must be validated to ensure compliance with ISO 13849 [8] and the associated functional safety standards.

2.2. Objective of the Investigation

The objective of this investigation is to evaluate the diagnostic behaviour of the safety function *"Avoid bucket collision with detected obstacle"* implemented by the movement limiter under selected failure conditions derived from the Safety Function-FMEA [4,10]. The safety function limits hazardous machine movements in the relevant directions, with the bucket–obstacle collision used as a representative use case. The focus is on assessing failure detection, system response, and diagnostic coverage using simulation-based fault-injection tests. Test success is evaluated by comparing the achieved diagnostic coverage (DC) with the required DC larger than 90% for PL d in a Category 2 safety function structure.

3. SIMULATION MODEL

3.1. Machine Model

The simulation model represents the excavator including its hydraulic actuators, control logic and virtual sensing system. All safety-relevant components are connected according to a Category 2 structure, consisting of a functional channel and an independent test channel for periodic diagnostic checking, as defined in ISO 13849 [8]. Figure 3-1 shows the simulation model consisting of an excavator model (2) that is moved by the hydraulic control system (1). The excavator model provides information about coordinates of the bucket tip (2B), but also outputs the angular values for each steel part of the attachment, so that sensor raw data can be generated and signals used in the test equipment (4). Sensor data feeds the movement limiter function (3) that can scale the control command (7). The test equipment (B) compares deviations between the redundant sensors signals and can deactivate a hydraulic pilot pressure switch (6) if critical deviations outside the tolerance band of +/- 2°are detected. The model also features an integrated manipulator (A) used for failure injection and signal variation of the arm angle sensor. The functional channel processes the sensor signals of the safety function, including redundant sensor inputs, whereas periodic diagnostic checking is realised via an independent test path in accordance with the applied Category 2 architecture. The manipulator (A) is used exclusively in the simulation to inject

defined failures derived from the Safety Function-FMEA [1, 10] into the signal paths, shown in Figure 3-1 to extend the simulation model for the representation of sensor-related failure scenarios. The hydraulic enable block (C) represents the actuation path for implementing and observing failure effects on the physical system behaviour. This setup supports the systematic assessment of the diagnostic performance by analysing failure detection behaviour and achievable diagnostic coverage under controlled failure conditions, following established principles of model-based diagnosis and failure-tolerant control [15, 16]. The simulation model as such represents a digital model of the machine, as it reproduces structure, behaviour, and failure responses without direct coupling to a physical asset. Figure 3-1 shows the simulation model structure with manipulator (A), test equipment (B), and hydraulic enable path (C) according to a Category 2 architecture.

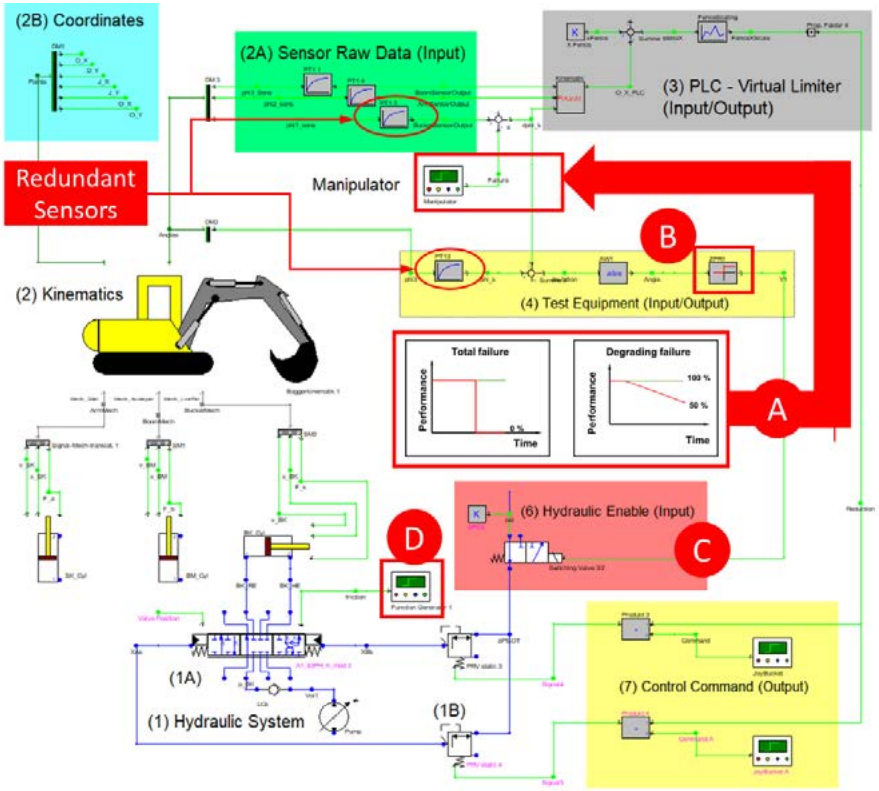

Figure 3-1. Simulation Example of Digital Model with Manipulator for an Excavator Arm representing Category 2 Structure according to ISO 13849 [8, 11, 12]

3.2. Valve Model

The directional control valve (1A in Figure 3-1) is modelled in detail to analyse the influence of mechanical failures on system behaviour. The focus is on the main valve stage, where effects such as increased friction, temperature-dependent spool motion, or a stuck valve spool can occur. Such failures can lead to unsafe machine states if the hydraulic actuation continues even though a stop command is requested. For this purpose, the valve position is derived from the equilibrium of forces on the spool that includes also terms for viscous

friction in the housing bore and a dry friction force that can be externally applied by the force manipulator D. The valve is actuated via electro-hydraulic pilot valves, which generate a differential pilot pressure acting on the ends of the main valve spool. This pilot pressure shifts the spool against spring forces, which in turn controls the hydraulic flow to the actuator. In the simulation model, external manipulation of the spool friction is used to reproduce an undesired stuck condition of the valve spool. The simulation example Figure 3-1 illustrates a failure scenario in which the valve spool remains stuck after a stop command. Although a corresponding closing signal is activated, the hydraulic flow is not fully interrupted and the actuator does not stop as intended. Reproducing this malfunction in the simulation allows the evaluation of control logic responses and virtual sensing mechanisms, as well as the assessment of potential countermeasures such as additional stroke sensing or parameter monitoring.

3.3. Test Procedure derived from FMEA

This section describes the execution of the simulation-based fault-injection tests and the associated evaluation workflow. The excavator simulation starts with arm and bucket cylinder at total extension, so that bucket is close to the cabin and bucket teeth. Both, arm and bucket cylinder are simultaneously retracted, so that arm moves away from the cabin and bucket turns leading to a bucket moving towards the obstacle. Under normal conditions, a movement limiter reduces speeds of arm and bucket with regard to the distance and stops without colliding. Defined failure scenarios are introduced at specific simulation times, and the system response is analysed using consistent evaluation criteria. An overview of the considered failure scenarios and their corresponding test objectives is provided in Table 3.1.

Table 3.1. Simulation-based Fault-Injection Scenarios and Evaluation Objectives for the Safety Function “Avoid bucket collision with detected obstacle” [10, 11, 12, 15, 16]

Injected failure scenario	**Description**	**Diagram reference**
Calibration / degrading failure	Evaluation of the influence of sensor drift on failure detection time and final stop position during bucket motion.	Failure Detection – Drift vs. Movement / Time
Performance test of bucket movement	Assessment of start and stop dynamics and their effect on the timing accuracy of failure detection and controlled stopping behaviour.	Failure Detection – Drift vs. Stop Position over Time
Total failure of inclination sensor	Analysis of the impact of complete inclination sensor signal loss on stop distance, safety margin to the obstacle, and diagnostic response.	Failure Detection – Inclination Sensor Offset
Stop behaviour	Evaluation of the influence of increasing angular offsets on stop distance and diagnostic tolerance within the specified sensor accuracy range.	Failure Detection – Inclination Sensor Angular Offset

Each virtual experiment follows a defined sequence answering the key questions of the test design:

(A.) **Baseline simulation:** The machine is simulated under nominal conditions to establish reference curves for pressure, flow and velocity. This serves as a benchmark for later comparison with failure scenarios;

(B.) **Fault-injection:** A selected failure mode, such as sensor drift, offset, or valve friction is activated at a predefined simulation time using the manipulator module. All test parameters are managed and executed automatically within Cube® [1, 2], ensuring repeatability and efficient data handling.;

(C.) **Detection analysis:** The system response is analysed to determine the safe failure detection time t_{detect}, defined as the interval between failure activation and detection by the diagnostic logic. Diagnostic performance is evaluated using two complementary coverage measures: $DC_{t_failure}$, addressing time-based detection behaviour, and $DC_{x_position}$ addressing the remaining permissible positional margin at the time of detection. This combined assessment supports a differentiated evaluation of diagnostic effectiveness with respect to temporal detection and positional safety, particularly for slowly developing failures;

(D.) **Diagnostic evaluation:** Based on ISO 13849 [8], the Diagnostic Coverage (DC) [8] is used to assess the effectiveness of the implemented diagnostic logic, while the time-resolved evaluation of failure detection follows system-level validation principles as defined in ISO 26262 [9]. The critical detection time $t_{detect.critical}$ is defined as the maximum allowable detection time interval derived from the safety function requirements. DC is calculated as the ratio of this critical detection time to the reference cycle time $t_{cycle,ref}$ and expresses the proportion of failures that can be detected within the allowable detection time interval;

The described evaluation approach enables a quantitative basis for comparing diagnostic quality across different failure types. The systematic approach enables direct comparison of failure scenarios and yields quantitative results on detection speed, reaction behaviour, and overall robustness. By combining DSHplus® [1, 2] with Cube® [1, 2] automated evaluation functions, a large number of test cases can be executed efficiently, forming the basis for the result analysis presented in Chapter 4.

3.4. Data management system structure for automated simulation

The virtual test setup for evaluating the excavator's stop function was realised in a combined simulation and automation environment. The excavator system model, including the machine structure, kinematics hydraulic components, and safety-related logic, was implemented in DSHplus® [1, 2], while parameter management, simulation control, and result evaluation were executed in the Cube® platform [1, 2]. The interaction between the simulation model and the workflow environment is based on a structured exchange of parameters, simulation control signals and result data, enabling automated, repeatable and traceable fault-injection testing of safety-relevant functions. Based on the system structure and data flow shown in Figure 3-2, the automated testing approach relies on a systematic parameterisation of test conditions applied within the simulation model. Test-relevant parameters are provided to the DSHplus® [1, 2] simulation model, where the fault-injection tests are executed and the dynamic system behaviour is calculated. The resulting simulation data are then transferred to the Cube® [1, 2] workflow environment for automated processing, evaluation, and visualisation, ensuring that every test case is executed under

clearly defined and reproducible conditions. This separation between simulation execution and result evaluation allows fault-injection tests to be automated and repeated without manual interaction with the simulation model.

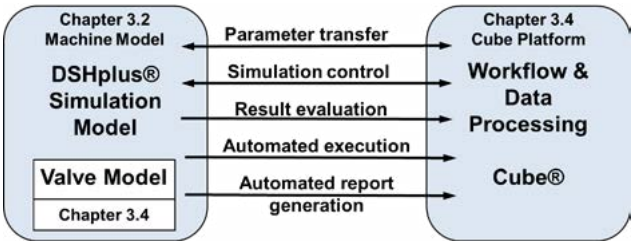

Figure 3-2. System Structure and Data Flow between DSHplus® and Cube® [1, 2]

The parameter set used for automated testing comprises several categories. Failure-related parameters describe the type and characteristics of the injected failure, such as the failure mode, activation time, magnitude, and duration. These parameters are directly derived from the Safety Function-FMEA [4, 10] and FMEDA [3, 10] results and represent the analytical basis for fault-injection testing. Machine operating conditions define the system state at the start of each test, including machine position, velocity, load conditions, and actuator states, ensuring that safety functions are evaluated under representative operating scenarios. In addition, environment-related parameters may be considered, for example the presence of obstacles or moving objects within the working area, if relevant for the investigated safety function. Sensor-related parameters, such as sensor placement or signal availability, allow the influence of sensing configurations on failure detection and diagnostic behaviour to be analysed. Finally, software-related parameters define internal settings of the safety function implementation, including limit values, timing parameters, and logic configurations used for monitoring and failure detection. All parameter variations are defined at workflow level and transmitted automatically from Cube® [1 ,2] to DSHplus® [1, 2] as input data for simulation execution. Simulation control, parameter transfer, and result feedback are handled within the automated workflow, allowing a large number of test cases to be executed efficiently. The resulting data, including system response, detection times, and diagnostic states, are returned to Cube® [1, 2] for structured processing and evaluation.

4. SIMULATION RESULTS

The conducted simulations show how the digital machine model and the automated workflow can be used to analyse functional safety aspects under defined failure conditions. The results illustrate how individual component and system failures influence the diagnostic behaviour of the safety function *"Avoid bucket collision with detected obstacle"*. The evaluation is performed both at virtual machine level and at system level with a focus on hardware-related failures. Based on simulation-based fault-injection, the diagnostic coverage is assessed in a structured and reproducible manner. The automated Cube workflow enables a process-safe and transparent evaluation, comparable to established SIL (Software-in-the-Loop) or HIL (Hardware-in-the-Loop) test procedures and allows efficient iterations in the process, e.g. when modifications in the algorithms become necessary. It can be used to automatically generate diagrams and key-figures that support the approval process. In addition, the simulation results are compared with the original data-

sheet-based evaluation approach, allowing additional insights and recommendations for the assessment of diagnostic coverage to be derived.

4.1. Investigation of Sensors Failures

Sensor-related failure effects on the safety function are analysed based on time-dependent signal behaviour. Characteristic signal trajectories of sensor output, hydraulic enable signal, cylinder position and actuator pressure are evaluated to illustrate the interaction between sensor failures, diagnostic logic, and system response. This allows a clear distinction between normal operation, detected failures and undetected failures, as well as the assessment of delayed failure recognition and its impact on the stop response. To represent safety-relevant sensor failures derived from the Safety Function FMEA, one of the redundant inclination sensor signals is manipulated. The applied failure patterns include time-dependent drift and step-like deviations, while the second redundant sensor provides the nominal reference signal. The diagnostic logic monitors the deviation between both signals and classifies a failure as detected once the predefined diagnostic threshold is exceeded. The resulting system behaviour is illustrated in Figure 4-1.

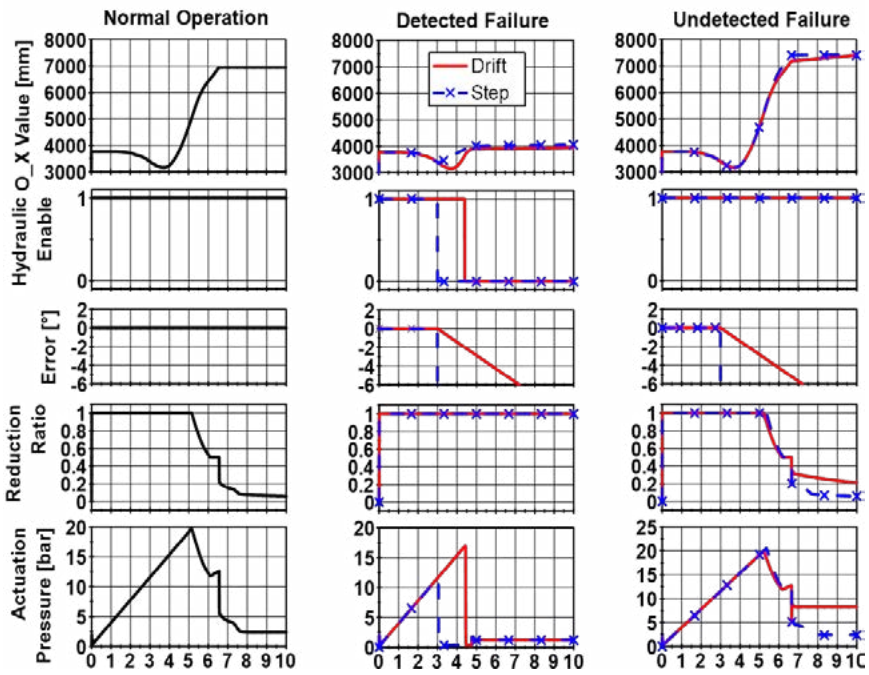

Figure 4-1. Sensor Drift, normal Operation, detected & undetected Failures [11, 12, 15, 16]

Normal operation has no error and applies the reduction ratio from the movement limiter to stop the bucket at 7000 mm in a reference cycle time $t_{cycle,ref} = 6.6\,sec.$ In the detected failure case, the injected deviation exceeds the diagnostic threshold, leading to deactivation of the hydraulic enable signal and thus, immediately stops movement at 4000 mm. Undetected failures remain below the threshold and therefore do not trigger the stop command, despite deviation of the manipulated sensor signal from the nominal signal. The failure causes a stop exceeding 7m and thus causes a collision with the obstacle. The results demonstrate the influence of failure severity on detection capability and confirm the

suitability of the simulation-based approach for assessing diagnostic coverage for sensor-related failures.

4.1.1 Sensor Drift

Figure 4-2(a) shows the bucket position at failure detection and the corresponding stop position for different sensor drift rates. Higher drift rates lead to earlier detection and shorter stopping distances, ensuring collision avoidance. Medium drift rates are detected sufficiently early but operate closer to the defined safety limit. Very small drift rates result in late detection or remain within tolerance, reducing the available safety margin. The results highlight the relevance of defined tolerance bands for achieving sufficient diagnostic coverage. The left-shift of the −0.5 °/s curve results from late detection at small bucket displacement.

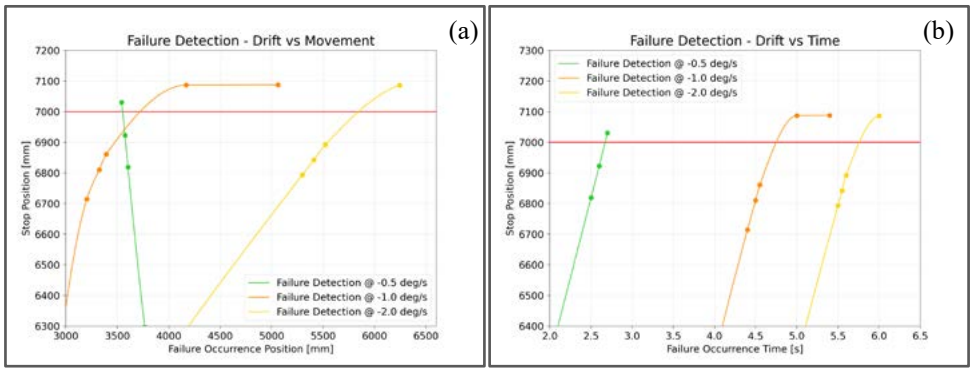

Figure 4-2. Failure Detection Characteristics [11, 12, 15, 16]

Figure 4-2(b) relates the time of fault-injection to the bucket position at stop. Faster drift rates cause early detection shortly after failure onset, whereas slower drifts lead to delayed detection closer to the obstacle. This behaviour demonstrates the time-dependent nature of drift faults and underlines the criticality of slow sensor drifts for diagnostic algorithms. For the automated data processing, the time-based diagnostic coverage $DC_{t_failure}$ is calculated according to equation (4.1) using the simulation-derived detection timing for the failure setting crashing into the obstacle and the reference cycle time $t_{cycle,ref}$:

$$\mathrm{DC_{t_failure}} = \frac{\mathrm{t_{failure\ occurance,crash}} + \Delta \mathrm{t_{detect}}}{\mathrm{t_{cycle,ref}}} \times 100 \qquad (4.1)$$

In addition, a position-based diagnostic coverage $DC_{x_position}$ is introduced. The $DC_{position}$ describes the ratio of the position at which failure occurrence leads to a crash and the position of the obstacle and is defined as equation (4.2):

$$\mathrm{DC_{x_position}} = \frac{\mathrm{x_{failure\ occurance,crash}}}{\mathrm{x_{obstacle}}} \times 100 \qquad (4.2)$$

The quantitative results for the investigated drift cases are summarised in Table 4.2. The results show that the two DC values differ from each other, but also that the demanded rate of 90% and higher could not be performed by the current design and algorithm of the movement limiter. A higher absolute drift rate corresponds to a more severe sensor failure, leading to a faster deviation of the perceived inclination from the actual machine state,

whereas smaller drift rates represent slowly developing failures that are typically more challenging to detect in time. The selected drift rates of −2°/s, −1°/s, and −0.5°/s therefore allow the diagnostic behaviour to be evaluated under clearly differentiated failure dynamics, while all other boundary conditions remain unchanged. This ensures that differences in detection time and diagnostic coverage can be directly attributed to the severity of the injected sensor drift.

Table 4.1. Quantitative Results for different Inclination Sensor Drift Rates obtained from Simulation-based Fault-Injection Test for a reference Cycle Time of 6.6 sec

Case	Drift rate [°/s]	Δt_{detect} [s]	Δt_{detect} [s]	$DC_{tfailure}$ [%]	x [mm]	$DC_{xposition}$ x [%]
D1	-2°/s	5.6	0.89	98.33	5750	82.14
D2	-1°/s	4.6	1.42	91.21	3600	51.43
D3	-0,5°/s	2.6	2.93	83.78	3600	51.43

The results in Table 4.1 show a clear relationship between drift severity, detection time, and diagnostic coverage. Larger drift rates lead to shorter detection times, as the sensor signal reaches the diagnostic decision limits more rapidly. Consequently, the proportion of the admissible reference cycle time during which the failure is detected increases, resulting in higher DC_{time} values. In contrast, smaller drift rates result in a more gradual signal deviation and longer detection times. This reduces the available safety margin before the permissible displacement is exceeded and leads to lower diagnostic coverage. The complementary metric $DC_{position}$ further highlights how early failure detection preserves spatial safety margins, underlining the criticality of slow sensor drifts. The result illustrates that the diagnostic effectiveness is not only determined by the implemented logic itself, but also strongly depends on the temporal characteristics of the failure itself. This underlines the importance of time-resolved, system-level fault-injection testing for evaluating diagnostic coverage beyond static or datasheet-based assumptions.

Figure 4-3 illustrates the relationship between the sensor drift rate and the time to failure detection Δt. Failure detection occurs once the predefined ±2° tolerance band is exceeded (to be verified in the simulation). The results show that higher drift rates are detected earlier, while slow drift rates lead to significantly delayed failure detection. The depicted trend follows a nonlinear inverse relationship.

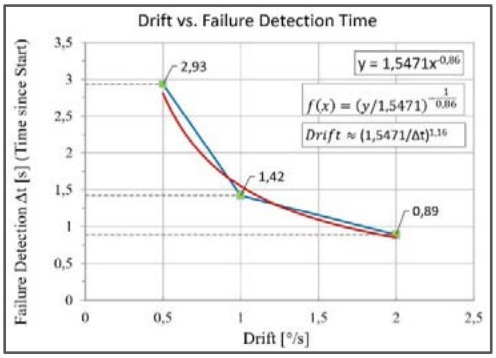

Figure 4-3. Failure Detection Characteristics [11, 12, 15, 16]

In addition, Figure 4-3 shows clearly that high drift rates are uncritical, as detection occurs early and sufficient safety margins remain. In contrast, slow sensor drifts are critical, since failure detection happens late and close to the safety limit, reducing the available stopping distance. This behaviour of slowly developing sensor drifts motivates the introduction of an intermediate Zone B in the safety algorithm, where operation continues at reduced speed before a safe stop in Zone A with a defined distance to the obstacle is initiated. Figure 4-3 therefore emphasizes the importance of defined tolerance bands and staged safety reactions to ensure adequate diagnostic coverage for slow sensor drifts.

4.1.2 Total and offset failures

Figure 4-4 illustrates the influence of inclination sensor offset failures on the diagnostic behaviour of the safety function in accordance with the principles of ISO 13849 [8] and ISO 19014 [17]. In contrast to drift failures, an offset represents a static deviation and leads to a constant discrepancy between the redundant inclination sensor signals. Figure 4-4(a) shows the resulting bucket stop position for angular offsets of 3° started at different time instants during the bucket approaching the obstacle. As the offset does not increase over time, failure detection is determined by the absolute deviation relative to the defined tolerance band of +/- 2°. Variations in the resulting stop position are caused by the system state at the time of fault-injection. The distance shown represents the absolute bucket position relative to the obstacle highlighted by the red line. Figure 4-4(b) presents the evaluation for increasing offset magnitudes. Offset values within the permissible angular tolerance band of +/- 2° are handled by plausibility monitoring in the test equipment of the safety function and do not lead to a safety reaction. The system fails to react for negative offset values as stop positions are beyond the limit of 7000 mm. Positive offset values bring the system to the safer side and stop in front of the obstacle instead. Once the offset exceeds the predefined diagnostic threshold, the inconsistency between both sensor signals is detected and the stop command is initiated. This behaviour is consistent with the diagnostic principles defined for Category 2 architectures according to ISO 13849 [8], where systematic sensor failures are detected by periodic or continuous plausibility checks. The results indicate that the applied tolerance band method in the movement limiter may lead to stop position deviations of up to 100 mm, therefore an additional safety offset distance in stop area Zone A, Figure 2-1, is recommended.

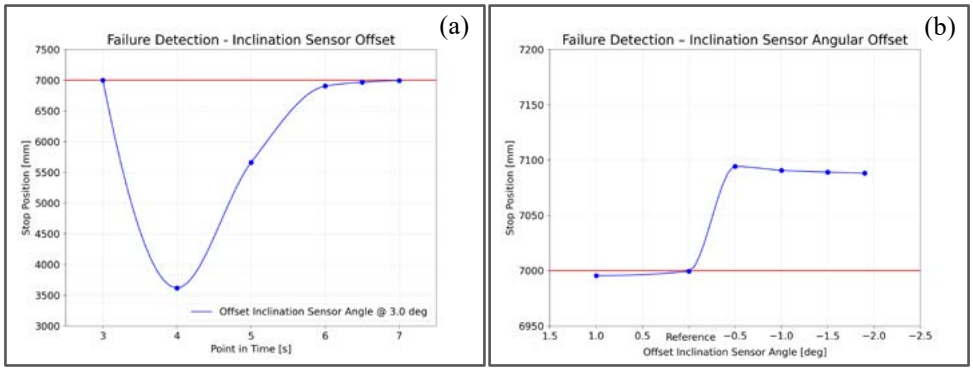

Figure 4-4. Total Failure of Inclination Sensor & Inclination Sensor Angular Offset [11, 12, 15, 16]

4.2. Valve spool behaviour

The results for wrong valve actuation behaviour and an active movement limiter are illustrated in Figure 4-5. In the friction scenario shown in Figure 4-5a, the valve spool opens to 40% that only allows a slow movement of the bucket while approaching the obstacle. The friction in the valve spool gap delays the valve closing after the stop demand at 4 sec. As a consequence, the valve spool stroke decreases progressively until the actuator motion comes to a standstill at an effective stroke of approximated 20% that is below the positive overlap of the metering edge geometry. The valve closing time of few seconds indicate, that the such frictions can become more serious when the valve already has higher openings before stop command is initiated. In contrast, the stuck piston failure illustrated in Figure 4-5b represents a mechanical blockage of the valve spool that avoids the valve closing. The stop command at 5 sec cannot be executed by the valve spool. The valve opening remains at 60%, so that the hydraulic flow is still further transmitted to the actuator. As a result, the bucket does not stop in front of the obstacle. Both behaviours indicate a total loss of controllability and a decoupling between the control signal and the physical actuator response.

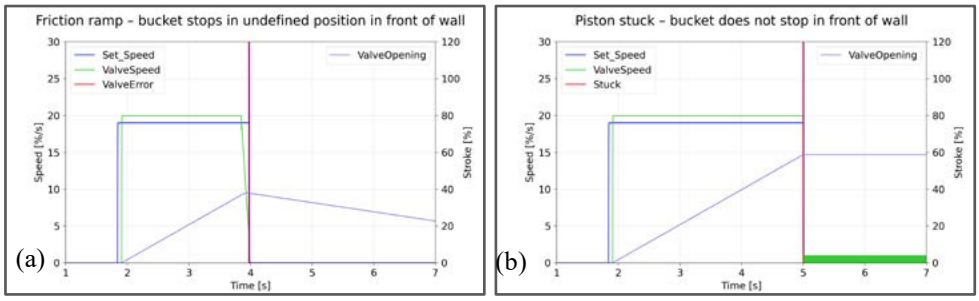

Figure 4-5. Comparison of friction-induced and mechanically blocked piston behaviour in the hydraulic valve section [11, 12, 15, 16]

The resulting bucket stop behaviour is shown in Figure 4-6(c) and Figure 4-6(d). In the friction ramp scenario shown in Figure 4-6(c), the reduced actuator speed leads to a controlled deceleration of the bucket, which comes to rest in front of the obstacle.

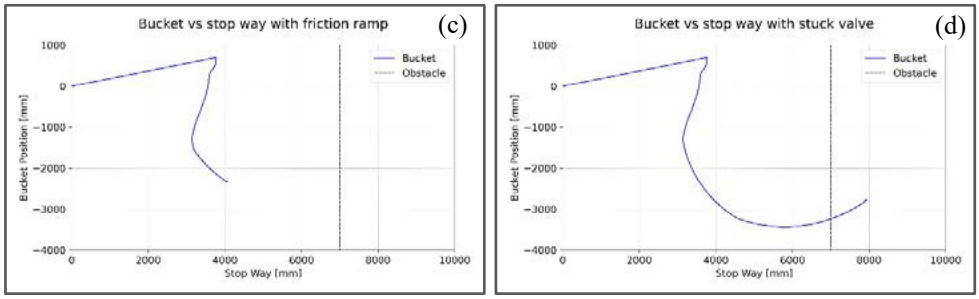

Figure 4-6. Bucket stopping behaviour under valve failure behaviour

In contrast, the stuck valve failure shown in Figure 4-6(d) causes continued bucket motion beyond the defined stopping position. The movement stops in the mechanical end position of the excavator attachment. This behaviour indicates that the hydraulic flow through the

valve is not interrupted, despite the presence of a stop command, and illustrates a safety-relevant failure mode in which unintended motion persists due to clamping of the valve.

4.3. Evaluation

The simulation results show that the implemented diagnostic concept reliably detects sensor drifts, signal offsets and hydraulic malfunctions before the defined safety limit is exceeded. The Category 2 architecture [8] with redundant sensors which is consistent with the functional safety objectives for earth-moving machinery as defined in ISO 19014 [7], increases failure tolerance and enables early detection of degrading behaviour. The combination of DSHplus® [1, 2] and Cube® [1, 2] allows systematic execution and evaluation of extensive test series while maintaining traceability. To place the obtained diagnostic coverage results in a broader context, Table 4.2 compares the proposed simulation-based DC evaluation with conventional datasheet-based approaches. The comparison highlights differences in scope, validation depth, and the integration of FMEA-derived failure modes [4, 10], illustrating the added value of time-resolved, system-level fault-injection-tests for assessing diagnostic effectiveness.

Table 4.2. Comparison of datasheet-based & simulation-based DC evaluation

Aspect	**Datasheet-based Evaluation**	**Simulation-based Evaluation (Fault-Injection-Test)**
Scope	Component Level	System level (including software logic)
Basis	Static manufacturer data (MTTFD, DC values)	Dynamic failure behaviour under realistic conditions
Focus	Hardware reliability	Algorithmic failure detection and reaction
Detection proof	Assumed via design parameters	Verified through time-resolved detection response
Performance Level Validation	Theoretical	Practical validation within virtual environment
Limitation	Cannot assess control algorithm or reaction time	Requires modelling and simulation effort
Added value	Quick estimation	Realistic validation of functional safety behaviour of the machine
Integration of FMEA results	Not considered - datasheet assumes ideal operation	FMEA-identified failure used for targeted fault-injection tests
Phase in V-Model	Hardware validation	System and machine validation

4.4. Cube-Based Evaluation

The simulated test cases are evaluated using the automated Cube® [1, 2] workflow environment, which coordinates simulation execution, data processing, result visualisation, and documentation in a predefined and reproducible sequence. In combination with the automated Cube® workflow for execution, parameter management, and result evaluation, the virtual twin is extended to a digital twin [1, 14] representation in accordance with the concepts described in the literature [14] and their implementation in an automated simulation and workflow [1]. Coupling the DSHplus® [1, 2] simulation model with the Cube® workflow enables automatic execution of parameter variations and failure scenarios

under consistent test conditions. The evaluation shows a substantial reduction in manual engineering effort, while the numerical simulation runtime per test case remains comparable for manual and automated execution. The observed efficiency gain is achieved by eliminating repetitive manual tasks such as parameter configuration, data storage, post-processing, and result documentation rather than by accelerating the simulation itself. Individual simulation runs require only a few seconds, allowing parameter studies with numerous failure scenarios to be completed within minutes. In contrast, equivalent real-machine tests typically require several minutes per test case due to machine setup, repeated execution, and data acquisition, which limits the number of scenarios that can be investigated. In a manual simulation workflow, the surrounding engineering activities typically dominate the total effort per test case, whereas the Cube®-based execution performs these steps deterministically without user interaction. In addition, the automated workflow improves reproducibility and result quality by applying all test parameters consistently and eliminating handling errors associated with repeated manual testing. The simulation environment further allows the investigation of critical or hazardous scenarios, such as collision conditions or complete failure of safety functions, which cannot be systematically explored in real-machine experiments. Overall, the Cube-based evaluation provides a reproducible framework for system-level assessment of diagnostic performance, enabling higher test coverage with significantly reduced engineering effort compared to conventional manual or real-machine testing. The benefit of the Cube®-based approach therefore lies not in faster simulation, but in the systematic reduction of manual effort and variability in the evaluation process.

5. SUMMARY AND CONCLUSION

This work shows that simulation-based fault-injection testing can be used to evaluate diagnostic behaviour of safety-related control functions in a time-resolved and system-level manner. The purpose of the presented approach is not the simulation itself, but the generation of early and reproducible evidence for diagnostic performance under defined failure conditions, which is difficult to obtain by conventional testing methods. The results demonstrate that diagnostic coverage is strongly influenced by the temporal characteristics of failures and by the domain in which failures occur. Slowly developing sensor degradations and hydraulically induced effects may lead to delayed detection, even if the implemented diagnostic logic is functionally correct. This highlights that diagnostic effectiveness cannot be assessed solely on a structural or datasheet level, but requires dynamic evaluation under realistic operating conditions. From a development perspective, the approach supports decision-making by shifting extensive diagnostic validation from late-stage physical testing to an earlier simulation-based phase. This enables systematic comparison of design variants, monitoring strategies, and parameter settings before hardware availability, while maintaining traceability to FMEA-derived failure assumptions. In summary, the presented methodology provides a means to validate diagnostic concepts with respect to timing, coverage, and system interaction, thereby supporting robust safety design and reducing the risk of late-stage design iterations. Although the movement limiter already provides a high level of operational safety, the results indicate that the dynamic diagnostic coverage identified by the FMEA-based digital model cannot yet fully satisfy the performance requirements. Consequently, the simulation results reveal the need for further refinement of both the movement limiter algorithms and the associated diagnostic strategy.

Abstract.

During hydraulic equipment service, solid particles infiltrate the oil due to component wear or external contamination, leading to oil contamination. The ingress of contaminated particles into spool valve clearances can cause abrupt increases in spool friction force, resulting in control valve malfunctions and even catastrophic hydraulic system failures. This study focuses on a threaded cartridge directional valve, constructing a contamination susceptibility test rig to investigate the effects of particles with varying contamination levels (10-300 mg/L) and size ranges (0-3 μm, 0-5 μm, 0-10 μm, 0-20 μm, 0-30 μm) on spool friction. It was found that for a unilateral clearance of 5-10 μm, "sensitive particles" (0-10 μm, comparable to the clearance size) induced the maximum electromagnetic driving force on the spool, reaching 150.5 N at 200 mg/L—5 times greater than in clean oil. To unveil the microscopic mechanism of friction escalation caused by sensitive particles, a visualized model experiment was designed, capturing the complete process of particle ingress and aggregation within the clearance using high-speed cameras. Finally, the particle ingress rate in the clearance was calculated via the Discrete Phase Model (DPM), and three optimized structures were proposed based on visualization and simulation results, reducing particle ingress by 80% and mitigating spool sticking risks. This study elucidates the macro-phenomena and micro-mechanisms of "sensitive particle"-induced spool sticking while providing improvement strategies, offering experimental methodologies and theoretical foundations for high-reliability hydraulic spool valve design and contamination control.

Keywords. hydraulic spool valve, friction force, sensitive particles, visualization, structural improvements.

1. INTRODUCTION

Cartridge valves are widely used in hydraulic control systems of engineering machinery and marine equipment due to their compact structure and ease of installation [1]. Among them, spool-type cartridge valves employ high-precision spools with a typical unilateral clearance of 5–10 μm, which provides sealing and guidance functions. As a typical configuration of control valves, the spool features a long cylindrical shaft structure that regulates the flow direction and throttling area of the fluid, thereby determining key parameters such as flow rate and pressure[2-5]. Under high temperature, high pressure, and heavily contaminated conditions, the spool is susceptible to sticking caused by multiphysics coupling effects, which severely compromises control accuracy and response performance[6-9]. Therefore, conducting experimental studies on contaminant-induced jamming and visualizing particle migration and accumulation in spool valves will contribute to improving the theoretical framework of spool design.

Research indicates that spool valve sticking is primarily caused by radial unbalanced forces, non-uniform thermal deformation, and particle intrusion into the clearance. Lin et al. systematically analyzed the mechanisms of these three factors and proposed corresponding suppression strategies; their numerical study based on a solid-liquid two-phase flow model further revealed the migration and sticking patterns of particles within the clearance[10, 11]. Qian et al. found that particles tend to accumulate in the pressure balancing groove regions, and the groove geometry affects the magnitude of the sticking force[12]. Among different groove shapes, the triangular groove demonstrated the best anti-sticking performance due to its minimal fluid deflection and the tendency for particles to settle at the bottom of the groove. Brazhenk experimentally determined the influence of particle size and concentration on the sticking and wear of hydraulic valves, noting that aerospace hydraulic valves are particularly sensitive to certain particle sizes[13]. Furthermore, numerous scholars have experimentally and numerically investigated particle migration, retention, dynamics, and force characteristics in fluid media[14-17].

In terms of visualization studies, Jianjun Zhang et al. employed fluid-structure interaction simulations and high-speed photography of enlarged models to reveal the dynamic process of micron-sized particles entering the clearance, validating the effectiveness of the numerical approach[18]. Xinqiang Liu et al. conducted microscopic observation and simulation analysis to systematically investigate particle trajectories and erosion characteristics at the throttle orifice of servo valves, clarifying the influence of pressure difference, particle shape, and size on erosion behavior. These studies provide important insights for understanding the microscopic movement mechanisms of particles and for structural optimization [19][20].

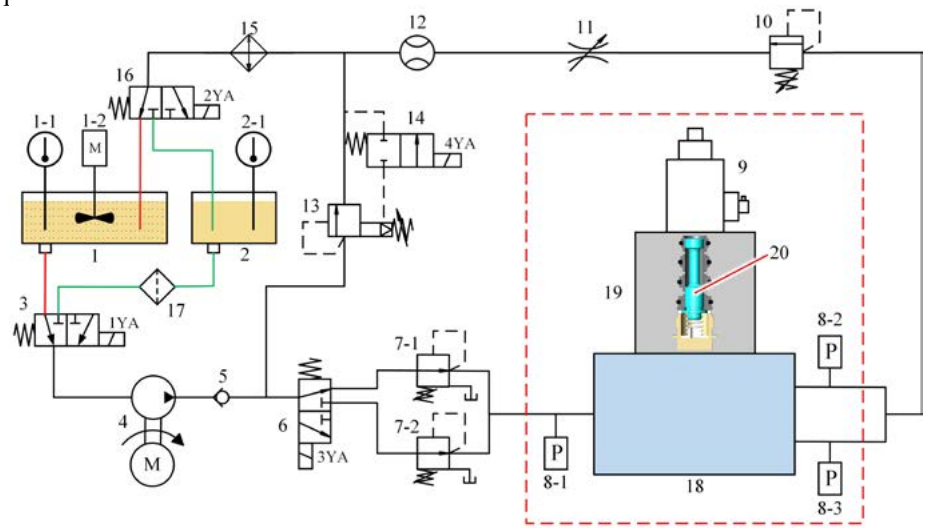
Figure 1.1. Physical and Three-Dimensional Structural Diagrams of the Spool-Type Directional Control Valve



The studied object is a spool-type directional valve used to regulate hydraulic circuits in a hydraulic system. Its structure and operating principle are shown in Figure. 1.1. The valve consists of a screw cover, spring seat, spring, sleeve, and spool. It is a two-position, three-way valve with a pressure inlet (P) and two outlet ports (A and B). When the actuation force (Ps) is not applied, the spool remains in the right position due to the spring force, connecting P to B. When Ps is applied, the spool moves to the left against the spring force, thereby connecting P to A.

2. MEASUREMENT OF CONTAMINATION-INDUCED FRICTION FORCE IN SPOOL-TYPE DIRECTIONAL CONTROL VALVES

2.1. Design of the Experimental Plan

2.1.1. Test Principle, Working Medium, and Selection of Critical Components

Figure 2.1 shows the schematic diagram of the component contamination susceptibility test. Pressure and flow rate can be adjusted by controlling the throttle valve and the electric motor. A switching mechanism between the contaminated oil tank and the clean oil tank is adopted: the contaminated tank is used to evaluate the external characteristics of the valve under working media of different contamination levels, while the clean tank serves to flush out solid particles remaining in the system, thereby facilitating subsequent test cycles. A water-cooled oil cooler is employed to provide forced heat exchange, dissipating heat generated during system operation and minimizing the impact of temperature on the experimental results.

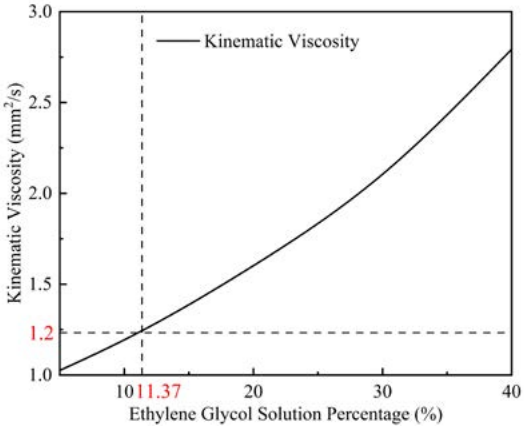
Figure 2.1. Schematic diagram of the external characteristic test for contamination sensitivity

For other key components in the system, such as the hydraulic pump, an Italian HAWK high-pressure piston pump, model NHD1525L, was employed. This pump features ceramic pistons, which offer high hardness and strong contamination resistance. Its inlet filtration accuracy is 150 μm, allowing it to accommodate the particle sizes introduced in the experiments. The high contamination resistance makes it suitable for contamination susceptibility tests on this platform, as the addition of particles to the working fluid has minimal impact on the pump's performance and does not affect the final test results of the valve. To further minimize the influence of particles introduced into the system during experiments, all tubing and valve components were made of stainless steel.

Given the physical properties of aviation kerosene at 20°C – density range 775–830 kg/m³ and kinematic viscosity 1.25 mm²/s – an ethylene glycol aqueous solution was formulated to match these characteristics. Experimental curve fitting of kinematic viscosity versus glycol concentration at 20°C (Figure 2.2) revealed that an 11.37% ethylene glycol solution by mass exhibits the closest match to the kerosene's properties. Consequently, this 11.37% concentration was ultimately selected as the working fluid substitute.



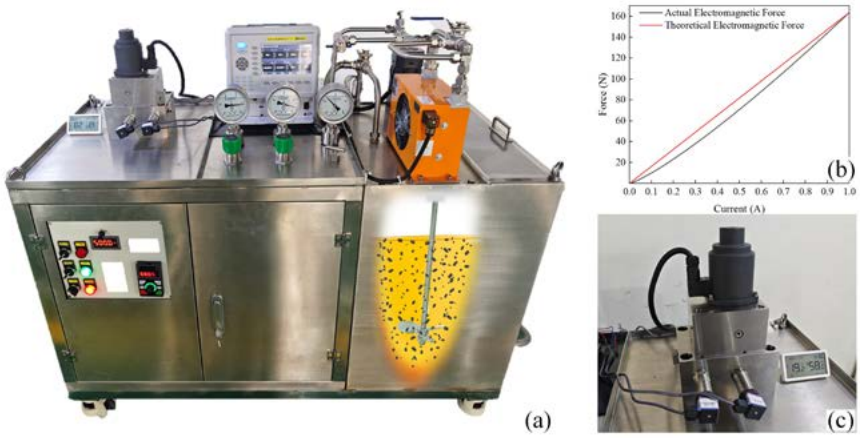


Figure 2.2. Kinematic Viscosity of Ethylene Glycol Aqueous Solutions at Varying Concentrations

2.2. Test Bench Construction and Experimental Results Analysis

2.2.1. Test Bench Construction

The test bench model is shown in Figure. 2.3(a). It features an integral frame structure with a triple-compartment tank arranged on the right side. From back to front, these are the contaminated oil tank, the clean oil inlet tank, and the clean oil return tank. The contaminated oil tank is equipped with an agitator operating at 60–200 r/min, suitable for mixing low-viscosity fluids. The agitator shaft and impeller are made of 304 stainless steel, and a thermocouple is installed in the tank to monitor the oil temperature in real time. Components such as the cooler, agitator, and manual directional valve are mounted on top of the tank. The operating panel is equipped with an adjustable shut-off valve, two pressure-reducing valves, pressure gauges, and a paperless recorder. The test valve block is placed separately on the left side for easy disassembly and installation. The lower cabinet contains the electric motor, frequency converter, flow meter, and solenoid directional valve. To measure the friction force during the movement of the spool in the directional valve, a proportional

solenoid with a rated stroke of 8 mm was selected. Within its rated stroke range, the thrust force is proportional to the current supplied to its coil. The stroke-force characteristic curve of the solenoid is shown in Figure. 2.3(b). Within the rated stroke range, the variation in stroke has almost no effect on the force.

(a) Test Bench Model; (b) Solenoid Current-Force Characteristic Curve; (c) Physical Views of the Base and Test Manifolds

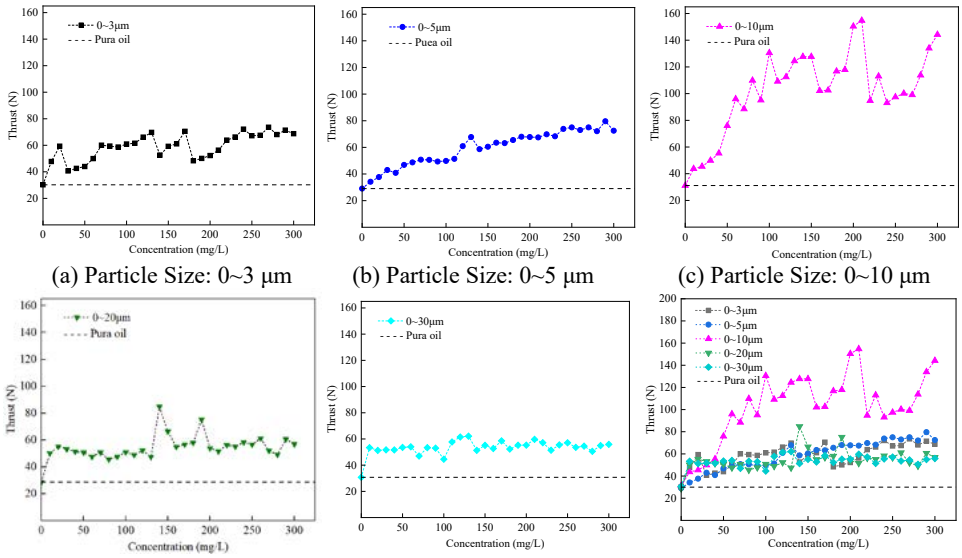

Figure 2.3. Test Bench Model and Physical Views of the Base and Test Manifolds

2.3. Analysis of Experimental Results

The experiment maintained an inlet pressure of 2 MPa and an outlet pressure slightly below 2 MPa, with a flow rate of 3–4 L/min. The directional valve spring preload was set to 22.4 N. After 3 minutes of continuous operation, force was gradually applied to the right end of the valve spool via the solenoid. Pressure transients in both outlet branches were monitored while solenoid current values were recorded to indirectly determine the stiction force magnitude. To investigate variations in the valve's external characteristics under contamination, particle size ranges were selected: 0~3 μm, 0~5 μm, 0~10 μm, 0~20 μm, and 0~30 μm. To prevent frequent spool seizure from high initial concentrations, particle concentration was incrementally increased from 10 mg/L to 300 mg/L in 10 mg/L steps. For each particle size, 31 distinct concentration levels were tested. Stiction force was measured every 3 minutes per condition, with four consecutive measurements averaged per data point.

As shown in Figure 2.4, the line plots illustrate variations in solenoid thrust force under different particle sizes and concentrations. Initially, the solenoid thrust force in particle-free working medium was 26.6 N. For particle sizes of 0~3 μm, the maximum solenoid thrust force reached 73.54 N; for 0~5 μm particles, it increased to 79.63 N; and for 0~10 μm particles, the thrust force surged to 127.7 N. A pronounced stiction phenomenon was observed with rising particle concentrations. Notably, once the concentration exceeded 300 mg/L, the solenoid-driven spool movement could not be reset by the spring force after actuation. For 0~20 μm particles, the maximum solenoid thrust force decreased to 84.73 N, representing a 33.6% reduction compared to the 0~10 μm particle case. With 0~30 μm particles, the maximum thrust force further dropped to 62.14 N, and no stiction occurred during testing. These results indicate that 0~10 μm particles act as critical particles (sensitive particles) in this system. Particles smaller than 0~10 μm are flushed out of the spool valve clearances by the fluid medium, while larger particles (exceeding 0~10 μm) cannot enter the

narrow clearances, thereby failing to generate significant stiction forces. 0~10μm particles caused larger thrust fluctuations, while other sizes also caused fluctuations but with smaller amplitude than 0-10μm particles.

(a) Particle Size: 0~3 μm (b) Particle Size: 0~5 μm (c) Particle Size: 0~10 μm

(d) Particle Size: 0~20 μm (e) Particle Size: 0~30 μm (f) Solenoid Thrust Force Variation with Particle Size and Concentration

Figure 2.4. Line Plots of Solenoid Thrust Force Variation with Particle Size and Concentration

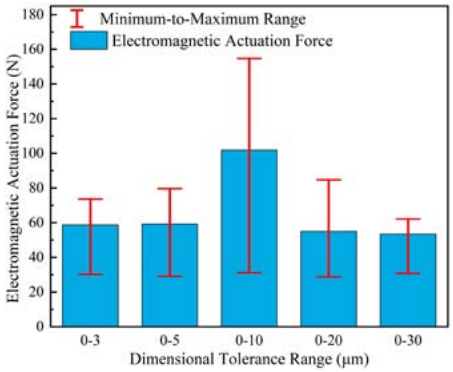

Figure 2.5. the maximum, minimum, and average solenoid forces under different particle sizes

As shown in Figure 2.5, the maximum, minimum, and average solenoid forces under different particle sizes are presented. The stiction force increases with particle size until the particle size exceeds the spool valve clearances, beyond which the stiction force diminishes accordingly.

As shown in Figure 2.6, during spool valve operation, solid particles smaller than the valve mating clearance enter the clearance with the fluid medium. A portion of these particles exit with the fluid flow, while others remain trapped within the clearance. Over time, particles gradually accumulate in the clearance. For an individual particle, when its upper and lower

surfaces simultaneously contact the spool and valve body, the particle rotates under torque due to spool movement. To further investigate particle retention within valve clearances, subsequent sections present simulation and experimental visualization studies of particle ingress dynamics.

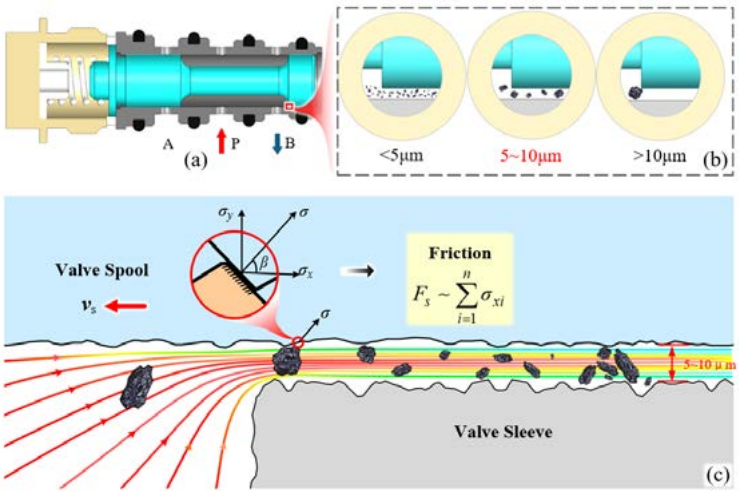

Figure 2.6. Schematic of Particle Invasion into Clearances

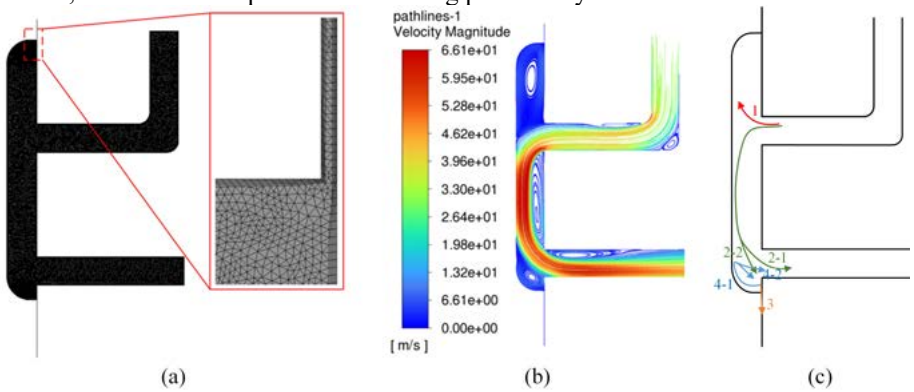
3. VISUALIZATION STUDY OF PARTICLE INVASION INTO CLEARANCES



3.1. Flow Field Simulation and Results Analysis

3.1.1. Simulation Model and Parameter Settings

Given the substantial number of particles invading the clearance and the requirement for computational efficiency, the three-dimensional spool valve model with clearances was simplified to a two-dimensional model, with simulations conducted exclusively for the P-B operating condition (P port connected to B port). The spool-sleeve clearance range of 5~10 μm was represented by a 10 μm clearance in the simulation model. Local mesh refinement ensured grid skewness below 0.6, yielding a final mesh of 500,000 cells; the partitioned fluid domain mesh is illustrated in Figure 3.1 (a).

The fluid phase is fuel, with boundary conditions set as a pressure inlet (1 MPa) and pressure outlet (0 MPa). Three outlets were defined in the simulation: two clearance outlets and one main flow path outlet. For the particle phase, iron particles were selected for trajectory tracking, capturing their motion from injection to escape from the valve chamber fluid domain. Three particle sizes were tested: 5 μm, 8 μm, and 10 μm. Particles were injected from the inlet surface with incident directions spanning an angular range of 30° to 150°. Each simulation cycle injected 10 particles of each size (30 particles per cycle), repeated for 20 cycles (totaling 600 particles). The inlet and outlet boundaries were defined as escape boundaries, while the walls were set as rebound boundaries. Figure 3.1(b) displays flow streamlines within the valve chamber, revealing distinct vortices in the upper and lower regions where particles become entrained in rotational motion.

Figure 3.1(c) illustrates the particle trajectory diagram. A minority of particles follow Path 1 into the upper chamber, while most migrate downward via Path 2. Particles along Path 2-1 flow directly to the outlet, whereas those on Path 2-2 collide with the wall. Post-collision, some particles invade the lower clearance via Path 3, while others enter Path 4, entrained in the vortex flow. Vortex-driven particles either escape through the outlet or invade the lower clearance. Over time, more particles accumulate in the lower clearance than in the upper clearance, with numerous particles circulating persistently in the lower vortex.

(a) Simulation Model Mesh Generation; (b) Flow Trace Diagram; (c) Particle Trajectory Diagram

Figure 3.1. 2D Simulation Model and Mesh Generation

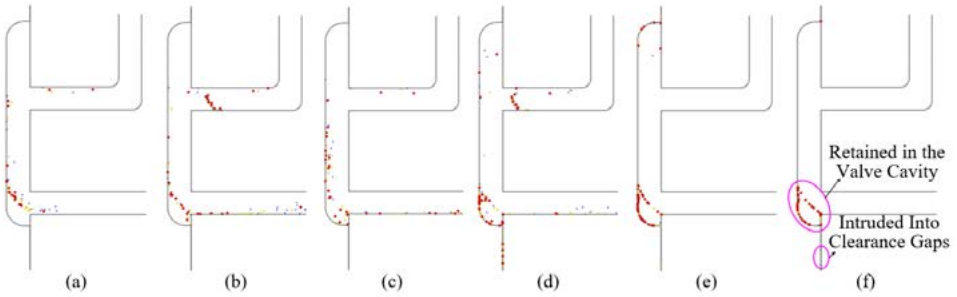


Figure 3.2. Particle Position Diagrams at Different Time Instants

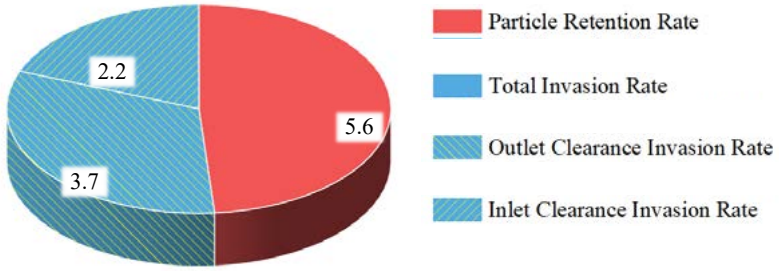
Figure 3.2 depicts particle positions in the valve chamber at different simulation stages. For clarity, particles are magnified 30 times. Blue, yellow, and red represent 5 μm, 8 μm, and 10 μm particles, respectively. Initially, particles are dispersed randomly. As the simulation progresses, their migration patterns align with flow dynamics. In later stages, 34 particles remain trapped in the chamber, rotating along the lower vortex traces.

3.1.2. Particle Migration and Invasion Analysis

The particle retention rate (mechanical trapping ratio) is defined as the ratio of particles remaining in the valve chamber at the end of the simulation to the total injected particles, while the invasion rate represents the ratio of particles invading the clearances to the total injected particles. For the P-B operating condition, the particle retention rate in the valve chamber was 34/600 = 5.6%, with a total invasion rate of 35/600 = 5.9%. Specifically, the

invasion rate into the lower clearance was 22/600 = 3.7%, and into the upper clearance was 13/600 = 2.2%. The retention and invasion rates are summarized in Figure 3.3.



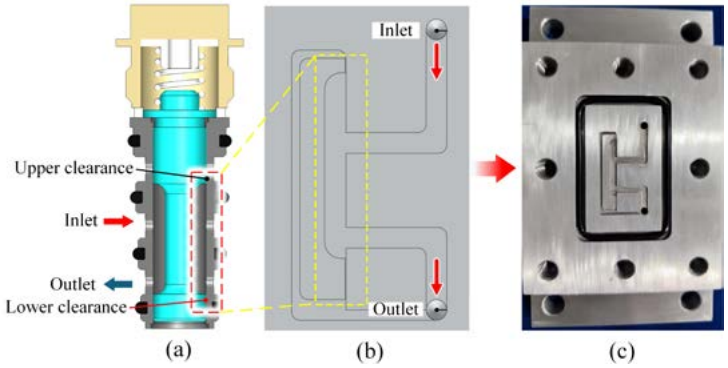


Figure 3.3. Retention and Invasion Rates of Particles in the Valve Chamber

3.2. Experimental Model Design

To investigate particle invasion dynamics within valve clearances, the 3D spool valve chamber was simplified to a 2D planar model. Flow channels were machined into an aluminum alloy plate with a uniform groove depth of 0.6 mm. Given the practical impossibility of directly observing sub-micron particle motion within the actual 5~10 μm spool-sleeve clearance and manufacturing constraints for experimental models at this scale, the clearance was geometrically scaled up by 10× to 0.1 mm (100 μm), with contaminant particles proportionally enlarged to 70~120 μm. Figures 3.4(a) and (b) show the 3D spool valve configuration and its corresponding 2D planar flow channel equivalent.

(a) 3D Directional Control Valve Model; (b) Simplified Experimental Model Schematic; (c) Physical Assembly of the Experimental Model

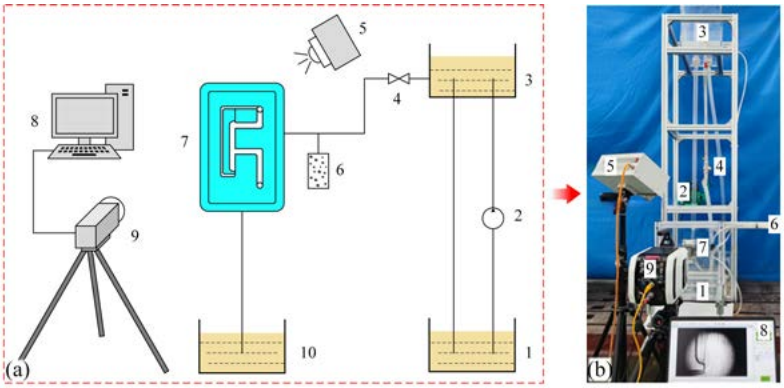

Figure 3.4. 3D Valve Model, Simplified Experimental Model, and Experimental Assembly

The 2D visualization setup comprises two layers: Lower layer: Aluminum alloy base plate featuring machined flow channels and perimeter sealing grooves, with side-mounted threaded ports for fluid connections. The clearance outlet connects to the flow channel at the end of the plate. Upper layer: A transparent acrylic plate for real-time observation of particle motion. The two layers are sealed using a rubber sealing gasket and fastened with bolted connections. The assembled experimental model is illustrated in Figure 3.4(c).

3.3. Test Bench Design

Considering the hazardous nature of fuel and the need for high imaging clarity, a water-based medium with comparable density and viscosity was selected as the working fluid. The

schematic of the visualization system is shown in Figure 3.5(a). The experimental setup consists of a hydraulic water system and a high-speed camera system. A constant pressure is supplied to the system by an elevated water tank 3. The water pump 2 draws fluid from the supply tank 1 to feed the elevated tank 3. The outlet of the elevated tank 3 is connected to the test model 7 via a pipeline with a shut-off valve 4. Contaminant iron particles are injected into the flow upstream of the test model 7 using a particle injector 6. The fluid then returns to the return water tank 10. During high-speed camera recording, lighting 5 illuminates the test section. The motion of particles within the flow field of the test model 7 is captured by the high-speed camera 9 and transmitted to the computer 8 for analysis.

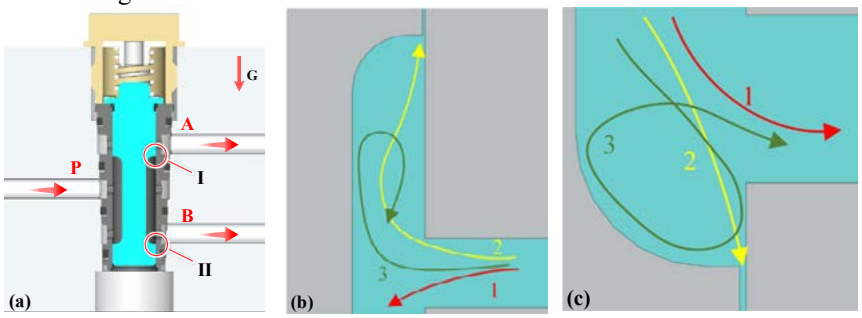
Figure 3.5. Schematic and Physical View of the Visualization Test System

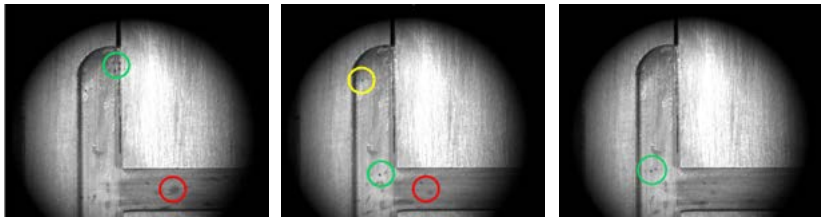
As shown in Figure 3.5(b), the physical experimental system is displayed. The test frame is constructed entirely from aluminum alloy profiles. Both the low-level and high-level water tanks are fabricated as bonded assemblies of transparent acrylic panels, enabling real-time monitoring of water levels. The 1.6 m height difference between the water level and the manifold inlet corresponds to an inlet pressure of 15.68 kPa (calculated via hydrostatic pressure: P=ρgh$P=\rho gh$).



3.4. Analysis of Experimental Results

During testing, the two clearance regions of the spool valve were primarily imaged to observe particle invasion into the clearances. Since post-shutdown particle accumulation is a critical factor in spool stiction, particle deposition within the valve chamber and clearances was recorded 5 minutes after system shutdown. The high-speed camera captured 10,000 frames per second (fps), with a maximum recording duration of 3 seconds per session. To focus on critical dynamics, the motion trajectories of select particles within the valve chamber and invading the clearances were selectively recorded. Due to the camera's limited field of view, imaging was divided into the upper and lower valve chamber regions.

Figure 3.6(a)(b) shows the 3D schematic of the spool valve and the imaged upper chamber and upper clearance. Three primary particle trajectories are marked: Path 1: Particles migrating toward the outlet. Path 2: Particles invading the clearance. Path 3: Particles colliding with the wall and subsequently flowing toward the outlet. The majority of particles follow Path 1 toward the outlet, while a portion of particles collide with the wall along Path



2, either invading the upper clearance or moving along the wall surface. Another subset of particles collides with the upper spool wall along Path 3 before redirecting toward the outlet.

Figure 3.6(a)(c) shows the 3D schematic of the spool valve and the imaged lower chamber and lower clearance. Three primary particle trajectories are marked: Path 1: Particles migrating toward the outlet. Path 2: Particles invading the clearance. Path 3: Particles colliding with the wall, rotating within the chamber, and subsequently flowing toward the outlet. The majority of particles follow Path 1 toward the outlet. A subset collides with the wall along Path 2 and invades the clearance, while others collide with the wall along Path 3 before redirecting to the outlet.

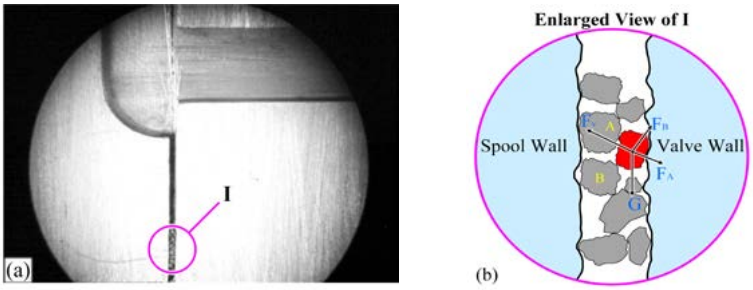
Figure 3.7. Particle Positions in the Upper Valve Chamber at Different Time Instants

Figure 3.7 illustrates the particle positions in the upper valve chamber at different time instants. Key observations include: Particles along Path 1 exhibit significantly higher velocities as they flow toward the outlet. Particles along Paths 2 and 3 demonstrate lower velocities. Specifically, particles along Path 3 ascend briefly under fluid forces before



descending under the influence of gravity. Particles invading the clearances move slowly within the valve chamber and are fewer in number.

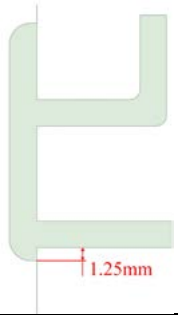
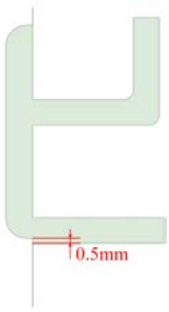
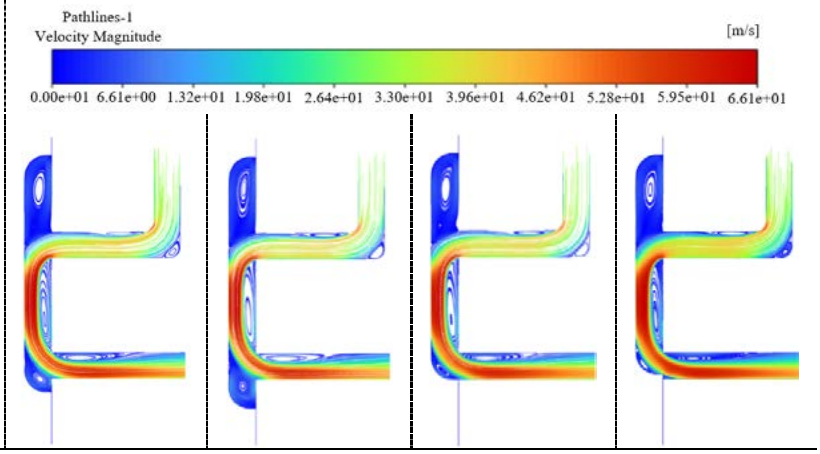
Figure 3.9. Particle Retention After System Shutdown

Figure 3.8 illustrates particle positions in the lower valve chamber at sequential time instants. Observations reveal: Particles following Path 1 exhibit significantly higher velocities toward the outlet. Particles along Path 2 collide with the sleeve wall surface, subsequently descending to invade the lower clearance. Particles traversing Path 3 rebound upward upon collision with the sleeve wall, ultimately exiting along the wall surface.

Figure 3.9. illustrates the particle retention after shutting off the shut-off valve and system shutdown. Significant particle accumulation is observed in the lower clearance. This phenomenon arises because the interaction forces between aggregated particles, frictional forces exerted by the clearance walls, adhesive forces between particles and walls, and the gravitational force collectively cause the particles within the clearance to reach force equilibrium, thereby remaining trapped.







4. VALVE STRUCTURAL OPTIMIZATION

4.1. Structural Design Variations

For the P-B operating condition, three distinct structural designs were developed: (1) Lowering the spool shoulder by 1.5 mm, (2) Aligning the spool shoulder flush with the outlet

port, (3) Raising the spool shoulder by 1.75 mm. The geometric configurations of these designs are detailed in Table 1.

Table 1 Modified Spool Shoulder Models and Post-Modification Flow Trace Diagrams

Designation	Original Model	Lowering the Spool Shoulder	Spool Shoulder-Aligned	Raising the Spool Shoulder
Model Number	**O**	**I**	**II**	**III**
Geometric Model				
Flow Trace Diagrams				

4.2. *Simulation of Different Structures*

A comparative simulation analysis was conducted for the three designs. Performance was evaluated based on particle retention rate and clearance invasion rate, leading to the identification of the optimal design. The flow trace diagrams for each structure are summarized in Table 1.

Structure I: 40 particles remained in the valve chamber at the end of the simulation. Total invasion rate: 44/600 = 7.3% (29 particles in the lower clearance (29/600 = 4.8%); 15 particles in the upper clearance (15/600 = 2.5%)).

Structure II: 92 particles were retained within the valve chamber at the end of the simulation. Total invasion rate: 7/600 = 1.2% (3 particles in the upper clearance (3/600 = 0.5%); 4 particles in the lower clearance (4/600 = 0.6%)).

Structure III: 24 particles remained in the valve chamber at simulation completion. Total invasion rate: 10/600 = 1.7%, with all invading particles exiting through the upper clearance outlet. Lower clearance invasion rate: 0/600 = 0% (no particles invaded). Upper clearance invasion rate: 16/600 = 2.6%.

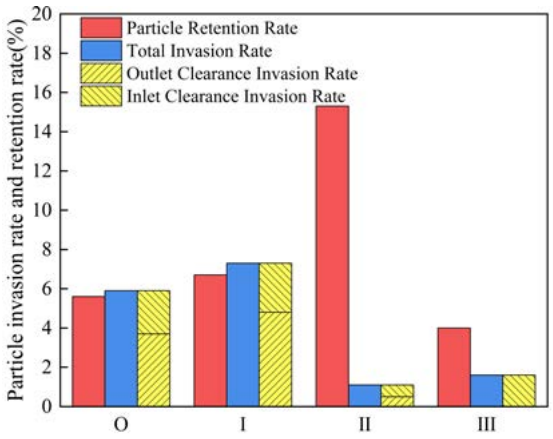


Figure 4.1. Particle Retention and Invasion Rates for Different Structural Models

Figure 4.1 illustrates the particle retention and invasion rates for different structural models. A comparative analysis of four models — the original model, spool shoulder-lowered model, spool shoulder-aligned model, and spool shoulder-raised mode — reveals the following:

- (1) Retention Rate Analysis: The spool shoulder-raised model reduced particle retention by 1.7% compared to the original model. The spool shoulder-lowered and spool shoulder-aligned models exhibited increased retention rates of 1.1% and 9.6%, respectively.
- (2) Invasion Rate Analysis: The spool shoulder-aligned and spool shoulder-raised models reduced invasion rates by 4.8% and 4.3%, respectively. Notably, the lower clearance invasion rate for the raised model was 0%. The spool shoulder-lowered model increased the invasion rate by 1.4%.

Conclusion: Considering both retention and invasion rates, the spool shoulder-raised model demonstrates optimal performance.

5. CONCLUSIONS

(1) Experimental results demonstrate that particles within the 0~5 μm, 0~10 μm, 0~20 μm, and 0~30 μm size ranges induce maximum stiction forces of 79.63 N, 127.7 N, 84.73 N, and 62.14 N, respectively, in the 5~10 μm clearance between the spool and sleeve. The 0~10 μm particles generated the highest stiction force, confirming that critical particles (sensitive particles) with sizes comparable to the spool clearance are the primary contributors to spool friction.

(2) Simulation analysis revealed particle migration and clearance invasion dynamics. At simulation completion, the retention rate in the valve chamber was 5.6%, with a total invasion rate of 5.8%. Smaller particles dominated invasion into the inlet-side clearance.

The vortex phenomenon significantly influenced particle trajectories, causing some particles to circulate within the chamber and eventually become trapped.

(3) Visualization experiments showed that most particles entering the valve chamber with the fluid were flushed out. A small fraction remained trapped in vortex-driven rotations near the outlet or invaded the upper/lower clearances. Post-shutdown, particles invading the clearances were not expelled by gravity but aggregated due to particle-wall interaction forces. Particles rotating in vortices settled at the chamber base after shutdown.

(4) Three spool shoulder optimizations were tested: lowering, aligning, and raising the shoulder. Simulations yielded retention rates of 6.7%, 15.3%, and 4%, and total invasion rates of 7.3%, 1.1%, and 1.6%, respectively. The spool shoulder-raised design demonstrated superior performance when balancing retention and invasion metrics.

Performance analysis of rotary mechanical pulsation compensators for different types of pumps

Gudrun Mikota[1], David Holzer[2]

Institute of Machine Design and Fluid Power, Johannes Kepler University Linz, Altenbergerstrasse 69, A-4040 Linz, Austria, [1]gudrun.mikota@jku.at, [2]david.holzer@jku.at

Abstract.

Rotary mechanical pulsation compensators require a torsionally compliant coupling attached to the pump rotor. To quantify their performance for different types of pumps, the pump outlet pressure magnitude minimum at the compensation frequency and the bandwidth of the compensation effect are considered. For these performance criteria, closed-form solutions are found with an undamped hydraulic oscillator or a simple capacitance at the pump outlet. Experiments are carried out with a compensator coupling and an internal gear pump attached to different hydraulic systems. Measurement results are compared with frequency domain response from appropriate theoretical models. Compensator performance is derived from experiments to validate closed-form solutions. Using these, pressure magnitude minimum and compensator bandwidth are predicted for an axial piston pump.

Keywords. Piston pump, gear pump, pressure pulsation, compensator coupling, pressure magnitude minimum, bandwidth.

1. INTRODUCTION

A novel pulsation compensation principle for hydraulic pumps and motors was introduced in [1]. This principle uses the mass moment of inertia of the machine rotor and requires a torsionally compliant coupling in the drivetrain. Assuming a suitable stiffness of such a coupling, numerical studies were provided in [2]. The design of a compensator coupling was described in [3], where the novel assembly was classified as rotary mechanical pulsation compensator. Measurements with a radial piston pump were presented in [4]. Although the desired effect could be demonstrated, better performance was expected for other types of pumps. In [2-4], theoretical predictions on compensator performance were made by plotting frequency response functions of the coupled hydraulic-mechanical system for particular sets of parameters.

In this paper, performance criteria for rotary mechanical pulsation compensators shall be specified. They address narrow-band pulsation compensation for constant speed applications and broadband pulsation reduction for relevant speed ranges. With respect to the attached hydraulic system, resonant and non-resonant conditions are distinguished. The

All Open Access articles are peer-reviewed, distributed under the Creative Commons Attribution-Non Commercial 4.0 International

coupled hydraulic-mechanical assembly is modelled by an analogue hydraulic system, which is transformed into a dual mechanical system [5] to apply the existing theory of mechanical vibration absorbers [6]. Closed-form solutions are derived for the relationships between system parameters and performance criteria. These solutions are verified by measurements on an internal gear pump attached to different hydraulic systems, which are compared to a coupled hydraulic-mechanical model in the frequency domain. Besides flow rate excitation as in previous models, torque excitation from geometric pulsation is also included. Finally, closed-form solutions are applied to predict compensator performance for an axial piston pump.

2. PERFORMANCE MEASURES

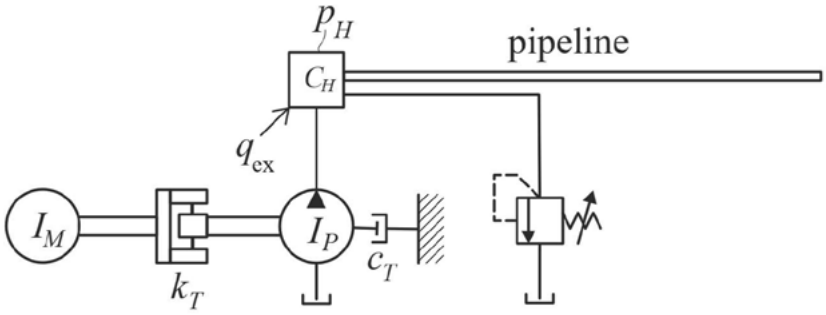

Figure 2.1. Schematic of setup with radial piston pump and pipeline

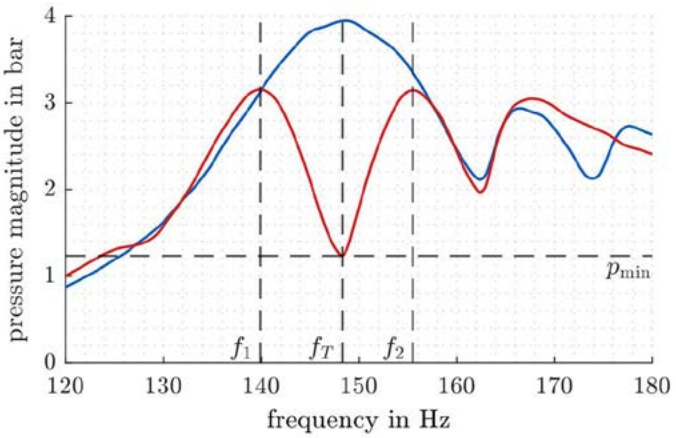

Figure 2.2. Pressure pulsations of radial piston pump. Blue: without compensator, red: with compensator

In [4], an assembly according to Figure 2.1 was used for first measurements on a rotary mechanical pulsation compensator. A compensator coupling with torsional stiffness k_T was arranged between the driving motor and a radial piston pump with mass moments of inertia I_M and I_P, respectively. The inevitable torsional damping on the pump rotor was denoted by c_T. Pump pulsations were considered as an external flow rate excitation q_{ex} into the

hydraulic capacitance C_H at the pump outlet, which was connected to a pressure relief valve. A closed pipeline was attached at the pump outlet to obtain a hydraulic resonator. The pressure relief valve was known to be heavily damped with cut-off frequency far below the first pipeline resonance. In an alternative configuration, the compensator coupling was replaced by a comparatively stiff connection between the driving motor and the pump. The magnitudes of measured pressures p_H are shown in Figure 2.2. With compensator coupling, a minimum p_{min} occurred at the compensation frequency f_T between the side resonance frequencies f_1 and f_2.

Pulsation compensators can be used in different application cases. For constant speed applications, narrow-band compensation may be sufficient unless overshooting side resonances are passed during run-up or run-down. A range of pump speeds requires an appropriate bandwidth of the compensation effect. The pressure magnitude minimum p_{min} at the pump outlet constitutes an obvious performance criterion in all application cases. A second criterion is given by the compensator bandwidth $b = (f_2 - f_1)/f_T$, which roughly describes the pulsation reduction range. With respect to both criteria, compensator performance is rather limited for the radial piston pump. Therefore, pressure magnitude minimum and compensator bandwidth shall be analyzed for other types of pumps.

3. SYSTEM TRANSFORMATION

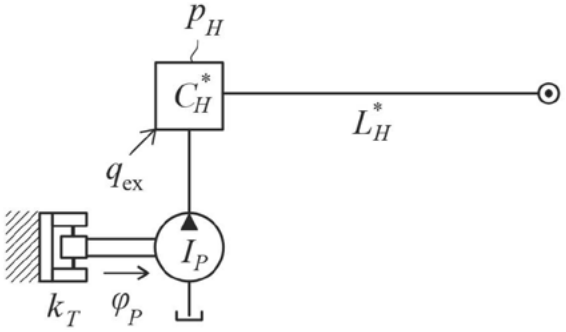

Figure 3.1. Coupled hydraulic-mechanical assembly with hydraulic oscillator

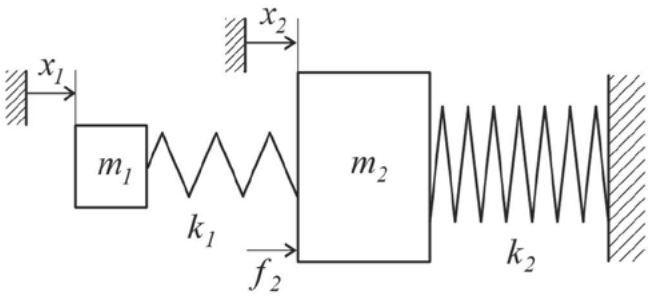

Figure 3.2. Dual mechanical system with fixed boundary

A simplified hydraulic-mechanical setup according to Figure 3.1 can be transformed into a mechanical system as follows. With the displacement V_P of the pump, the transmission ratio

between the angle φ_P of the pump shaft and the displaced volume at the pump outlet is $2\pi/V_P$. In an analogue hydraulic system, the compliance of the compensator coupling becomes a hydraulic capacitance

$$C_T = \left(\frac{V_P}{2\pi}\right)^2 \frac{1}{k_T}, \tag{3.1}$$

and the pump inertia turns into a hydraulic inductance

$$L_T = \left(\frac{2\pi}{V_P}\right)^2 I_P. \tag{3.2}$$

Hydraulic capacitance C_H^* and hydraulic inductance L_H^* represent an undamped hydraulic oscillator at the pump outlet. The inductance L_H^* is connected to a constant pressure boundary. Considering the pressures

$$p_T = -\frac{2\pi}{V_P} k_T \varphi_P \tag{3.3}$$

and p_H as state variables, this hydraulic system corresponds to the dual mechanical system in Figure 3.2 with

$$m_1 = C_T \tag{3.4}$$

$$k_1 = \frac{1}{L_T} \tag{3.5}$$

$$m_2 = C_H^* \tag{3.6}$$

$$k_2 = \frac{1}{L_H^*} \tag{3.7}$$

and a fixed end boundary condition [5]. The state variables of the dual mechanical system are the velocities $\dot{x}_1 = p_T$ and $\dot{x}_2 = p_H$. It can be seen that the classical mechanical vibration absorber setting corresponds to a rotary mechanical pulsation compensator with resonant conditions of the attached hydraulic system.

Non-resonant conditions are obtained for a simple hydraulic capacitance at the pump outlet as shown in Figure 3.3. This setting corresponds to the dual mechanical system in Figure 3.4. With C_H instead of C_H^* Equations (3.1) to (3.6) still apply, free boundaries result, and state variables are defined as above.

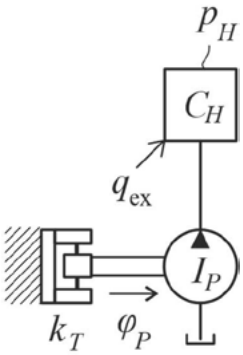

Figure 3.3. Coupled hydraulic-mechanical assembly with hydraulic capacitance

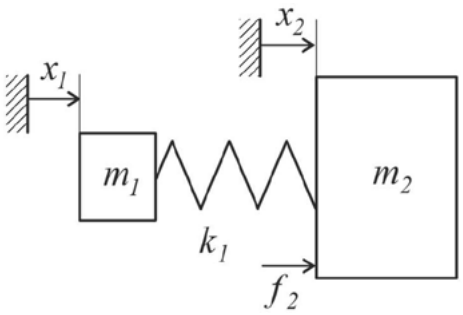

Figure 3.4. Dual mechanical system with free boundaries

4. CLOSED-FORM SOLUTIONS

For mechanical vibration absorbers, bandwidth considerations are available in [6]. Referring to Figure 3.2,

$$\frac{k_1}{m_1} = \frac{k_2}{m_2} \tag{4.1}$$

is assumed, which becomes

$$\frac{k_T}{I_P} = \frac{1}{C_H^* L_H^*} \tag{4.2}$$

with Equations (3.1 – 3.2) and (3.4 – 3.7). The bandwidth b of the absorber is obtained from the difference of the side resonance frequencies divided by the compensation frequency

$$f_T = \frac{1}{2\pi}\sqrt{\frac{k_1}{m_1}}. \tag{4.3}$$

An eigenvalue analysis of the system in Figure 3.2 yields the side resonance frequencies f_1 and f_2. With the mass ratio

$$\mu = \frac{m_1}{m_2}, \tag{4.4}$$

the bandwidth results as

$$b = \frac{f_2 - f_1}{f_T} = \sqrt{\frac{2+\mu+\sqrt{4\mu+\mu^2}}{2}} - \sqrt{\frac{2+\mu-\sqrt{4\mu+\mu^2}}{2}}. \tag{4.5}$$

For the hydraulic-mechanical assembly in Figure 3.1, Equations (3.1), (3.4), and (3.6) are used to calculate

$$\mu = \left(\frac{V_P}{2\pi}\right)^2 \frac{1}{k_T C_H^*}. \tag{4.6}$$

The compensator bandwidth b increases with μ, which means that the compensator coupling should be as compliant as possible.

For non-resonant conditions as in Figures 3.3 and 3.4, the lower side resonance does not exist. The compensator bandwidth can be calculated as

$$b_n = \frac{f_2\text{-}f_T}{f_T} = \sqrt{1+\mu}\text{-}1 \tag{4.7}$$

with μ according to Equations (4.4) or (4.6).

To determine the pump outlet pressure magnitude minimum p_{min} under resonant conditions as in Figure 3.1, torsional damping c_T on the pump rotor must be taken into account. According to the assumption (4.2), the attached hydraulic system is capable of autonomous pulsations at the compensation frequency

$$f_T = \frac{1}{2\pi}\sqrt{\frac{k_T}{I_P}}. \tag{4.8}$$

The remaining torsional single-degree-of-freedom oscillator yields the relationship

$$(-\omega^2 I_P + i\omega c_T + k_T)\frac{2\pi}{V_P}Q_{ex}(i\omega) = -i\omega\frac{V_P}{2\pi}P_H(i\omega) \tag{4.9}$$

with the angular frequency ω and the Laplace Transforms Q_{ex} and P_H of q_{ex} and p_H, respectively. At $\omega = \omega_T = 2\pi f_T$, this becomes

$$P_H(i\omega_T) = -c_T\left(\frac{2\pi}{V_P}\right)^2 Q_{ex}(i\omega_T). \tag{4.10}$$

For the fundamental harmonic of the flow rate excitation,

$$Q_{ex}(i\omega_T) = \frac{V_{ex}}{2\pi}\cdot\frac{\omega_T}{z} \tag{4.11}$$

results with the displacement amplitude V_{ex} and the number z of pulsations per revolution of the pump shaft. As the pressure magnitude minimum will occur near $\omega = \omega_T$,

$$p_{min} \approx \frac{2\pi\omega_T c_T V_{ex}}{zV_P^2} \tag{4.12}$$

is obtained as an approximation.

Under non-resonant conditions, it is possible to calculate a pressure magnitude reduction compared to the pressure magnitude p_C resulting form the flow rate excitation q_{ex} into the closed hydraulic capacitance C_H. For the assembly in Figure 3.3, it can be shown that

$$\frac{p_{min}}{p_C} \approx \frac{1}{\sqrt{1+\frac{1}{\left(c_H\left(\frac{2\pi}{V_P}\right)^2\omega_T c_T\right)^2}}}. \tag{4.13}$$

Apparently, the torsional damping on the pump rotor should be as small as possible.

5. EXPERIMENTS WITH INTERNAL GEAR PUMP

The existing compensator coupling is combined with an internal gear pump and different hydraulic systems at the pump outlet. Figure 5.1 shows the experimental setup. The drivetrain consists of an electric motor, a torque measurement shaft, the compensator coupling, and the internal gear pump. The pipeline at the pump outlet can be closed at

different lengths or disconnected completely. The mean pressure is adjusted by a pressure relief valve. The compensator coupling is realized by a spoke wheel according to Figure 5.2, which also shows one of the rotation angle sensors mounted on each side of the compensator coupling.

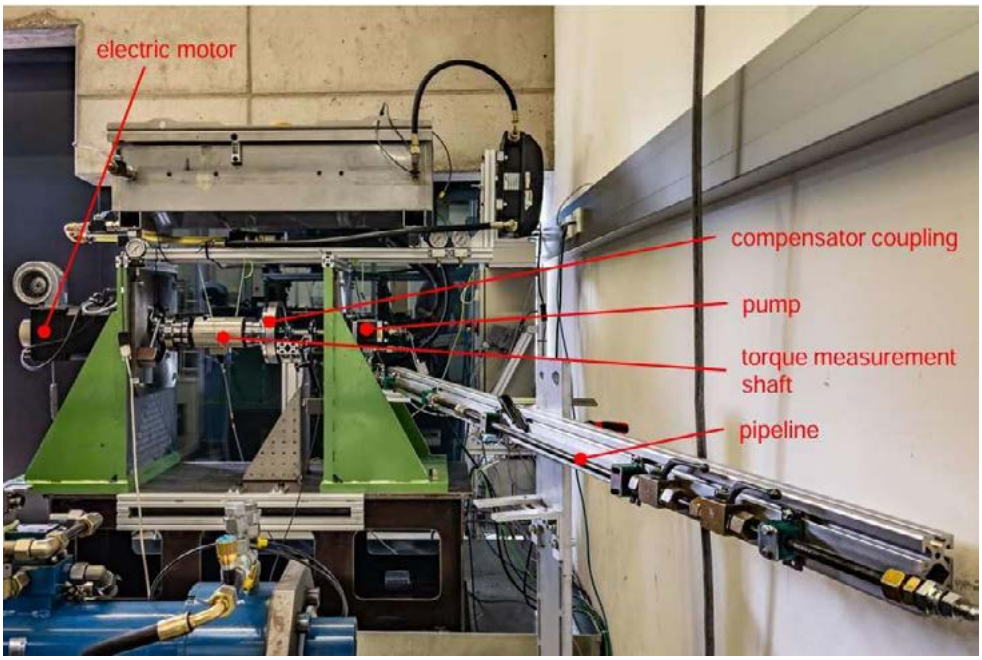

Figure 5.1. Experimental setup

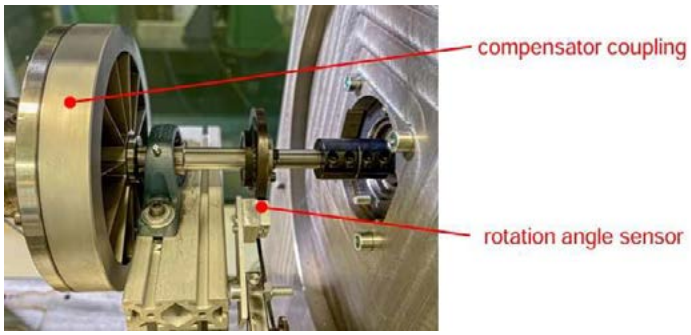

Figure 5.2. Detail with compensator coupling

The hydraulic systems at the pump outlet consist in pipelines of different lengths and the inevitable capacitance of the fittings between pump, pressure relief valve, pressure sensor, and pipeline attachment. If the pipeline is disconnected, this capacitance remains. The rotational speed of the driving motor is increased stepwise from 500 to 2000 rpm. Ten full rotations are performed after each step of 4 rpm. For each rotational speed, rectangular

windows of measured signals are considered with a trigger on the pump shaft angle, and Fourier coefficients of the fundamental pulsation frequency are calculated. In this way, the phase with respect to flow rate excitation can also be obtained. All experiments are repeated without compensator coupling.

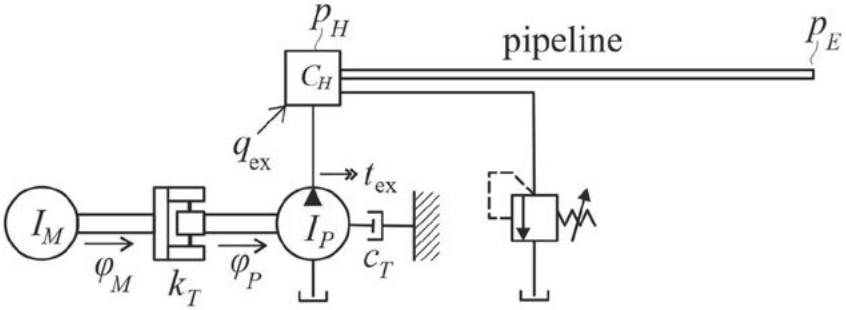

Figure 5.3. Schematic of setup with internal gear pump and pipeline

The coupled hydraulic-mechanical model in Figure 5.3 is implemented for comparison with measurements. In addition to previous models, an excitation torque t_{ex} is considered on the pump rotor. This excitation applies for geometric pulsations and originates from the fluctuating transmission ratio between the mean pressure and the torque on the pump rotor, which is determined by the respective displacement amplitude $V_{ex,g}$. In contrast, dynamic pulsations do not imply an excitation torque and only contribute a flow rate excitation.

Flow rate pulsations of external gear pumps have been studied extensively [7]. Comparable information on internal gear pumps can be found for a particular tooth profile [8]. It is concluded from literature that for both types of gear pumps, geometric and dynamic pulsations can be relevant. Therefore, q_{ex} and t_{ex} are considered as independent excitations.

The model further includes the dynamic behavior of the pipeline and the resistance R of the pressure relief valve. It is assumed that this resistance depends on the mean flow rate, which is proportional to the fundamental pulsation frequency. The state variables of the model are the rotation angles φ_M and φ_P on motor and pump side of the compensator coupling, the pressure p_H at the pump outlet, and the pressure p_E at the closed end of the pipeline. The respective Laplace transforms are denoted by Φ_M, Φ_P, P_H, and P_E, while Q_{ex} and T_{ex} denote the Laplace transforms of flow rate excitation and excitation torque, respectively.

In the frequency domain, the model can be formulated as

$$\left(-\omega^2\begin{bmatrix} I_M & 0 & 0 & 0 \\ 0 & I_P & 0 & 0 \\ 0 & -\frac{V_P}{2\pi} & C_H & 0 \\ 0 & 0 & 0 & 0 \end{bmatrix} + i\omega\begin{bmatrix} 0 & 0 & 0 & 0 \\ 0 & c_T & 0 & 0 \\ 0 & 0 & \frac{1}{R(i\omega)} + S(i\omega) & T(i\omega) \\ 0 & 0 & T(i\omega) & S(i\omega) \end{bmatrix} + \right.$$

$$\left. + \begin{bmatrix} k_T & -k_T & 0 & 0 \\ -k_T & k_T & \frac{V_P}{2\pi} & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{bmatrix}\right)\begin{bmatrix} \Phi_M(i\omega) \\ \Phi_P(i\omega) \\ P_H(i\omega) \\ P_E(i\omega) \end{bmatrix} = \begin{bmatrix} 0 \\ T_{ex}(i\omega) \\ i\omega Q_{ex}(i\omega) \\ 0 \end{bmatrix} \qquad (5.1)$$

with the functions

$$S(i\omega) = -\frac{iA}{\sqrt{E\rho}\, f(i\omega)} \cdot \cot\left(\frac{f(i\omega)\omega l}{\sqrt{E/\rho}}\right) \tag{5.2}$$

and

$$T(i\omega) = \frac{iA}{\sqrt{E\rho}\, f(i\omega)} \cdot 1/\sin\left(\frac{f(i\omega)\omega l}{\sqrt{E/\rho}}\right) \tag{5.3}$$

describing the dynamic behaviour of the pipeline with

$$f(i\omega) = \sqrt{-\frac{J_0(ir\sqrt{i\omega/\nu})}{J_2(ir\sqrt{i\omega/\nu})}}, \tag{5.4}$$

where J_0 and J_2 are Bessel functions of first kind [9]. For an internal gear pump, the fundamental frequencies of geometric and dynamic pulsations coincide and the corresponding angular frequency is denoted by ω. The resistance model is formulated as

$$R(i\omega) = p_{ref} / \left(\frac{V_P}{2\pi} \cdot \frac{\omega}{z}\right), \tag{5.5}$$

where pump leakage is considered by choosing the reference pressure p_{ref} higher than the pump outlet pressure. In the frequency domain, the flow rate excitation from geometric pulsations reads

$$Q_{ex,g}(i\omega) = \frac{V_{ex,g}}{2\pi} \cdot \frac{\omega}{z}, \tag{5.6}$$

in which z is the number of teeth of the gear on the pump shaft. The corresponding excitation torque becomes

$$T_{ex}(i\omega) = -\frac{V_{ex,g}}{2\pi} \cdot p_m, \tag{5.7}$$

where p_m denotes the mean pressure at the pump outlet. In an operating point, the flow rate excitation from dynamic pulsations can be written as

$$Q_{ex,d}(i\omega) = \frac{V_{ex,d}}{2\pi} \cdot \frac{\omega}{z} \cdot e^{i\alpha} \tag{5.8}$$

in analogy to Equation (5.6) with a phase shift α which is assumed to be frequency independent for simplicity. Then, the total flow rate excitation becomes

$$Q_{ex}(i\omega) = Q_{ex,g}(i\omega) + Q_{ex,d}(i\omega) = \frac{V_{ex}}{2\pi} \cdot \frac{\omega}{z} \cdot e^{i\beta} \tag{5.9}$$

with a resulting phase shift β.

Model parameters are summarized in Table 1. For the reference case without compensator coupling, a rigid connection of electric motor and pump is assumed so that the angles φ_M and φ_P coincide. In this case, the excitation torque t_{ex} acts directly on a high mass moment of inertia with negligible effect on the resulting motion. Therefore, the parameter V_{ex} could be identified by comparing measured and calculated pressure magnitude maxima under resonant conditions of the hydraulic system. With compensator coupling, the parameters I_P, c_T, $V_{ex,g}$, and β have been adjusted by respective comparisons of compensation frequencies, pump outlet pressure magnitudes at compensation and side resonance frequencies, and phase curves of the pump outlet pressure.

Table 5.1. Model parameters

motor sided mass moment of inertia	I_M	0.16 kg m^2
compensator coupling stiffness	k_T	2350 Nm/rad
pump sided mass moment of inertia	I_P	0.0008 kg m^2
pump displacement	V_P	25 cm^3
number of teeth	z	13
total displacement amplitude	V_{ex}	0.025 V_P
geometric pulsation displacement amplitude	$V_{ex,g}$	0.0125 V_P
phase shift	β	80°
torsional damping constant	c_T	0.01 Nms/rad
dead volume at pump outlet	V_d	1.8 V_P
bulk modulus	E	16000 bar
hydraulic capacitance at pump outlet	C_H	V_d/E
reference pressure	p_{ref}	150 bar
mean pressure	p_m	100 bar
pipeline length	l	221 / 189 cm
pipeline radius	r	6 mm
fluid density	ρ	870 kg/m^3
kinematic viscosity	υ	50 mm^2/s

In addition to the pressure p_H at the pump outlet, a torque equivalent pressure

$$p_T = \frac{2\pi}{V_P} k_T(\varphi_M - \varphi_P) \tag{5.10}$$

in the compensator coupling is considered in both measurements and calculations. Frequency domain measurements for 221 cm pipeline length are shown in Figure 5.4. Figure 5.5 shows the respective calculations. The blue curves apply for the case without compensator coupling, where the torque equivalent pressure cannot be calculated. With compensator coupling, the torque equivalent pressure p_T reaches much higher values than the pressure p_H at the pump outlet and is therefore downscaled by a factor of 5. Measured and calculated pressures match fairly well, which is also the case for 189 cm pipeline length (see Figures 5.6 and 5.7).

For 221 cm pipeline length, the compensation frequency and the resonance frequency of the hydraulic system coincide at 258 Hz, which corresponds to a pump speed of 1191 rpm. With compensator coupling, both measurement and model result in a pump outlet pressure magnitude minimum of 0.15 bar, which corresponds to a reduction to 5 % of the magnitude without compensator coupling. The closed-form solution (4.12) yields a value of 0.083 bar. This solution does not account for the excitation torque, which explains the deviation from the measured value. It should be noted that the closed-form solution relies on the identified displacement amplitude V_{ex} and the adjusted torsional damping constant c_T.

According to measurements, the compensator bandwidth amounts to 24 %, while 27 % are obtained from the model. Increasing the dead volume V_d by a third of the pipeline volume to estimate the hydraulic capacitance C_H^* in Equation (4.6), the closed-form solution (4.5) for the bandwidth becomes 29 %, which is in fair agreement with measurements.

The compensator exhibits excellent performance at the compensation frequency and is robust with respect to small variations in pump speed. However, an overshooting upper side resonance occurs, and the respective pulsation frequencies should be avoided.

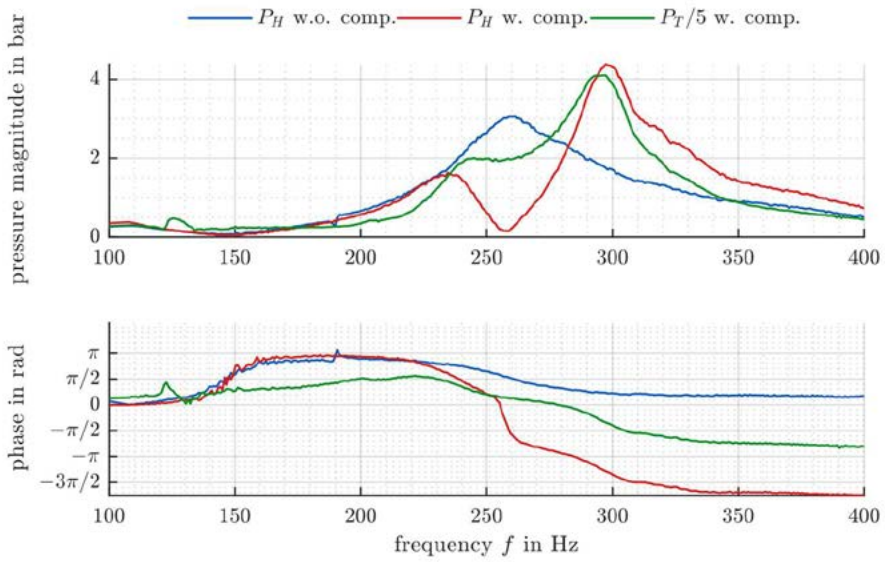

Figure 5.4. Measured pressures for 221 cm pipeline length

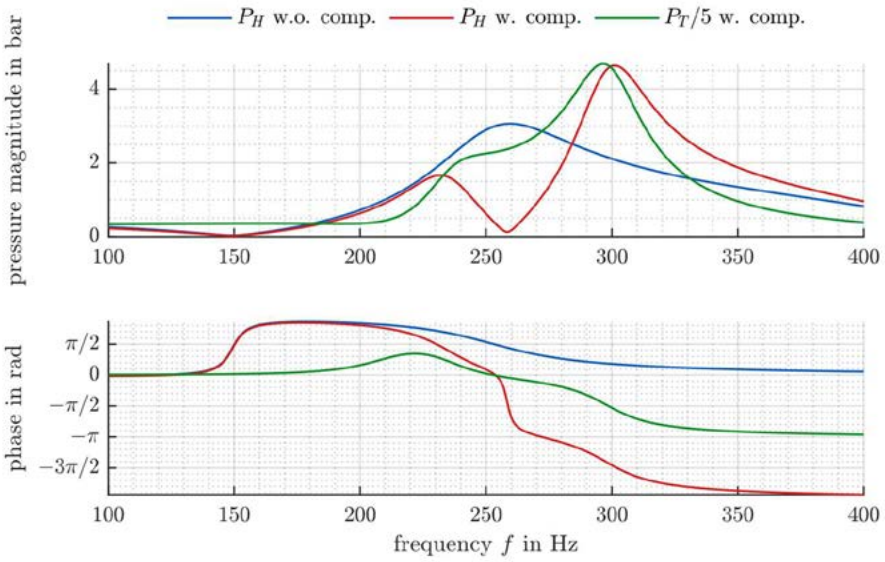

Figure 5.5. Calculated pressures for 221 cm pipeline length

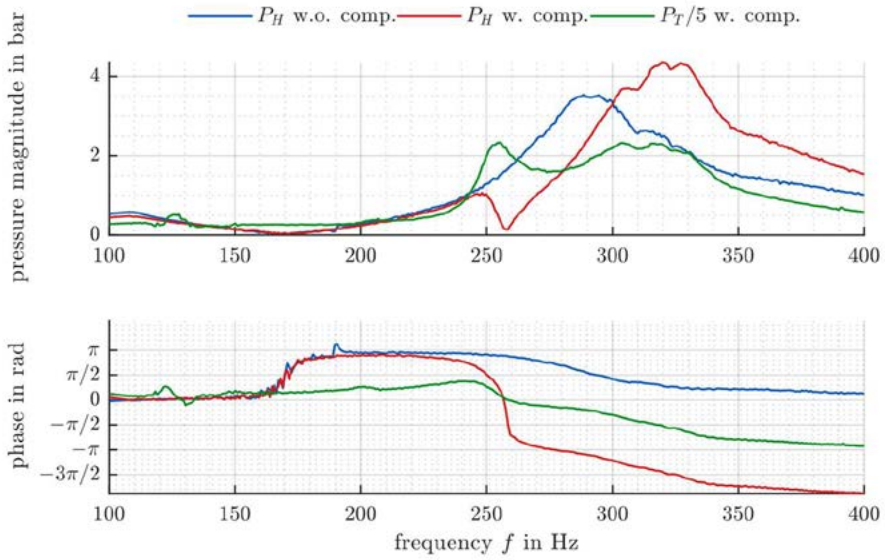

Figure 5.6. Measured pressures for 189 cm pipeline length

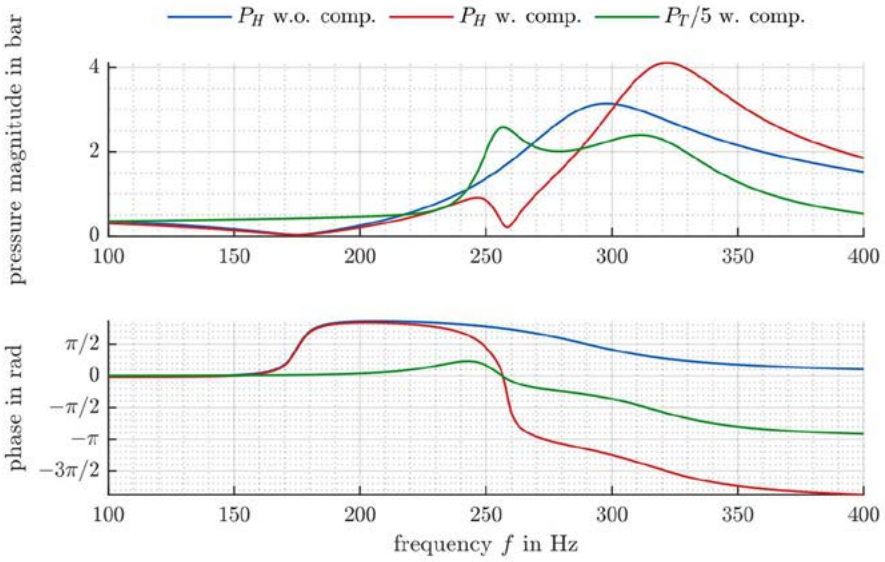

Figure 5.7. Calculated pressures for 189 cm pipeline length

By reducing the pipeline length to 189 cm, the resonance frequency of the hydraulic system is increased and no longer coincides with the compensation frequency. Around the compensation frequency, the compensator still reduces the pump outlet pressure magnitude.

Condition (4.2) is no longer fulfilled so that the closed-form solutions are not applicable in this case.

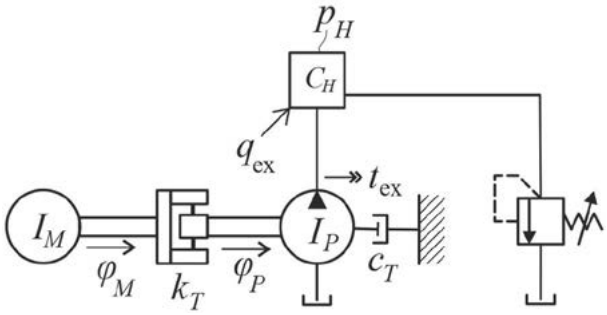

Figure 5.8. Schematic of setup with internal gear pump and outlet capacitance

If the pipeline is disconnected from the pump outlet, the model in Figure 5.8 applies. The respective frequency domain formulation reads

$$\left(-\omega^2\begin{bmatrix} I_M & 0 & 0 \\ 0 & I_P & 0 \\ 0 & -\frac{V_P}{2\pi} & C_H \end{bmatrix} + i\omega\begin{bmatrix} 0 & 0 & 0 \\ 0 & c_T & 0 \\ 0 & 0 & \frac{1}{R(i\omega)} \end{bmatrix} + \right.$$

$$\left. + \begin{bmatrix} k_T & -k_T & 0 \\ -k_T & k_T & \frac{V_P}{2\pi} \\ 0 & 0 & 0 \end{bmatrix}\right)\begin{bmatrix} \Phi_M(i\omega) \\ \Phi_P(i\omega) \\ P_H(i\omega) \end{bmatrix} = \begin{bmatrix} 0 \\ T_{ex}(i\omega) \\ i\omega Q_{ex}(i\omega) \end{bmatrix}. \quad (5.11)$$

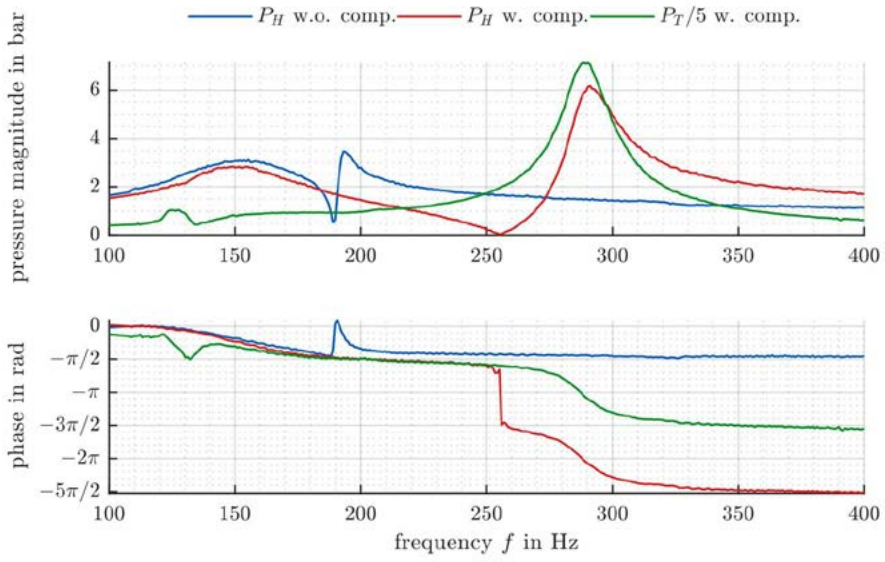

Figure 5.9. Measured pressures with outlet capacitance

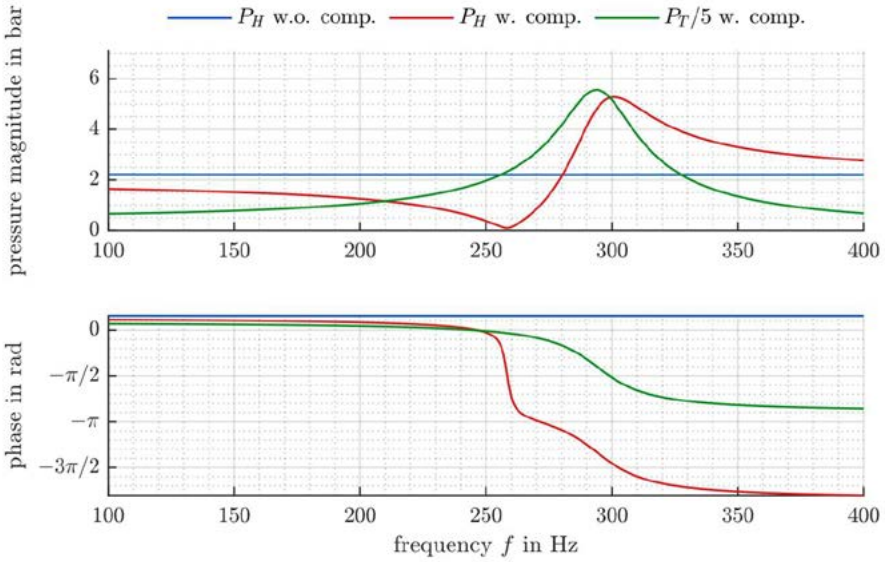

Figure 5.10. Calculated pressures with outlet capacitance

Figure 5.9 shows the corresponding measurements. Around 190 Hz, they contain an additional effect from the torque measurement shaft, which is not included in the model. Calculated results are shown in Figure 5.10. At the compensation frequency, the pump outlet pressure magnitude is almost cancelled. The closed-form solution (4.13) results in a pressure magnitude reduction to 3 %. There is no lower side resonance, and broadband pulsation reduction is achieved below the compensation frequency. Above this frequency, a heavily overshooting side resonance is observed. The measured bandwidth amounts to 13.7 %, and the frequency domain model yields a bandwidth of 16.7 %. For comparison, the closed-form solution (4.7) results in a bandwidth of 11.3 %.

6. PREDICTIONS FOR AXIAL PISTON PUMP

Under non-resonant conditions, closed-form solutions for compensator performance shall be evaluated for an axial piston pump with seven pistons, 25 cm^3 displacement, and 0.0017 kg m^2 mass moment of inertia at a rotational speed of 1500 rpm. In a first approach, the hydraulic capacitance at the pump outlet and the torsional damping constant are taken from the internal gear pump with the same displacement. The compensator is tuned to the fundamental frequency of dynamic pulsations, which occurs at 175 Hz. Equation (4.8) can be used to calculate the required torsional stiffness of the compensator coupling. With Equation (4.6), Equation (4.7) yields a bandwidth of 12.9 %. Equation (4.13) results in a pressure magnitude reduction to 2.0 %. At 3000 rpm, a bandwidth of 3.4 % and a pressure magnitude reduction to 3.9 % are obtained. Smaller bandwidth is due to higher stiffness of the compensator coupling required for 350 Hz compensation frequency. If damping is increased by a factor of five, pressure magnitude reductions to 9.7 % and 19.2 % result for 1500 rpm and 3000 rpm, respectively.

7. CONCLUSIONS

For the investigated internal gear pump, the rotary mechanical pulsation compensator shows excellent performance at a mean outlet pressure of 100 bar and a constant rotational speed near 1200 rpm. Due to sufficient bandwidth, it is robust with respect to small speed variations. Similar performance is expected from an equally sized axial piston pump at a rotational speed of 1500 rpm. At higher pump speeds, the remaining pulsation will be higher and the bandwidth will decrease.

For external gear pumps, geometric pulsations may dominate and cause a significant excitation torque. In this case, the closed-form solutions for compensator performance are no longer applicable. Appropriate investigations of external gear pumps will be presented in the future.

Abstract.

In the final stage of production, External Gear Pumps (EGPs) must be run-in following a specific working cycle in which the pump body is subject to material removal resulting in a consequent increase in energy demand. The run-in cycle impacts the pump performance and the production costs. In this study, five new run-in cycles are defined with the objective to analyse the impact on the power absorbed during and after the cycle, the material removed from the body and the impact on pump performance. The work shows that the use of different run-in cycles can result in a higher pump volumetric efficiency, up to + 2%, combined with a cost reduction of 1.74% and an increase of productivity of 78%. Subsequently, experimental data were used to define a preliminary AI based algorithm to predict the run-in cycles parameter. The AI algorithm, which was trained and validated on the experimental data, demonstrated a high predictive capability with a maximum error of 6%.

Keywords. External Gear Pump, Run-in cycle, Efficiency, AI Algorithms.

1. INTRODUCTION

External Gear Pumps (EGPs) are positive displacement machines widely used in fluid power applications across both mobile and industrial sectors. EGPs are widely chosen, having a good combination of performance, reliability and cost-effectiveness. The EGP under study, manufactured by Hydreco (HY2.16 pump), is a fixed positive displacement machine of 16 cm^3/rev capable of operating at a maximum pressure of 260 bar and a rotational speed range of 500 – 3200 rpm. It finds application in a wide range of fields, from agriculture to material handling and aeronautics devices. In Figure 1. 1, an exploded view of HY2.16, a pressure compensated (PC) EGP, is shown.

Before being delivered to customers, EGP is end-of-line (EoL) tested with a specific run-in cycle in which the pressure forces cause the gears translation and inflection towards the suction side. In this condition, the tips of gears' teeth interfere with the pump body. Due to these micro-movements of the gears, typically made of hardened steel, the body on the low-pressure side undergoes a milling phase. The gears dig their optimal seats into the body and,

All Open Access articles are peer-reviewed, distributed under the Creative Commons Attribution-Non Commercial 4.0 International

as a result, leakage flows can be minimized (maximization of the volumetric efficiency) at that operating condition.

The run-in cycle has a relevant importance for EGPs, as it defines the internal profile of the pump housing (or body) and, consequently, its efficiency. This cycle is usually performed at a constant speed within the operative pump range, but different levels of speed can be adopted [1, 2].

Figure 1. 1– Exploded view of Hydreco HY2 pump (aluminium housing)

The amount of removed material is related to the operative working conditions and the clearance variability [1]. Once the material removal phase is complete, a performance check (testing) phase is conducted to verify the pump's performance. The duration time of the cycle depends on the pump tested, it can vary from a couple of minutes [1] until to 15 minutes [3]. This time impacts on the total cost of an EGP which is given by the summation of the components, assembly and EoL testing (run-in and performance check) costs. Specifically, the assembly and EoL testing costs are strictly dependent on the hourly operating cost, which typically ranges between the 30 – 60€/h.

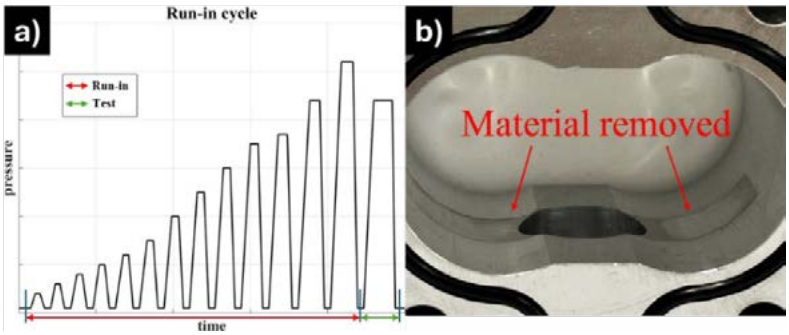

Figure 1. 2 – a) Standard run-in cycle; b) Gear seats with removed material after the run-in cycle.

Figure 1. 2.a shows an example of a typical run-in cycle in which the load pressure has a step variation; the run-in and testing phase are highlighted. Figure 1. 2.b shows how the gear seats appear after the cycle in Figure 1. 2.a.

In the open literature, there are only a limited number of studies focused on the run-in cycles and correlated effects on the pump performance. The first work was published by M. Borghi et al. [2]. The authors developed a simple analytic model to predict the internal profile of the pump body for different run-in pressures and rotational speeds. The gear position was defined by two contributions, the recovery of radial clearances, as in [4] and the eccentricity contribute evaluated with the Sommerfield theory. In [2], the impact for different run-in speeds in range 500 – 3000 rpm was presented. In [2] and [4], the calculation of the internal body profile is integrated into lumped-parameter models, thus enabling the correlation of post-run-in geometrical variations with the unit performance. In [1], a lumped parameter model for EGPs was adapted to predict the run-in cycle and the amount of material removed was calculated in each pressure step. The authors verified experimentally and numerically that the major amount of material was removed in the first low pressure ramps, and they proposed a shorter cycle removing four out of thirteen ramps at the middle-hight pressures and extending two ramps at low pressures. In [3], the authors proposed a mathematical model for EGPs that can predict the volume of material removed under different operating conditions and define a run-in cycle for applications up to 400 bar. The proposed cycle has been defined to have the same depth of asportation for each pressure ramp. In these studies, the authors refer to cycles with a standard shape as reported in Figure 1. 2.a. and no references to different shapes are present. More recently, there has been an ever-increasing diffusion and interest in the AI algorithms, including their application in the study of EGPs. In [5] neural networks were used to predict the output flow-rate of an EGP, while in [6], machine learning algorithms were used for predictive maintenance. However, based on the best knowledge, studies using AI algorithms to investigate the run-in cycle on EGPs are not present in the open literature.

In the present work, starting from a baseline run-in cycle, used as a reference, and the authors' expertise, five new cycles have been defined. A sample of thirty EGPs was tested and for each pump, its performance characterization was performed to evaluate in detail the impact of the new run-in cycles. In addition, torque and pressure have been acquired during the run-in cycle to estimate the absorbed energy and to identify the phases in which the material removal occurs. Moreover, the wear profile on the gear seats was measured using a 3D Coordinate Measuring Machine (CMM). Finally, a preliminary model based on AI algorithm has been developed. The acquired experimental data were used in part to train AI algorithm and in part to test it, showing a very good alignment.

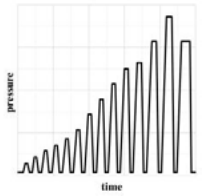
The aim of the present work is to define new run-in cycles that allow to have a shorter test time and to preserve and improve the pump performance. Cycles with an innovative pressure shape which differ from [1, 3] will be presented and analysed.

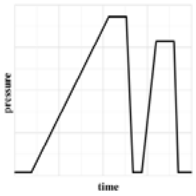
2. EXPERIMENTAL ACTIVITY – RUN-IN CYCLES AND PUMPS DEFINITION

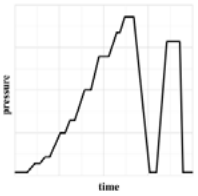
Five new run-in cycles, with a shorter time duration, were defined to reduce both the pump cost and energy consumption to have as resulting also economic and environmental benefits. For each cycle, five pumps have been properly assembled and tested.

2.1. Run-in cycles

The run-in cycle is defined as a load cycle performed at a specified rotational speed (N), which can be either constant or variable over time. The term load cycle refers to the evolution of pressure over time. In this work six run-in cycles have been defined through five different load cycles that can be grouped in three different families identified as A, B and C. Table 2. 1 summarises the parameters that define each cycle.







A	B	C
		
$\#\boldsymbol{S}\,;\boldsymbol{p_i^{max}}\,;\boldsymbol{t_i^j}\,;\boldsymbol{p_{test}}\,;\,\boldsymbol{t_{test}}$	$\boldsymbol{p^{max}}\,;\boldsymbol{t^j};\boldsymbol{p_{test}}\,;\,\boldsymbol{t_{test}}$	$\#\boldsymbol{S}\,;\boldsymbol{p_i^{max}}\,;\boldsymbol{t_i^j}\,;\boldsymbol{p_{test}}\,;\,\boldsymbol{t_{test}}$
$i = 1, 2, \dots, \#S$ $j = 1, 2, \dots, 4$	$j = 1, 2, \dots, 4$	$i = 1,2, \dots, \#S$ $j = 1, 2, 3\ if\ i = 1, 2, \dots, \#S - 1$ $j = 2, 3, 4\ if\ i = \#S$

Table 2. 1 – Load cycles definition

The variable $\#\boldsymbol{S}$ is the number of pressure steps, $\boldsymbol{p_i^{max}}$ the pressure of the i-th ramp and $\boldsymbol{t_i^j}$ one of the four times that define the ramp i-th. The times $\boldsymbol{t^j}$ used to define the pressure ramps are: 1) t^1 : time at low pressure; 2) t^2: time to pass from low to high pressure; 3) t^3 : time at high pressure; 4) t^4 : time to pass from high to low pressure. The parameters $\boldsymbol{t_{test}}$ and $\boldsymbol{p_{test}}$ define the test ramp that for this study has been maintained constant for all the cycles. Another common parameter for all the cycles is the $\boldsymbol{p_S^{max}}$, which value is the one used to run-in the pump for the maximum operative pressure. The defined run-in cycles are reported in the Table 2. 2. Although the actual values of these parameters are not disclosed for confidentiality reasons, it can be stated that $N_2 = 2 * N_1$, $S_{New} < S_{STA}$, $t^2_{1STEP\ 3} = 4 * t^2_{1STEP\ 1}$ and the t^3_S (time at maximum pressure) is the same for all cycles.

The last two columns of Table 2.2 show the percentage variations in the new cycles compared to the current reference, called STA N1.

Table 2. 2 - Run-in cycles defined

ID cycle	Load cycle	$\#\boldsymbol{S}$	$\boldsymbol{N_{Run-in}}$	$\boldsymbol{N_{test}}$	$\boldsymbol{t_{cycle}}$	$\boldsymbol{E_{cycle}}$
STA N1	*A*	S_{STA}	N_1	N_1	t_{STA}	E_{STA}
STA N2	*A*	S_{STA}	N_2	N_1	*+0.0%*	*+100%*
STAIR	*C*	S_{STA}	N_1	N_1	*-34.6%*	*-17.4%*
New STA	*A*	S_{New}	N_1	N_1	*-29.5%*	*-32.9%*
1STEP 1	*B*	*1*	N_1	N_1	*-57.4%*	*-49.3%*
1STEP 3	*B*	*1*	N_1	N_1	*-39.7%*	*-23.4%*

As shown in Table 2. 2, all new cycles, except for STA N2, are better than STA N1 in terms of cost reduction, thanks to their shorter duration and lower theoretical energy demand (equation 2.1).

$$E\ [J] = \int_{t=0}^{t_{cycle}} T_{th} * \omega * dt \qquad (2.\ 1)$$

The new cycles, with a reduced run-in time compared to STA N1 provide an increment of the test rig productivity $\#Pumps/h$, defined as the number of pumps tested hour (Table 2. 3). It was considered constant the time to allocate the pump on the test rig as the cycle changes.

Table 2. 3 – Test rig productivity compared to the STA N1 cycle

	STA N2	**STAIR**	**New STA**	**1STEP 1**	**1STEP 3**
$\#\boldsymbol{Pumps/h}$	*+0.00%*	*+36.12%*	*+29.29%*	*+78.61%*	*+43.99%*

A shorter run-in time allows for reducing the production cost and finally, combined with the lower energy demand, impacts on the greenhouse gas emissions (GHG) due to the production process, an aspect not negligible considering the objective of a zero net GHG by 2050 established by the Daikin Group, of which Hydreco is a member.

2.2. Samples assembly

Five pumps have been tested for each run-in cycle. To avoid that experimental results could be influenced by the manufacturing capability, pumps have been assembled combining the components to keep basically constant the average radial clearance between gears and body $\boldsymbol{\delta_r^{av.}}$, and the maximum radial shift of the shafts $\boldsymbol{\epsilon_{max}^{av.}}$. Five kits composed of two thrust plates, driven and driving gears were defined and kept constant. Consequently, thirty pump bodies have been selected, ensuring the smaller possible variability of radial interference $\boldsymbol{int}$. Refer to appendix for the definition of $\boldsymbol{\delta_r^{av.}}$, $\boldsymbol{\epsilon_{max}^{av.}}$ and $\boldsymbol{int}$.

The relative standard deviation (RSD) of $\boldsymbol{int}$, defined as the ratio between the standard deviation and the mean value, was 4.6%. This corresponds to a value within the measurement accuracy of the CMM used for measuring the pump bodies (section 3.3), and it was considered acceptable. As concerns axial clearance, there was more variability, with an RSD of 24.6%; nevertheless, for the purposes of this study, this variability was considered not to impact and thus negligible.

2.3. Test bench layout

Figure 2. 1 shows the hydraulic scheme of the test bench used for the dynamic characterization of the run-in cycles and the acquisition of pump performances in steady-state conditions. During the run-in cycle were acquired the suction (1) and delivery (2) pressures, the torque (3) and the shaft speed (4). While the performance test also acquired the delivery flow rate (5).

Table 2. 4 - Sensors used for the experimental characterization

#ID	**Symbol**	**Component**	**Range**	**Accuracy**
1	p_1	Trafag 8845.73	0 - 1.6 barA	±0.5% of span
2	p_2	Trafag 8254.84	0 - 400 bar	±0.4% of span
3	T_{eff}	NCTE Series 3000-Model 250	0 - ±250 Nm	±0.2% of span
4	N	Rotary Encoder	0 - ±3000 r/min	±0.05% of span
5	Q_{eff}	Flow meter KRACHT - size 3	0 - 120 l/min	±0.3% of span

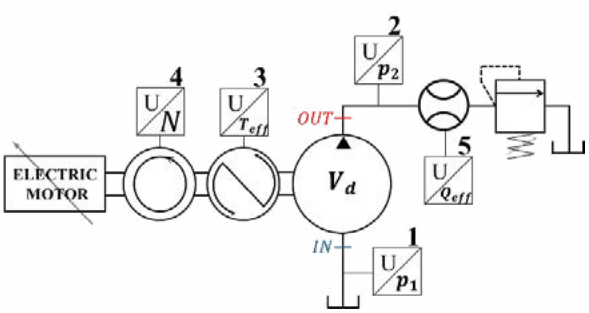


Figure 2. 1 - Test rig layout

The specifications of the used transducers are reported in Table 2. 4. For the dynamic acquisition of the run-in cycles, a sample frequency of 1kHz and a saving frequency of 20Hz were set. The steady state acquisition of the efficiencies, in the pressure range [60 - 240 bar] and in the speed range [1000 - 3000 rpm], has been performed with a sample and saving frequencies of 1kHz. An ISO VG-46 oil with a temperature setting of $39 \pm 2°C$ was used for the tests. The working operative point is varied by means the pressure control valve and the electric motor.

3. EXPERIMENTAL RESULTS AND DISCUSSION

A complete characterization of the new run-in cycles was executed and their impacts on the pump performance were analysed. Three separate acquisitions have been performed: 1) Run-in cycle; 2) Performance characterization; 3) Measurement of the material removal.

3.1. Run-in cycles – Instantaneous torque

The continuous acquisition of all the variables of interest marked from 1 to 4 in Figure 2. 1 was performed for the entire run-in cycle. The total efficiency, defined as the product of the volumetric and hydromechanical efficiencies, was calculated during the constant pressure portion of the test phase; refer to the last ramps of Figure 3. 1.

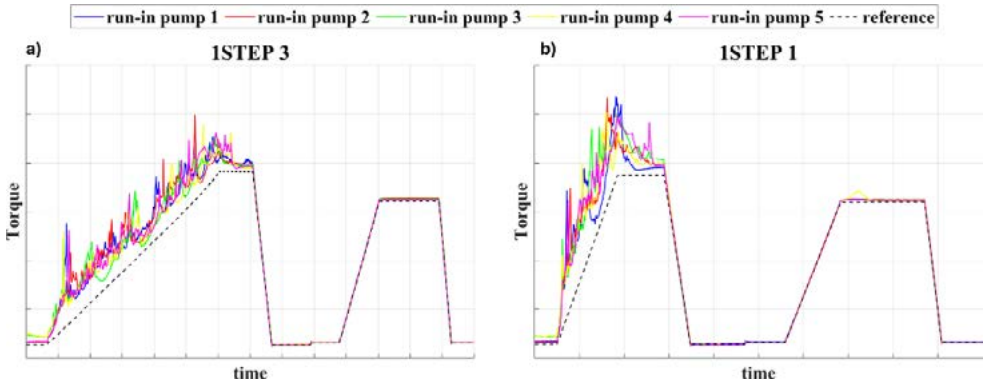

Figure 3. 1 - Torque absorbed during the run-in cycles #1: a) 1STEP 3 cycle; b) 1STEP 1 cycle. The scale factor of the time scale of graph "b" with respect to the graph "a" is 7:5.

Figure 3. 1 shows the torque during the run-in cycles of five pumps tested with 1STEP 1 and the 1STEP 3 run-in cycles (Table 2. 2). The black dashed line represents the torque absorbed when does no material removal occurs (after run-in is completed). It depends only on the pressure load and the pump mechanical losses, and it is identified as a reference curve. All the torque curves during the run-in phase show a higher mean value than the reference curves, as well as spikes and fluctuations due to interactions and contact between internal components during the material removal.

Table 3. 1 – Run-in cycles acquisition

ID cycle	δE^{th}[%]	δE^{eff}[%]	$E^{eff-mill}$ [kJ]	T_{av}^{add}[Nm]	δT_{max}[%]
STA N1	*0%*	*0%*	*51.8*	*2.8*	*0%*
STA N2	*+100%*	*+81.4%*	*32.1*	*0.8*	*-13.8%*
STAIR	*-17.4%*	*-14.3%*	*49.4*	*4.0*	*-14.8%*
New STA	*-32.9%*	*-26.3%*	*48.3*	*3.6*	*-6.8%*
1STEP 1	*-49.3%*	*-45.7%*	*32.4*	*4.0*	*-7.8%*
1STEP 3	*-23.4%*	*-19.6%*	*54.2*	*4.7*	*-15.9%*

Table 3. 1 shows the average values of the most relevant physical quantities, calculated on the five pumps tested for each cycle. The first two columns show the percentage deviation from the reference cycle of the theoretical $\boldsymbol{E^{th}}$ and the effective $\boldsymbol{E^{eff}}$ energy required for the new cycles. The effective energy reduction (except for the cycle *STA N2)* of the new run-in cycles results smaller than the theoretical one. The relationship between $\boldsymbol{\delta E^{th}}$ and $\boldsymbol{\delta E^{eff}}$ is described by equations (3. 1) and (3. 2); refer to the appendix for the simplifying assumptions adopted. Equation (3. 2) was obtained assuming that $\boldsymbol{E^{eff-mill}}$ (energy difference between the run-in cycles with and without material removal) is constant, however, experimental results have demonstrated that this is only true for four out of six cycles. The $\boldsymbol{E^{eff-mill}}$ required by the New STA and 1STEP 1 cycle is generally lower than that required by the other cycles. When $\boldsymbol{E^{eff-mill}}$ is not constant, equation (3. 2) becomes equation (3. 3).

$$\delta E_{i,j}^{eff}[\%] = \frac{\left(E_{i,j}^{eff-runin} + E_{i,j}^{eff-mill}\right) - \left(E_{STA\ N1,j}^{eff-runin} + E_{STA\ N1,j}^{eff-mill}\right)}{\left(E_{STA\ N1,j}^{eff-runin} + E_{STA\ N1,j}^{eff-mill}\right)} * 100 \qquad (3.\ 1)$$

With $i = \{STA\ N1, STA\ N2, STAIR, New\ STA, 1STEP\ 1, 1STEP\ 3\}$; $j = 1,2, \dots, 5$

$$\delta E_{i,j}^{eff}[\%] = \delta E_i^{th} * A \quad ; \ 0 < A < 1 \qquad (3.\ 2)$$

$$\delta E_{i,j}^{eff}[\%] = \delta E_i^{th} * A + B \ ; \ 0 < A < 1 \qquad (3.\ 3)$$

The parameter $\boldsymbol{T_{av}^{add}}$ represents the average additional torque required by the pump during the cycle. It is defined by equation (3. 4).

$$T_{av}^{add} = \frac{1}{t_{cycle}} \int_{t=0}^{t_{cycle}} \left[T_{Run-in\ 1}^{eff}(t) - T_{Run-in\ 6}^{eff}(t)\right] * dt \qquad (3.\ 4)$$

In the last column of Table 3. 1, the maximum torque values obtained in the selected cycles are reported. The data show that the maximum torque in the new cycles is lower than that of the reference cycle.

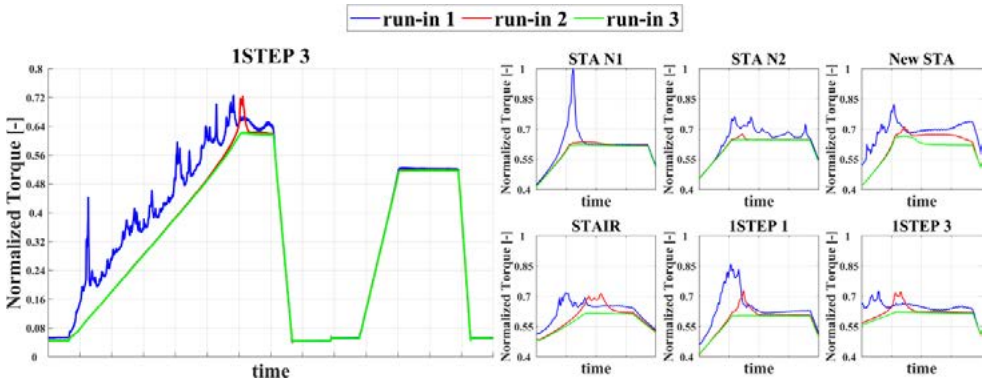

Figure 3. 2 - Torque absorbed by the 1STEP 3 run-in cycles 1, 2 and 3 of pump 1 with a zoomed view of the area at constant pressure of all the cycles.

The trend of $\boldsymbol{T_{av}^{add}}$ in Table 3. 1 is also confirmed in Figure 3. 2 in which the torque scales are normalized to the maximum torque of the STA N1 run-in 1. The left-hand side chart shows three consecutive run-in cycles of one pump during 1STEP 3 cycle. On the right-hand side, zoomed views of the area at the maximum constant pressure for all the six cycles are shown. It should be noted that the temporal extension shown is the same for all the zoomed views. Torque spikes were observed during the second and third consecutive run-in cycles for all tests except for STA N1. This seems to indicate that the material removal process was incomplete after the first run-in, suggesting that the selected $\boldsymbol{t_S^3}$ value was not optimal. Since, typically during the testing, the run-in cycle is performed only one time, it must be ensured that a complete material removal is obtained. Consequently, future run-in cycles will be designed with an increased value of $\boldsymbol{t_S^3}$ to be aligned to the actual one (STA N1).

For the EGP under investigation, the run-in phase (baseline cycle) represents the 3.95% of the production cost composed of: components, assembly phase and run-in cycle costs. In addition, the reduction of the run-in time allows not only to increase productivity (Table 2. 3) but, combined with a minor energy demand (Table 3. 1), allows for further reduction of the costs up to 1.74% (Table 3. 2).

Table 3. 2 – Pump cost compared to the STA N1 cycle

	STA N2	STAIR	New STA	1STEP 1	1STEP 3
Pump cost	*+0.03%*	*-1.04%*	*-0.90%*	*-1.74%*	*-1.20%*

Table 3. 2 shows as the major cost reduction is related to the reduction of the run-in time, in fact for STA N2 cycle a +81.4% of energy demand (Table 3. 1)corresponds to only +0.03% of the pump cost. In the present work, an energy cost of 0.12€/kWh was considered. Figure 3. 3 shows the efficiency values of each pump at the end of the run-in cycles. These efficiencies, referred to as the check operative point defined by the test phase, exhibit variation across different run-in cycles. The new run-in cycles seem to improve the pump performances; the benefit of the new run-in cycles is mainly impacting the volumetric efficiency that reaches values up to +1.5% respect to the one obtained with the standard run-in cycle.

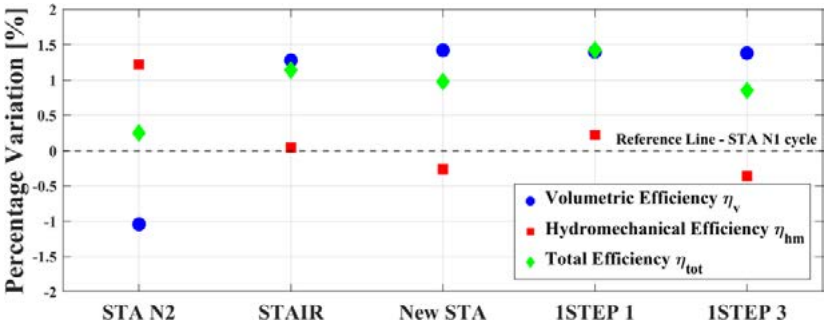

Figure 3. 3 - Run-in 1 efficiencies

3.2. Pump efficiencies

To confirm the results shown in the Figure 3. 3 a complete characterization of the pump efficiencies, acquiring #21 operative points, was performed. The characterization was carried out after repeated run-in, therefore the material removal phase can be considered complete for all bodies. The results pointed out nonsignificant variation for the hydromechanical efficiency (η_{hm}) while a more significant variation for the volumetric efficiency (η_v). Thus, Figure 3. 4 reports only the values of η_v in the different operating points.

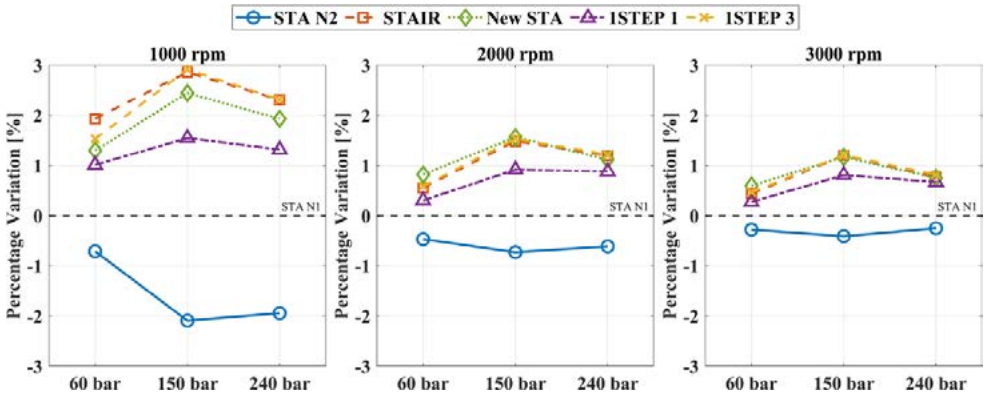

Figure 3. 4 - Volumetric Efficiency

The results show an effective improvement in volumetric efficiency for all cycles except STA N2, confirming the trend reported in Figure 3.3. The cycles defined in Table 2. 2 differ in shape, cycle time, and pump speed. The p_S^{max} value was the same for all the run-in cycles, but a reduction in cycle time corresponds to an increased pressure gradient. From the analysis of the volumetric efficiencies, it is possible state the following: 1) with fixed pressure gradient, an increase in run-in speed negatively impacts volumetric efficiency of the pump (STA N2 compared to STA N1); 2) with fixed run-in speed, an increased pressure gradient positively affects volumetric efficiency (STAIR, New STA, 1STEP 1 and 3 compared to STA N1). However, this effect reduces with excessive cycle time reduction (1STEP 1 compared to 1STEP 3); 3) with a fixed pressure gradient and rotational speed, a change of the cycle profile does not seem to have an impact on the volumetric efficiency

(STAIR compared to 1STEP 3). Cycles STAIR and 1STEP 3 have comparable cycle times and therefore comparable pressure gradients.

Regarding the cost reduction, the run-in cycle 1STEP 1, that is the shortest one, represents the optimal solution. However, considering the results reported in Figure 3. 4 the cycles 1STEP 3 and STAIR represent the best choices.

3.3. Measurement of the pump bodies

A CMM with an accuracy of 2 μm has been used to measure material removal. Results are presented in Figure 3. 5 and Table 3. 3, where the internal profiles measured in the central section of the pump body are reported.

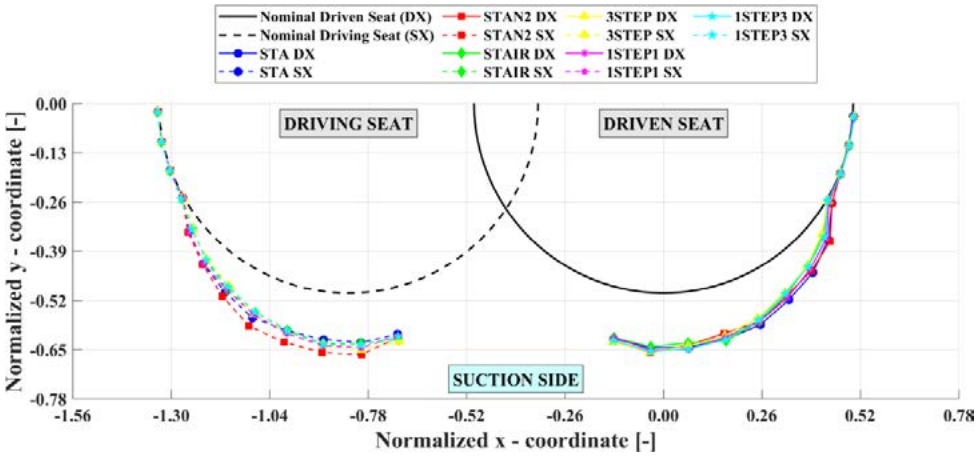

Figure 3. 5 - Measured material milled on the Internal pump body. DX identifies the driven gear while SX the driving one.

For confidential reasons, in Figure 3. 5 the axes are normalized to the tip diameter. The measured profiles differ slightly, with a maximum volume variation of 6%. The measured profile of the bodies run-in with cycle STA N2 shows a volume of material removed on the driving gear side comparable with the driven gear side (δV_{DX-SX}^{mill} below 4%). This can be directly correlated to the observed reduction of the volumetric efficiency (Figure 3. 4).

Table 3. 3 - Volume of material milled

	STA N1	**STA N2**	**STAIR**	**New STA**	**1STEP 1**	**1STEP 3**
$\boldsymbol{V_{DX}^{mill} + V_{SX}^{mill}}$	$V_{STA\,N1}^{mill}$	+5.94%	- 6.12%	-5.93%	-1.99%	-5.44%
$\boldsymbol{\delta V_{DX-SX}^{mill}}$	-15.82%	-3.82%	-16.56%	-13.93%	-16.53%	-17.43%

The use of a CMM permitted to obtain a 3D map of the milled regions, as showed in Figure 3. 6, and to estimate the volume of removed material (as reported in Table 3. 3). Figure 3. 6 and Figure 3. 7 show the 2D shape of the milled areas along the axial direction parallel to the rotation axis of gears and the 3D maps for the run-in cycles STA N2 and STAIR. For confidential reasons, the z-axes in Figure 3. 6 and Figure 3. 7 are normalized to the pump width. As previously observed in Figure 3. 5, for the STA N2 run-in cycle the depth of milling for the driving and driven gears seats are aligned. While for the STAIR run-in cycle the milling depth of the driven gear side is deeper than the one on the driving side.

Comparing the two cycles, a greater height of milling is observable for the STA N2 cycle with respect to the STAIR one, which returns a better volumetric efficiency.

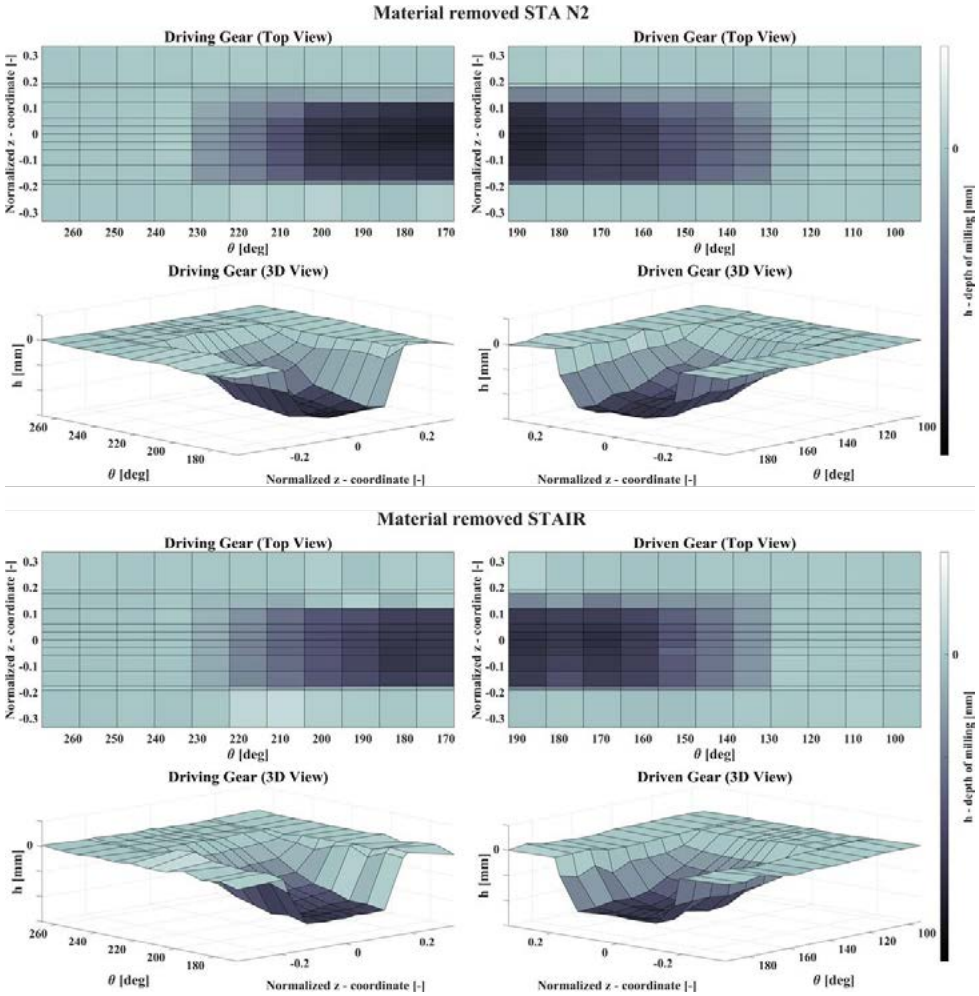

Figure 3. 6 - Top View and 3D view of the material removed on the suction side for the STA N2 and STAIR cycles

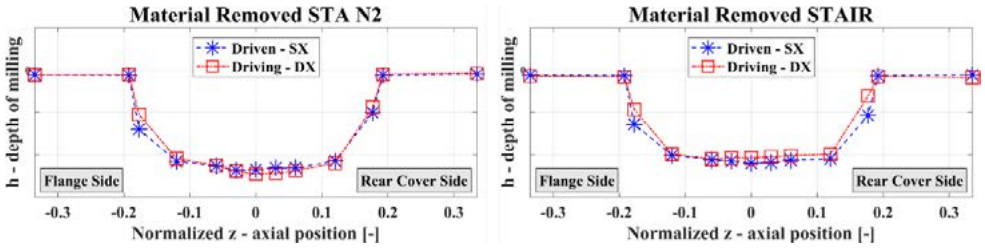

Figure 3. 7 - Milling line in the axial direction

Significant improvements in volumetric efficiency were observed with almost all the new cycles (Figure 3. 4), but the STA N2 with higher shaft speed and volume of material removed showed worsening performance. The pressure gradient or the run-in cycle seems to have an impact on the material removal. Varying the run-in cycles but maintaining constant p_S^{max} and t_S^3, the internal profile shape changes slightly. From the analysis of the removed volume, it is possible state the following: 1) under a fixed pressure gradient, as the run-in speed increases, the material removal on the driving and driven gears becomes comparable between the driving and the driven gears and a greater total volume of material is removed with a negative impact on the volumetric efficiency (cycle STA N2 compared to STA N1); 2) contrarily, with a fixed rotational speed, as the pressure gradient increases (reduction of the time cycle) the total removed material decreases impacting positively on the volumetric efficiency (cycles STAIR, New STA, 1STEP 1 and 3 compared to STA N1). The increase in volumetric efficiency (Figure 3. 4) is directly correlated with the reduction of the removed material volume in gears seats (as shown Table 3. 3), where a lower volume corresponds to a reduced milling height (as shown in Figure 3. 6 and Figure 3. 7). In conclusion, the combination of p_S^{max} and N defines the final internal profile shape [1] and the maximum depth of milling [2].

4. AI ALGORITHM: TORQUE PREDICTION

With the future goal of optimize the run-in cycle, a preliminary model based on AI algorithm has been developed. The use of an AI-based tool is motivated by the need to model a complex, non-linear and transient behaviour of an external gear pump, which is difficult to describe accurately using purely physics-based approaches. An EGP, equipped with sensors, generates data in the form of time series that represent the inputs and outputs for the model. For this activity, at this initial stage, the commercial software NeurEco® [7], with a specific dynamic template for processing time series data, has been used for the creation of a predictive model. The tool defines a neural network through a controlled topological enrichment process that uses parsimony to reach optimal accuracy [8]. The procedure starts from a minimal architecture that is progressively enriched by adding the most valuable neurons and connections as needed. This iterative expansion of the architecture allows the model to reach the global optimum for the problem. When no further enrichment improves the prediction, the process stops. This approach provides the model with the requested complexity. NeurEco® enforces a minimal model size, which eliminates overfitting by construction.

This commercial tool was used to develop a preliminary AI-based predictive model for the EGPs run-in cycle. The first application of the model was focused on predicting of the torque needed during the 1st and 6th run-in, having the delivery pressure profile as input. The analysis presented in this section refers to the cycles with the N1 speed. Considering that the 6th run-in was acquired only for one pump for each cycle type, the total data set available was composed of five continuous acquisitions (STA N1, STAIR, New STA, 1STEP 1 and 1STEP 3), while for the first run-in cycle all the five samples were available for each cycle.

Firstly, a dynamic physical model, called Model0, with the pressure profile as input, was built for predicting the 6th run-in (with no material removal). The model outputs are torque, which allows for estimating the hydromechanical efficiency, and the absorbed energy of the EGP. Three samples, STA N1, 1STEP 1 and New STA, were used for the training phase and

the remaining two, STAIR and 1STEP 3, were used for the blind test phase. Figure 4. 1 shows the acquired (*exp.*) and predicted (*pre.*) torque for the 6th run-in 1STEP 3. The average error on the torque prediction was 0.93% and, on the energy (calculated using equation 2.1) was 0.68%. Despite the small training sample size, the model showed a very good capability in the prediction of the torque in the absence of material removal (in fact, during run-in 6th there is no interference between gear teeth and pump body). In the second phase, the pressure profile and the predicted torque by the Model0 were used as inputs to a second model for predicting the torque needed during the run-in with material removal. Thus, the Model0 output was used as input for the improved model, called Model1. The inputs for Model1 were the pressure profile, as per Model0, and the torque predicted by Model0. The results of Model1 are reported in Figure 4. 1 and compared to Model0 and the experimental curve. Even if the *pre.* curve (red dashed line) associated to run-in 1 does not capture the spikes and fluctuations of the experimental torque curve, the results of Model1 can predict the average value of the torque during the material removal of the run-in cycle with an average error of 5.87% and an error less than 0.11% on the required energy (lower than Model0 as expected). Model1, with respect to the Model0, was trained on a sample of fifteen acquisitions. Starting from the duty cycle (pressure profile), the combinate use of Model0 and Model1 (Figure 4. 2.a) allows for predicting with a small error the run-in torque, energy and hydromechanical efficiency. In the present work, the AI model represented by Figure 4. 2.a was tested for a unique pump displacement and for load cycles belonging to the families defined in Table 2. 1.

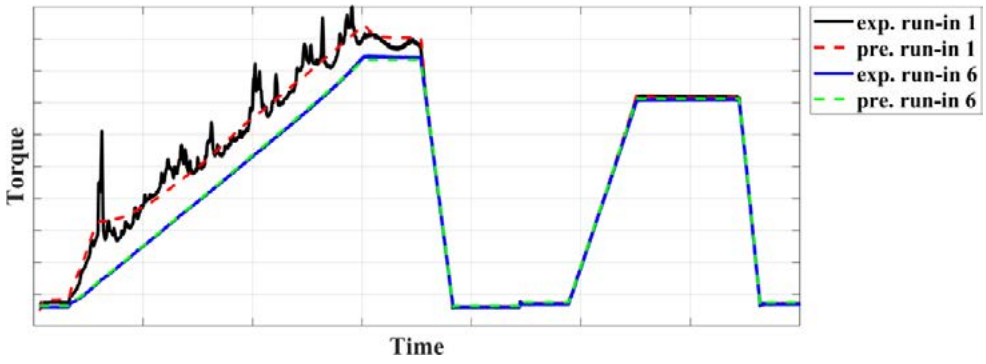

Figure 4. 1 – Experimental (exp.) and Predict (pre.) torque for the 1STEP 3 cycle

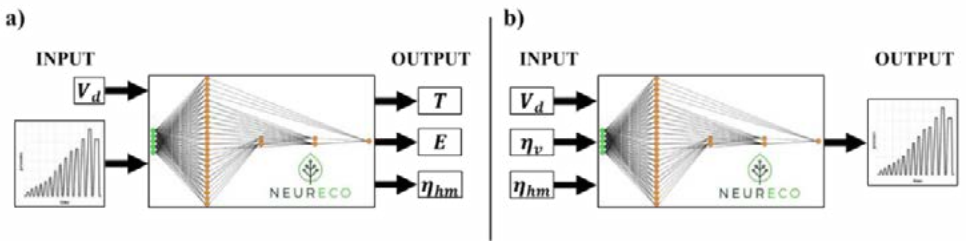

Figure 4. 2 – a) Actual predictive AI model; b) Desired predictive AI model

The present AI model represents a first step toward optimizing run-in cycles (as shown in the flowchart in Figure 4. 2.b); consequently, in future works, it will be tested on various pump displacements and duty cycles to better understand its behaviour far away the training

conditions. As said, at the present, the model is not able to predict the gears seats profile, torque spikes and fluctuation (but can be considered negligible, having the purpose of optimizing the run-in cycle) and the volumetric efficiency. The last can be included by recording the flow rate during run-in cycle.

5. CONCLUSION

The paper presents a deep analysis focused on the run-in cycle of EGPs made thought an extended experimental investigation and the definition of a preliminary AI-based model. Thirty pumps were tested with six different types of run-in cycles, showing interesting results in terms of pump performance improvement and cost reduction. For all the pumps, the same maximum load (p_S^m) was set and the same shape of the internal body profile, with slight differences in the height of milling and in the total volume removed, was obtained. One interesting result is that the final profile shape of the driver gears seats results deeper and aligned with the driven gear when the run-in speed increases, keeping constant the maximum pressure, impacting negatively on the volumetric efficiency. Moreover, adopting new cycles with the same maximum pressure but reduced cycle time the final profile shape of gears seats changes slightly (Table 3. 3) and a minor height of milling is achieved with significantly impacts on the pump efficiency (Figure 3. 4). For the shorter cycles, it was experimentally verified that, the complete material removal requires a time at the maximum load greater than the reference cycle STA N1; spikes of torque appeared on the second and third run-in cycles. Thus, for future activities, a variable t_S^3 will be considered to find the minimum time necessary to have the finished internal profile. The adoption of a shorter cycles ensured a pump cost reduction of 1.74% and an increase in the testing capability until to 78% for the 1STEP 1 cycle. At the same time, the shorter cycles, in particular the 1STEP 3 and the STAIR, showed an increment of pumps performances thanks to a higher volumetric efficiency. The latter benefit was predominant at the low speeds and at the medium-low pressures; working conditions in which the percentage weight of the tip leakages is more relevant. In the STAIR, 1STEP 1 and 1STEP 3 cycles, the run-in phase did not include time intervals for depressurisation, in which the body surface milled by the gears could cool down and the material could be easily removed, and this could have affected the surface quality. In future works, a detailed analysis of the surface asperities in the wear zone will be provided. Therefore, optimising the run-in cycle can ensure economic benefits and improved pump performance. A preliminary AI model for the prediction of the run-in process variables (torque) was developed using the commercial tool NeurEco®. Despite the small size of the training sample, the model was able to predict the absorbed torque, with an error below 6% for the run-in 1 and below 1% for the run-in 6. In future activities, the prediction of other physical quantities, such as the flowrate (therefore volumetric efficiency) and the material removed.

6. APPENDIX

6.1. Definition of $\delta_r^{av.}$, $\epsilon_{max}^{av.}$ and int

The three quantities $\delta_r^{av.}$, $\epsilon_{max}^{av.}$ and int are defined as:

$\delta_r = r^{body} - r^{gear}$; $\delta_r^{av.} = \left(\delta_r^{driving} + \delta_r^{driven}\right)/2$ where r identifies a radius and δ a radial clearance.

$\epsilon_{max} = \left(r^{body} - r_{ex}^{thrust\ plate}\right) + (r_{in}^{thrust\ plate} - r^{shaft})$ where ex and in identify the external and internal radius. Considering the two pump sides, flange and rear cover, and the two gears, driven and driving is obtained $\epsilon_{max}^{av.} = \left(\epsilon_{max}^{driving-flange} + \epsilon_{max}^{driving-cover} + \epsilon_{max}^{driven-flange} + \epsilon_{max}^{driven-cover}\right)/4$. Combining $\delta_r^{av.}$ and $\epsilon_{max}^{av.}$ the quantities int is defined as $int = \epsilon_{max}^{av.} - \delta_r^{av.}$. This last identifies the radius interference between the teeth of the gears and the pump body under the condition of max radial shift of the shaft ϵ_{max}.

6.2. Effective Energy Variation

The passage from equation (3. 1) to equation (3. 2) is possible under various simplifying assumptions.

Assuming that all the pumps with the same RB have the same hydromechanical efficiency, $\eta_{hm,j}^{STA\ N1} = \eta_{hm,j}^{STA\ N2} = \eta_{hm,j}^{STAIR} = \cdots = \eta_{hm,j}^{1STEP\ 3} = \eta_{hm,j}$ for $j = 1,2, \dots 5$, the equation. (3. 1) can be rewritten as:

$$\delta E_{i,j}^{eff} = \frac{\left(\frac{1}{\eta_{hm,j}}\right)\left[\left(E_{i,j}^{th} + \eta_{hm,j} * E_{i,j}^{eff-mill}\right) - \left(E_{STA\ N1,j}^{th} + \eta_{hm,j} * E_{STA\ N1,j}^{eff-mill}\right)\right]}{\left(\frac{1}{\eta_{hm,j}}\right)\left(E_{STA\ N1,j}^{th} + \eta_{hm,j} * E_{STA\ N1,j}^{eff-mill}\right)} * 100$$

Under the assumption that the energy required for the material remotion is the same for all the pumps tested (thirty), $E_{i,j}^{eff-mill} = E^{eff-mill} > 0$ for $j = 1,2, \dots 5$ and $i = \{STA\ N1, STA\ N2, STAIR, New\ STA, 1STEP\ 1, 1STEP\ 3\}$, the above equation becomes:

$$\delta E_{i,j}^{eff} = \frac{E_{i,j}^{th} - E_{STA\ N1,j}^{th}}{\left(E_{STA\ N1,j}^{th} + \eta_{hm,j} * E_{STA\ N1,j}^{eff-mill}\right)} * 100 = \delta E_i^{th} * \frac{E_{STA\ N1,j}^{th}}{\left(E_{STA\ N1,j}^{th} + \eta_{hm,j} * E^{eff-mill}\right)}$$

Defined A as:

$$A = \frac{E_{STA\ N1,j}^{th}}{\left(E_{STA\ N1,j}^{th} + \eta_{hm,j} * E^{eff-mill}\right)} < 1$$

The equation. (3. 2) is obtained. It is important to highlight that the assumption of a unique value of $E^{eff-mill}$ considers that for all the pumps there is the same amount of material removed. This hypothesis can be valid for two reasons: 1) All the run-in cycles have the same maximum pressure (defines the gears' inflection and shift towards the inlet); 2) The thirty pumps have been assembled, maintaining control of the variability of the radial clearances.

If $E_{i,j}^{eff-mill}$ is not constant the parameter B can be defined as:

$$B = \frac{E_{i,j}^{eff-mill} - E_{STA\ N1,j}^{eff-mill}}{\left(\frac{1}{\eta_{hm,j}}\right)\left(E_{STA\ N1,j}^{th} + \eta_{hm,j} * E_{STA\ N1,j}^{eff-mill}\right)} * 100$$

Using the parameters A and B the equation (3. 1) becomes the equation (3. 3). The sign of B depends by the relationship between $E_{i,j}^{eff-mill}$ and $E_{STA\ N1,j}^{eff-mill}$.

Biographies

Alfonso Rosario Apuzzo received the bachelor's degree in aerospace engineering from University of Naples Federico II in 2021, the master's degree in mechanical engineering from the University of Naples Federico II in 2024. In November 2024 started the PhD program born from the collaboration of the University of Sannio and the Duplomatic MS company. His research includes the study of the external gear pumps via numerical and experimental approaches.

Sara Bonati received her MSc degree in mechanical engineering from the University of Parma in 2016. At the same university, she carried out a research grant in 2016 concerning the development of lumped-parameter fluid dynamics models of positive displacement compressors. She has been working since 2017 in the field of Fluid Power, focusing on research and product development activities through CAE tools. She joined the Duplomatic Group in 2023 as R&D drive system engineer.

Dr. Emma Frosina is an Associate Professor in the Department of Engineering at the University of Sannio, Benevento. She received her M.S. degree in Mechanical Engineering from the University of Naples Federico II in 2012 and her Ph.D. degree in Mechanical Systems Engineering in 2016. She is the author of over 80 scientific papers published in peer-reviewed international journals and conference proceedings. Her research interests are in the field of fluid power, where she specializes in the modeling and optimization of components (machines, valves, etc.) using numerical approaches (both lumped parameter and three-dimensional CFD) and experimental testing.

Dr. Luca Riccò received his MSc degree in mechanical engineering in 2012 and his PhD in industrial engineering in 2015 from the University of Parma. After, he started his career in the field of fluid power with different R&D roles. Starting from July 2023 he leads the R&D drive system and global simulation team of the Duplomatic Group, a member of Daikin Group.

Influence of surface structuring on the hydrostatic and hydrodynamic pressure distribution of slipper sealing lands

Svenja Horn, Jürgen Weber

Institute of Mechatronic Engineering, TU Dresden, svenja.horn@tu-dresden.de

Abstract.

Modern operating conditions and upcoming lead-free material regulations challenge the tribological performance of axial piston pumps, particularly at low speeds where hydrodynamic support is weak. While meso-structures on slipper surfaces have shown practical success, a fundamental understanding of their working principles is lacking. This paper presents a systematic analysis of how specific geometric parameters of step and parabolic structures influence the hydrostatic and hydrodynamic performance of the slipper-swashplate interface. Simplified analytical models based on the Reynolds equation are used to evaluate the impact on hydrostatic balance and hydrodynamic tilting moments. The findings are qualitatively compared with results from a comprehensive Caspar FSTI simulation. Results show that a smaller gap height at the inner radius reduces the hydrostatic balance but generates a stabilizing tilting moment in the direction of movement. A reduced gap at the outer side of the sealing land by contrast, increases the hydrostatic balance but at the cost of a destabilizing negative tilting moment. The analytical trends are confirmed by the dynamic simulations, providing a foundational understanding for designing structured surfaces to improve pump reliability and efficiency.

Keywords. Surface structures, slipper geometry, axial piston pump, tribology

1. INTRODUCTION

New operating ranges motivated by electrification, start-stop applications or speed-variable drives challenge traditional hydraulic machines with respect to mixed friction conditions, low swash plate angles and partial load operation. At these critical conditions, the pumps are exposed to reduced hydrodynamic pressure in the lubricating gaps, leading to increased friction losses, wear, and a higher likelihood of failures. Traditionally, to ensure good run-in behavior and satisfactory dry-running performance under mixed friction, a combination of leaded bronze or brass and steel materials has been used. However, future EU regulations will prohibit the use of lead-containing materials. In light of these upcoming restrictions, it

All Open Access articles are peer-reviewed, distributed under the Creative Commons Attribution-Non Commercial 4.0 International

becomes imperative to find new solutions to withstand the harsh operating conditions without the use of lead-containing metals.

The main difficulty centers the lubrication gaps of the pump's rotating group. Illustration 3 and 4 in Figure 1.1 explain the principal correlation between surface geometry and power losses for the slipper / swash plate interface. There are two forces, that mainly determine the gap height between slipper and swashplate. The piston force F_{SK} from the pressure in the displacement chamber and the opposed lift force F_{fz} due to the pressure distribution of the fluid film lubrication in the gap. A trade-off arises due to the conflicting requirements on the gap height to allow good bearing properties while reducing leakage at the same time. Figure 1.1-4 shows the optimization problem between leakage and friction depending on the gap height. The larger the gap, the higher the leakage, with a simultaneous decrease in friction losses. As the curves have different optima depending on the operating point and design, there is an optimum slipper design for each operating point.

This optimization challenge is addressed by the design of meso-structures. Meso-structures are surface designs that exhibit small changes in height (in the µm range) over larger distances (in the mm range). The principal mechanism of surface structuring on power losses is illustrated in Figure 1.1, using results of chapter 4. Meso-structures allow to change the pressure field in the gap in a targeted way and thus to build up additional hydrodynamics, depicted exemplary for a step structure in Figure 1.1-1 and Figure 1.1-2. This again changes the balance of forces and moments (Figure 1.1-3), which ultimately determines the gap height and slipper's micro motion and associated power losses (Figure 1.1-4).

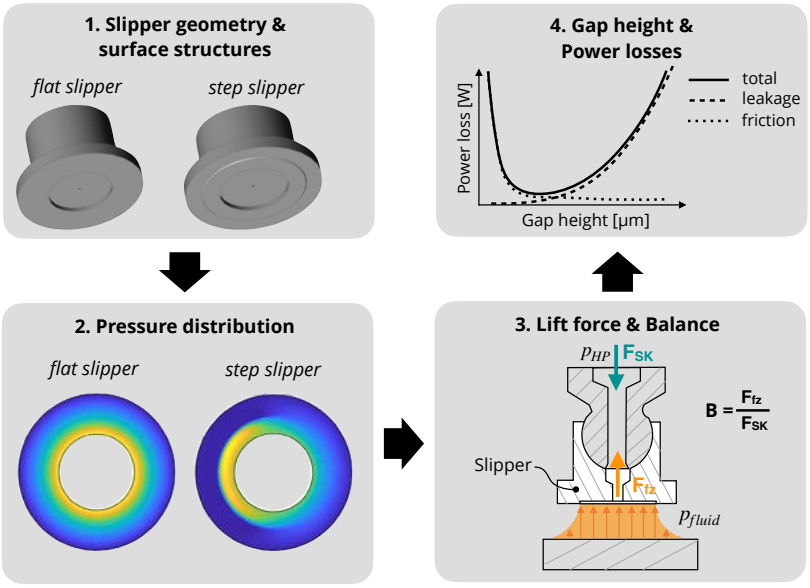

Figure 1.1. Principal mechanism of surface structuring on power losses

Our earlier publications have demonstrated the practical success of these structured surfaces. Several structures on the slipper sealing land have been investigated and optimized using the pump simulation software Caspar FSTI in [1]. The two most promising designs from

simulation were manufactured and validated on a dedicated pump test-rig, showing almost no wear [2] and an increase in efficiency for low speeds, low pressures as well as partial load conditions [3]. They were further investigated on the tribometer in [4] and [5] being exposed to extreme thermal conditions and different pressure pulsations.

While these results confirm the significant potential of meso-structures, a fundamental understanding of how specific geometric parameters influence the underlying hydrostatic and hydrodynamic mechanisms is still lacking. The objective of this work is to draw a systematic analysis to bridge this knowledge gap, which will not only enable more efficient design of new slipper geometries but also describes the effect of wear-induced surface changes. The findings are expected to be transferrable to other bearings within axial piston pumps and also to a broader class of plain bearings.

Chapter 3 establishes the theoretical foundation for pressure build-up in lubricating gaps, based on the Reynolds equation, and introduces the two selected surface structures for analysis. In chapter 4, the influence of key geometric parameters on both the hydrostatic balance and the hydrodynamic tilting moments are investigated in detail for each design. The findings for the first structure are also compared with results from a comprehensive simulation to contextualize the analytical approach in chapter 5. The paper concludes with a summary of the key findings and their implications for the design and optimization of tribological interfaces in axial piston pumps.

2. LITERATURE

The performance of the slipper-swashplate interface has been a subject of extensive research, with a particular focus on the influence of the slipper's surface geometry on the lubricating film. Early analytical investigations by Hooke established that a convex slipper profile is crucial for ensuring stable fluid film lubrication [6]. This finding was later reinforced by Borghi et al., who used simulations to show that an initially flat slipper is inherently unstable and will eventually wear into a convex shape to achieve stable operation [7]. However, the ideal profile is not straightforward. Manring, for instance, found that while a linear concave profile could increase load-carrying capacity, it came at the cost of higher leakage and power loss. His work further revealed that profile deformations have a greater impact on flow rate than on load-carrying capacity, highlighting the complex trade-offs inherent in slipper design [8].

More recent studies employing Elastohydrodynamic (EHD) models have provided deeper insights into the role of deformation. Hashemi et al. developed a "tribo-slipper-pump" test rig and showed through both measurement and simulation that a slightly concave slipper can deform elastically under high pressure to form a convex shape, thereby improving its hydrodynamic characteristics [9]. This underscores the importance of considering material deformation in any realistic analysis. Beyond general surface profiles, specific geometric structures have been proposed to actively manipulate the pressure field. A notable example of using a micro-step is found in the patent US 5,983,781 by Ivantysyn, from 1999 [10]. It is relevant to note that this patent has since expired, placing the described invention in the public domain. The patent describes a shallow recess at the inner diameter of the sealing land, which is designed to create a self-adjusting load-bearing capacity that changes with the gap height [10]. While the patent focuses on this specific self-adjusting mechanism, the present work undertakes a broader, systematic analysis of such step structures. It investigates

the fundamental effects of varying key parameters, including step height and position, on the hydrostatic and hydrodynamic performance. This allows for a more comprehensive understanding of the design trade-offs, building on the concepts introduced in earlier work. Another promising approach involves sinusoidal or wave-like structures. Baker and Ivantysyn investigated sinusoidal meso-structures on the sealing land of a valve plate, using simulation to optimize the wave's frequency, amplitude, and phase [11], [12]. The most promising design was manufactured and tested, demonstrating an increase in the total pump efficiency of up to 10 % at low displacement and pressure [11]. While this technology was patented in the United States in 2009, it was not extended elsewhere, making the application and further development freely available in other markets, including Europe [13]. The success of this wave profile on the valve plate provides a strong motivation for investigating a similar radial wave structure on the slipper surface, as is done in the previous studies.

Other approaches include surface texturing. Ye et al. used an EHD model to identify an optimal dimple area density and depth-to-diameter ratio to maximize load-carrying capacity [14]. Similarly, Wang et al. simulated micro-textures with varying dimple shapes and depths, also finding improvements in load-carrying capabilities and friction losses, though these results were not experimentally validated [15].

A significant contribution to surface optimization on the slipper sealing land was made by Darbani et al., who proposed an optimized convex shape derived from typical wear profiles [16]. Their work aimed to minimize total energy loss across various operating conditions, reporting a theoretical efficiency improvement of around 51%, mainly decreasing friction losses at high speeds [16]. However, the study has limitations: the results were not experimentally validated, and crucial geometric data such as the slipper balance factor were whether provided nor changed, making the findings difficult to transfer or compare directly. Despite these gaps, the promising results from this optimization approach motivate the inclusion of a similar convex profile in the present analysis. More recently, Mo et al. also analyzed the influence of different convex wear profiles on lubrication performance, though the analysis was limited to a single operating point and did not include an optimization perspective [17].

A key challenge in analyzing these complex interactions is to distinguish the contributions of hydrostatic and hydrodynamic effects. A recent methodological advancement by Ernst and Vacca demonstrated a technique for separating the hydrostatic and hydrodynamic force components from the simulated pressure distribution [18]. Their findings revealed that while the load is primarily carried hydrostatically, the hydrodynamic component can account for over 20 % of the total lift under certain conditions, playing a critical role in balancing the system [18]. This approach of separately analyzing hydrostatic and hydrodynamic effects is adopted in the present work to provide a fundamental understanding of how specific geometric parameters influence each mechanism.

3. THEORETICAL BACKGROUND AND METHODOLOGY

3.1. Pressure build-up in small lubricating gaps

The pressure distribution within the lubrication gaps of axial piston pumps determines the forces and moments acting on the components and can be described by the Reynolds equation, first derived from the Navier Stokes momentum and continuity equations by

Osborne Reynolds in 1886 [19]. Considering a very small fluid gap height in the range of micrometer together with a large gap length in the range of millimeter, as it is the case for the lubricating gaps in axial piston pumps, several assumptions can be made, that simplify the complex Navier Stokes equation. These include assuming constant pressure over the fluid film thickness $\partial p/dz = 0$, neglecting inertial and body forces as they are very small compared to the viscous and pressure forces, and considering the lubricant to be a Newtonian fluid, where shear stress is proportional to the shear rate. For the analytical approach in this work, the fluid is further assumed to be incompressible and of constant viscosity. Under these assumptions, the generalized Reynolds equation is given by [18]

$$\underbrace{\frac{\partial}{\partial x}\left(\frac{\rho h^3}{12\mu}\frac{\partial p}{\partial x}\right)+\frac{\partial}{\partial y}\left(\frac{\rho h^3}{12\mu}\frac{\partial p}{\partial y}\right)}_{\text{Poiseuille}}=\underbrace{\frac{\partial}{\partial x}\left(\frac{\rho h(u_\mathrm{a}+u_\mathrm{b})}{2}\right)+\frac{\partial}{\partial y}\left(\frac{\rho h(v_\mathrm{a}+v_\mathrm{b})}{2}\right)}_{\text{Couette}}$$
$$+\underbrace{\rho\left(w_\mathrm{a}-w_\mathrm{b}-u_\mathrm{a}\frac{\partial h}{\partial x}-v_\mathrm{a}\frac{\partial h}{\partial y}\right)}_{\text{Squeeze}}+\underbrace{h\frac{\partial \rho}{\partial t}}_{\text{Expansion}}. \tag{3.1}$$

The equation consists of several terms that represent different physical effects. The *Poiseuille* term describes the flow rates due to pressure gradients and is used to calculate the hydrostatic pressure field in the gap. The *Couette* term describes the hydrodynamic pressure build up due to the relative sliding motion of the surfaces. This hydrodynamic effect is primarily generated by a "physical wedge," where a converging geometry in the direction of motion creates positive pressure [20]. The squeeze term accounts for the cushioning effect when surfaces move towards or away from each other, generating pressure in response to a changing film thickness. The local expansion term describes the impact of mechanical or thermal deformations on the fluid film thickness. This paper focuses on the hydrostatic (Poiseuille) and hydrodynamic (Couette) effects to understand the fundamental influence of surface geometry.

A key metric for evaluating the hydrostatic design is the balance factor, calculated by dividing the hydrostatic lift force by the opposing piston force. A balance of 100 % indicates that the forces are in equilibrium. In industrial practice, slippers are often designed with a balance around 90 % to allow for additional hydrodynamic lift at higher speeds. However, this under-balance can lead to high friction and wear during start-up and at low speeds when hydrodynamic effects are weak. Conversely, a balance factor near or above 100 % can ensure separation but may lead to increased leakage losses.

The primary mechanism for generating hydrodynamic pressure is the wedge effect, which can be created by a tilted surface or a geometric feature like a step, as illustrated in Figure 3.1. The magnitude of hydrodynamic pressure generated is dependent on the ratio between the minimum gap height and the height of the geometric feature (i.e., step or inclination height). For the specific case of a parallel-step bearing, an optimal configuration that maximizes hydrodynamic lift was first derived by Lord Rayleigh [21]. As presented in detail in [20], this optimum is defined by the following dimensionless parameters for the step height ratio, H_0, and the step position ratio, n_s:

$$H_0 = \frac{h_0}{s_h} = 1.155,\ n_s = 0.7182. \tag{3.2}$$

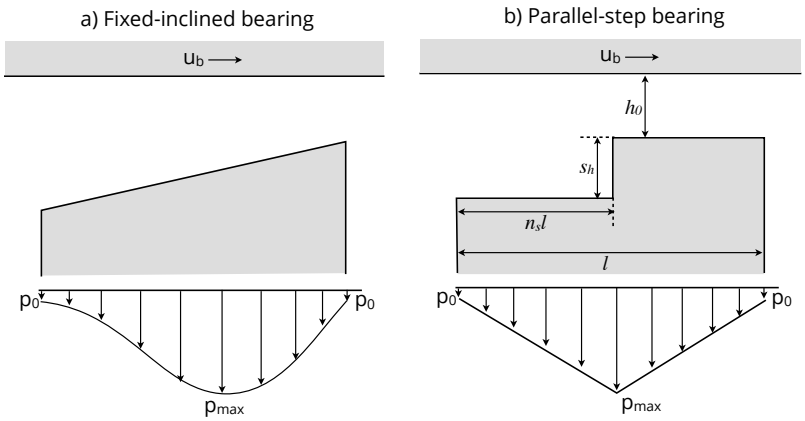

Figure 3.1.Comparison of pressure profiles of fixed inclined bearing (a) and parallel-step bearing (b)

3.2. Selected surface structures

The left plot in Figure 3.2 illustrates the slipper geometry, with the most important parameters the pocket diameter d_{inG}, the sealing land outer diameter d_{outG} and the gap height h. To further investigate the influence of surface structures on the hydrostatic and hydrodynamic pressure build-up, two representative surface designs (see Figure 3.2) from literature were selected for detailed analysis:

- **Design a):** A step structure several micrometers in height, resulting in a reduced gap at the inner land of the slipper surface. This concept is derived from classical step slider bearing designs and, compared to the other structures, offers significant advantages in terms of manufacturing simplicity.
- **Design b):** A parabolic surface profile, which mimics the typical run-in wear pattern of the slipper surface. This profile arises due to thermal and pressure-induced deformation, leading to abrasion at the inner radius, and tilting-induced wear at the outer radius. Darbani optimized this design using the CASPAR simulation environment [16]. However, no manufacturing or experimental validation has been reported to date.

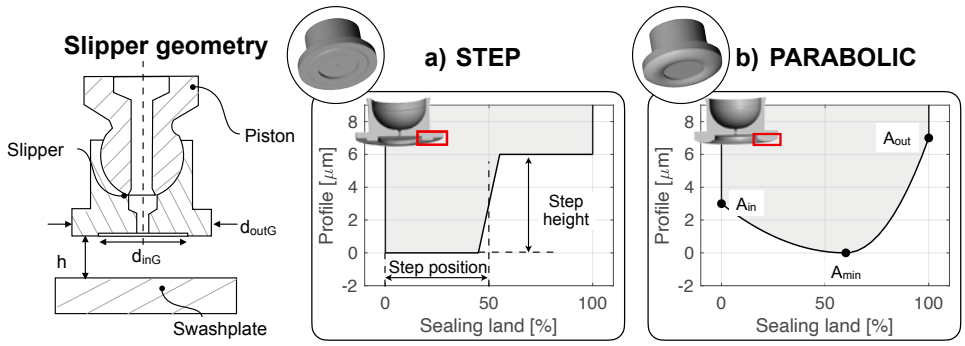

Figure 3.2. Slipper geometry and design spaces of two different surface structures

These surface structures were chosen to represent a spectrum of complexity and manufacturability, as well as to capture different mechanisms of pressure generation and

wear compensation. In the following, their impact on the pressure build-up in the lubricating gap will be systematically analyzed and compared.

3.3. Methodology

In the following, the influence of the design parameters on the hydrostatic and hydrodynamic lift force is investigated. In order to take into account the later dimensions of the test pump at this point and at the same time remaining company-neutral, the outer diameter d_{outG} of the slipper is set to 29.6 mm, which is an average value of industrial slipper outer diameters with a 21 mm piston. To directly see the influence of the surface structure, the inner radius is calculated such that a balance of 100 % is achieved. A gap height of h=20 µm during high pressure stroke is set to calculate the hydrostatic and hydrodynamic pressure build-up. To quantify the hydrostatic forces and hydrodynamic moments based on the principles of the Reynolds equation, simplified analytical methods are employed. Bergada detailly derives the calculation of the lift force of a multi-land slipper design in [22]. His approach is transferable to micro-structured sealing lands, as it discretizes the radial gap height *h(r)*, using the following formula to calculate the lift force F_{fz}:

$$F_{fz} = p_{\text{in}} \cdot \pi \cdot \left[\frac{\sum_{i=1}^{i=n} \frac{1}{h_i^3} \cdot \frac{r_{i+1}^2 - r_i^2}{2}}{\sum_{i=1}^{i=n} \frac{1}{h_i^3} \cdot \ln\left(\frac{r_{k+1}}{r_k}\right)} - r_1^2 \right] \tag{3.3}$$

This calculation accounts for the modified pressure profile caused by the structure. It is important to distinguish this from a conventional balance calculation based solely on the fixed pocket and sealing land diameters, which would not capture the influence of the meso-structure.

For the analysis of hydrodynamic effects, a simplified 1D analytical model, as implemented by Knoll is used [23]. This approach solves a one-dimensional form of the Reynolds equation (Equation (3.4), assuming the slipper sealing land is an infinitely wide bearing. This reduces the problem to the direction of motion (x_G) and allows for rapid evaluation of the pressure profile *p(x)* generated by the Couette term.

$$\frac{\partial}{\partial x_G}\left(h^3 \frac{\partial p}{\partial x_G}\right) = 6u\mu \frac{\partial h}{\partial x_G} \tag{3.4}$$

The resulting 1D pressure profile p(x) is then integrated across the sealing land width to calculate the hydrodynamic tilting moment M_y around the y_G-axis, providing a direct measure of the structure's tendency to generate a stabilizing or destabilizing pitch:

$$M_y = \int p(x) \cdot x \, dx. \tag{3.5}$$

4. RESULTS

This chapter presents the influence of key geometric parameters on the hydrostatic balance and the hydrodynamic tilting moments first for the step and second for the parabolic design. The findings for the step structure are further compared with results from a comprehensive simulation to contextualize the analytical approach.

4.1. a) Step structure

4.1.1. Influence on hydrostatic pressure and balance

The initial investigation focuses on the examination of the impact of the step design parameters, specifically the step height and position, on the hydrostatic. Figure 4.1 (left) shows, as a dashed black line, the typical logarithmic pressure drop across the sealing land for a flat, unstructured slipper with a balance of 100 % (pocket diameter of 14.4 mm) at a pocket pressure of 100 bar and a gap height of 20 µm (design *a3*). The colored lines represent three example pressure distributions for a step located in the middle of the sealing land, with varying step heights. Designs *a1* and *a2* feature a step with a reduced gap height at the inner radius, elevated by 6 µm and 3 µm, respectively. In contrast, design *a4* has a 3 µm-high step at the outer radius, reducing the gap height there. A smaller gap at the inner radius causes a more rapid pressure drop in the inner region, resulting in a lower lift force and thus a reduced balance. Conversely, a reduced gap at the outer radius (*a4*) leads to a slower pressure drop in that area, increasing the hydrostatic force and balance. The right-hand plot in Figure 4.1 shows the resulting balance as a function of step height and step position, with the four designs *a1–a4* indicated.

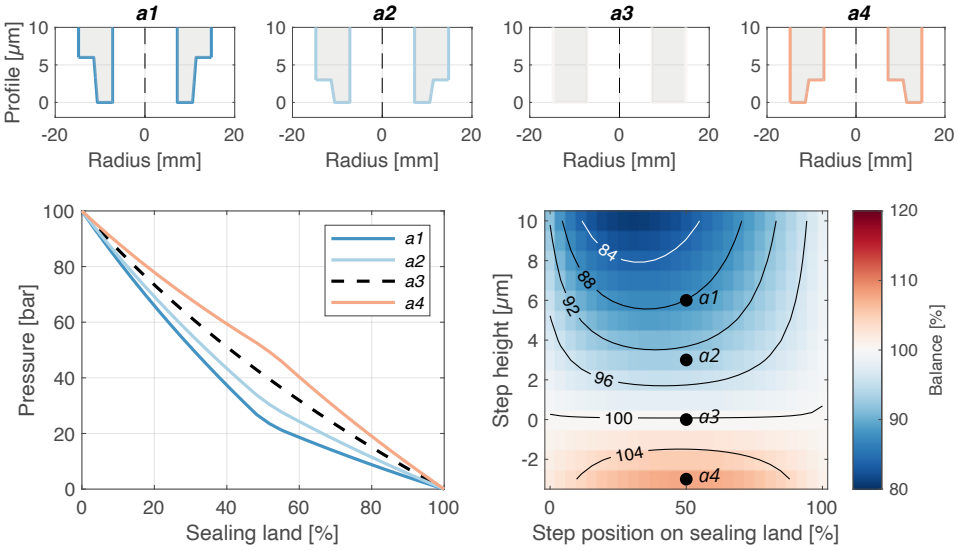

Figure 4.1. Sealing land Pressure drop over sealing land for different surface structured designs (*a1, a2, a4*) in comparison to an unstructured slipper *a3* (left) and balance for different step heights and step positions (right)

Figure 4.2 left shows that the gap height for an unstructured flat slipper (design *a3*) has no impact on the balance, while it strongly changes the balance for the structured slippers (*a1, a2* and *a4*) especially for smaller gap heights below 10 µm. It is particularly noticeable that the designs *a1* and *a2* with a smaller gap at the inner ring have less lift for smaller gap heights, dropping below 80 % for a 3 µm gap height. Design *a4* on the other side exhibits a balance of over 140 % for a 3 µm gap height providing extra lift in case of critical mixed friction conditions. All designs have a pocket radius of 7.2 mm.

Figure 4.2 right illustrates the balance for different pocket diameters ranging from 7-8 mm and gap heights from 3-30 µm for the structured design *a1*. While the pocket diameter has a linear impact on the balance value, the impact of the gap height on the balance value is significantly higher at lower gap heights.

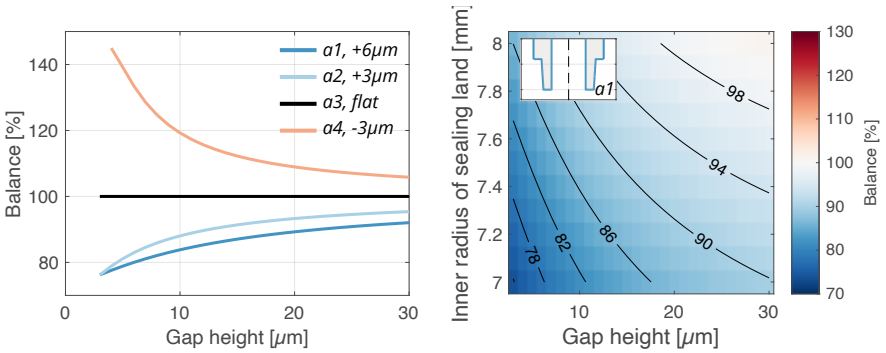

Figure 4.2. Influence of gap height on balance for different designs *a1*-*a4* (left) and balance for different pocket diameter and gap height combinations for design *a1* (right)

4.1.2. Influence on hydrodynamic lift and tilting moment

Figure 4.3 (top) shows the radial cross-sectional profiles of the three designs *a1, a2*, and *a4*. The lower part of the figure presents a qualitative representation of the resulting hydrodynamic pressure distribution, calculated at a rotational speed of 500 rpm and an external pressure of 0 bar without any slipper tilt. The direction of movement *u* is defined to the right. The triangular hydrodynamic pressure build-up caused by the step corresponds to that of a parallel-step bearing, as shown in Figure 3.1.

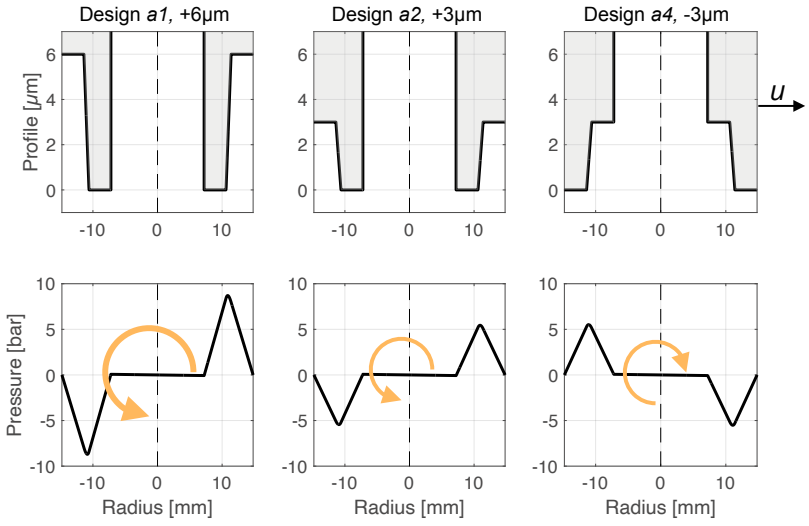

Figure 4.3. Radial cross-sectional profiles of designs *a1*, *a2*, and *a4* (top) and corresponding qualitative hydrodynamic pressure distribution at 500 rpm (bottom)

A diverging gap in the direction of motion leads to a positive pressure build-up, whereas a converging gap results in a negative pressure. While negative pressures cannot occur in reality and are merely the result of a mathematical solution under the given boundary conditions, the simplified example nonetheless illustrates the effect induced by the step. In a physical system, a liquid cannot sustain significant tension, and the pressure will not drop below the fluid's cavitation pressure. A smaller gap at the inner radius (as for *a1* and *a2*) causes an uneven hydrodynamic pressure distribution due to the wedge effect in the flow direction, resulting into a positive tilting moment, causing the slipper to pitch upward and align itself in a way that promotes further hydrodynamic pressure build-up. In contrast, a step in the opposite direction as for design *a4* induces a negative tilting moment, which may cause the slipper to "sink" or lose its load-carrying capacity.

Figure 4.4 illustrates the tilting moments generated by the step structure and calculated with a 20 µm gap height and a dynamic viscosity of $\eta = 0.0705$ Pas. Positioning the step near the inner radius results in a positive tilting moment, which acts to pitch the slipper upward and enhance hydrodynamic support. In contrast, a step near the outer radius creates a negative, potentially destabilizing moment. This fundamental behavior aligns with the principles first established by Lord Rayleigh for ideal parallel-step bearings, which predict an optimal configuration for maximizing lift (refer to formula (3.2)) [20].

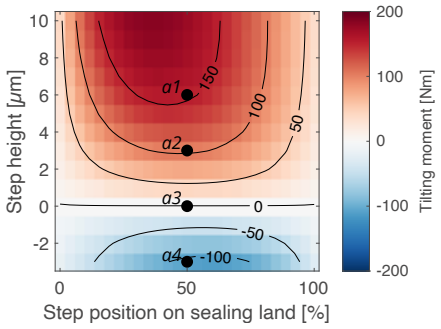

Figure 4.4. Tilting moment generated by hydrodynamic pressure for various step heights and step positions on the sealing land

The results in Figure 4.4 show that for the slipper geometry in this study, the maximum positive tilting moment is found for a step position of approximately 40 % of the sealing land width. This is in the same region as, though slightly outward from, the theoretical optimum of ~30 % predicted by Rayleigh's theory. Similarly, the optimal step height of around 10 µm (for a 20 µm gap) is in the same order of magnitude as the classical prediction, confirming the validity of the general principle.

4.2. b) Parabolic structure

4.2.1. Influence on hydrostatic pressure and balance

The parabolic design is showing a typical wear profile of the slipper sealing land. Starting with the influence of the parabolic design parameters A_{in}, A_{out} and A_{min} on the hydrostatic behavior, Figure 4.5 (left) shows the pressure profiles across the sealing land. The reference design *b3*, without any structural modification, is shown as a dashed line. The colored curves

illustrate four modified designs: *b1* and *b2* feature a parabolic recess at the outer radius with depths of 10 µm and 5 µm respectively, that can for example be caused by slipper tilting. *b4* and *b5* have a recess at the inner radius with the same depths and can be produced by convex deformation of the slipper surface. As already observed in the step design, material removal at the outer radius (*b1, b2*) causes a reduction in pressure compared to the unprofiled reference, whereas a recess at the inner radius (*b4, b5*) leads to an increase in pressure. This behavior corresponds to a decrease or increase in the hydrostatic balance of the slipper, as shown in the right plot of Figure 4.5. Here, the design space covers also quadratic designs with a recess at both, the outer and inner radius, with a curve minimum at A_{min}=50 %.

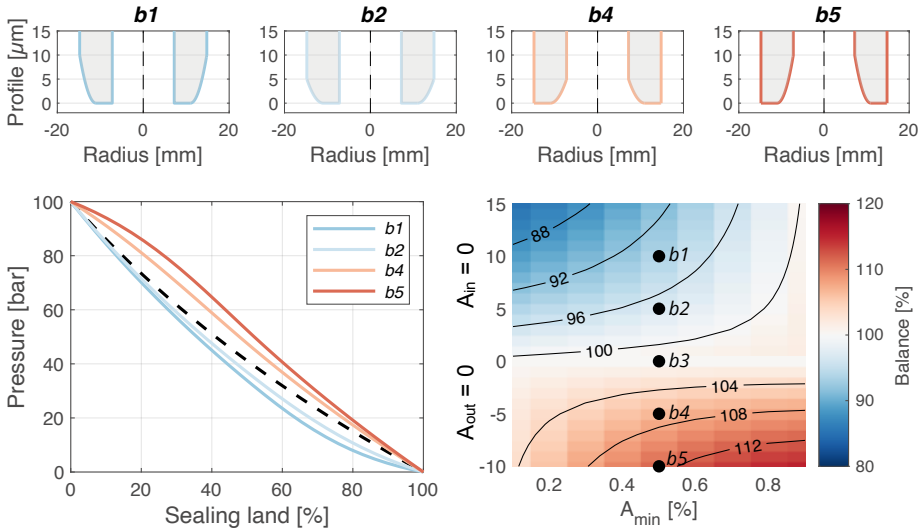

Figure 4.5. Hydrostatic pressure drop over the sealing land for different parabolic designs *b1-b5* (left) and hydrostatic balance map for different combinations of the parameters A_{in} and A_{out}, with different curve minimums A_{min} (right)

Further balance maps with different curve minimums at 20, 50 and 80 % are presented in Figure 4.6. A shift of the curve minimum to the inner radius reduces the balance while a shift to the outer radius increases the balance, aligning with the trends of the step design.

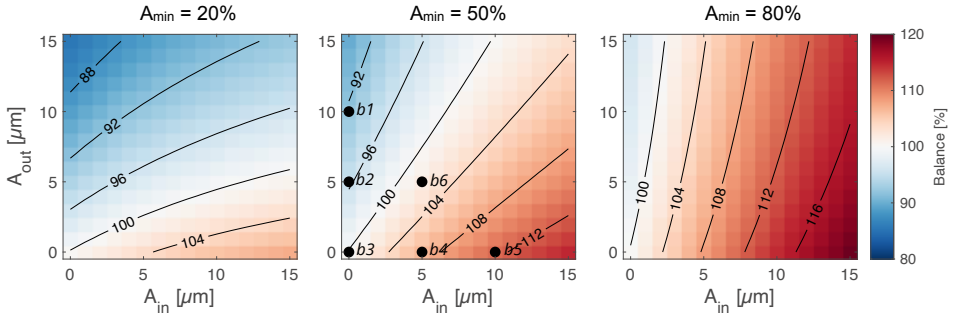

Figure 4.6. Influence of quadratic curve minimum A_{min} on balance for different combinations of A_{in} and A_{out}

4.2.2. Influence on hydrodynamic lift and tilting moment

In Figure 4.7 on the top, the radial cross-sectional profiles of the three designs *b2*, *b6* and *b4* are drawn in more detail. Below, the corresponding qualitative hydrodynamic pressure distributions are calculated at 20 µm gap height, 500 rpm and no slipper tilt. Design *b2* and *b4* produce the same hydrodynamic pressure however mirrored such that wear at the outer radius results in a positive tilting moment, while wear at the inner radius produces a negative tilting moment. A recess at the inner and outer radius (*b6*) varies the hydrodynamic pressure according to the positive and negatives edges of the profile. In total, a slightly positive tilting moment result.

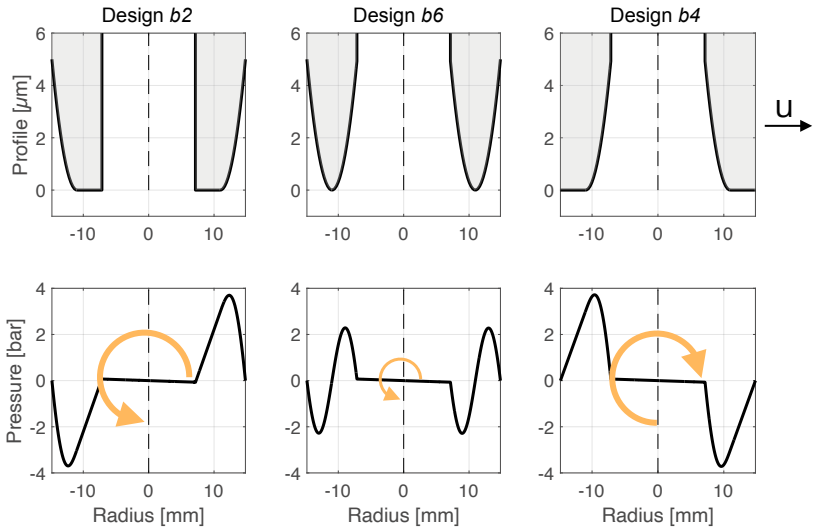

Figure 4.7. Radial cross-sectional profiles of designs *b2*, *b6* and *b4* (top); corresponding qualitative hydrodynamic pressure distribution at 500 rpm (bottom)

Figure 4.8 summarizes the tilting moments of a wide range of combinations of the parabolic design parameters A_{in} and A_{out} for three different values of A_{min}. The more at the inner radius, the curve minimum exists, the more the recess at the outer radius dominates resulting into a broader area of a positive tilting moment (compare the large red area in the left plot with the large blue area in the right plot).

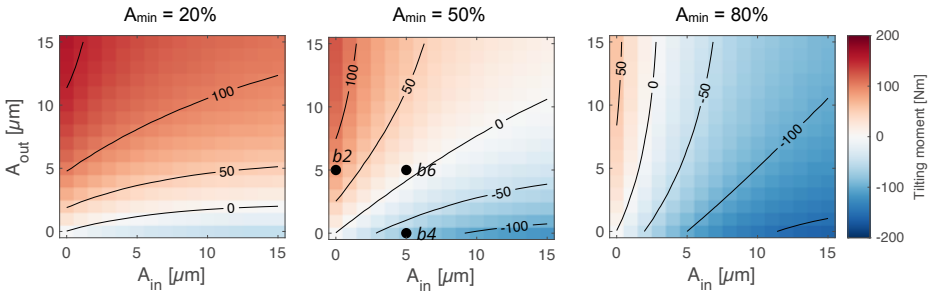

Figure 4.8. Tilting moment generated by hydrodynamic pressure for different quadratic curve minimums A_{min} over A_{in} and A_{out}

5. COMPARISON WITH SIMPLIFIED SIMULATION RESULTS

To validate the fundamental trends observed in the simplified analytical model, a comparison is made with the comprehensive FSTI CASPAR simulation. This step is necessary to confirm that the basic physical effects predicted by the static, analytical approach hold true within a more complex simulation that seeks a system's force and moment equilibrium. However, a direct quantitative validation presents a methodological challenge. The analytical approach calculates forces for a predefined, fixed gap height, producing maps of force balances versus geometry. In contrast, the FSTI simulation is designed to find the system's equilibrium state. It iteratively adjusts the gap height and slipper tilt until the forces and moments precisely balance the external loads (e.g., the piston force). Consequently, the simulation's primary output is the final equilibrium gap height for a given operating point, not a map of forces at various non-equilibrium gap heights.

5.1. Simulation setup and parameter selection

To create a qualitative comparison despite this fundamental difference, several steps were taken. First, the FSTI simulation was simplified to more closely match the assumptions of the analytical model by deactivating squeeze effects and deformations. Second, a key challenge was identifying simulation parameters that yielded stable, converged results with physically meaningful gap heights for all designs. Many initial simulations failed to converge. Therefore, only a smaller selection of the step designs *a1-a4* is chosen for the comparison. Runs with a smaller pocket radius (7.2 mm, as used in the analytical study) resulted in predicted gap heights that were too small, particularly for design *a1*. This approached a mixed-friction regime that the simulation cannot accurately depict. Consequently, a larger pocket radius of 8.2 mm was selected. At an operating condition of 100 bar and 500 rpm, this configuration produced reasonable and comparable equilibrium gap heights.

Figure 5.1 (left) illustrates the slipper coordinate system, in which the direction of movement is defined by x_G and the velocity by u. The high- and low-pressure regions are marked in red and blue and the angle of rotation is defined by ϕ, which ranges from 0 to 360°.

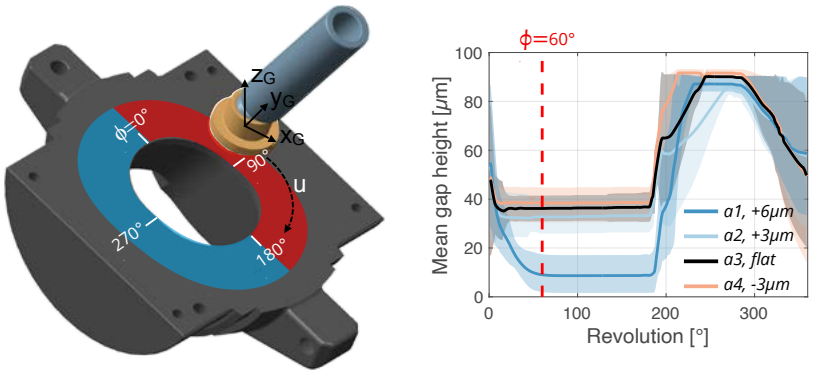

Figure 5.1. Mean gap height over one pump revolution for all designs *a1-a4* with shaded regions indicate min-max range (right)

Figure 5.1 (right) presents the resulting mean gap heights for designs *a1-a4* over one pump revolution, with shaded regions indicating the spread between minimum and maximum values. As predicted by the analytical balance calculations, design *a1*, which has the lowest hydrostatic balance, also exhibits the lowest minimum gap heights in the simulation. The maximum value of the curves during the low-pressure phase is due to the slipper hold-down mechanism, which limits the maximum gap height to 90 µm. The red dotted line indicates a rotation angle of 60°, at which point gap heights and pressure fields are evaluated further.

The next two paragraphs analyze the influence of the meso-structures on the hydrostatic and hydrodynamic pressure build-up in isolation. As the outputs of the FSTI simulation comprise the results of the total Reynolds equation, it is necessary to separate the hydrostatic and hydrodynamic components of the pressure field from the final simulation outputs. To achieve this, a post-processing script was used [23], which implements the methodology for pressure component separation proposed by Ernst and Vacca [18]. This method first uses the results from the full fluid-structure interaction simulation (total pressure p_{tot} and equilibrium gap height). It then resolves the Reynolds equation using only the hydrostatic (Poiseuille) term, treating the final gap height and fluid properties as known constants. The resulting pressure field is the pure hydrostatic component (p_s), and the hydrodynamic component (p_d) is subsequently found by subtraction: $p_d = p_{tot} - p_s$ [18].

Figure 5.2 illustrates the results of the pressure separation for design *a2* at 60° during the high-pressure phase. The gap height distribution (left) reveals the slipper's backward tilt, which directly influences the pressure fields. The hydrostatic component (middle) exhibits the expected radial symmetry, whereas the hydrodynamic component (right) reflects the wedge effect created by the tilt: regions of positive pressure (yellow) form where the gap converges, and sub-ambient pressure (blue) develops at the location of smallest gap height. It should be noted that the negative pressure values are a mathematical result of the separation methodology. In reality, the fluid cannot sustain such tensions and would cavitate; however, this does not affect the validity of the qualitative trends. The red dotted line in b) marks the path analyzed in Figure 5.3.

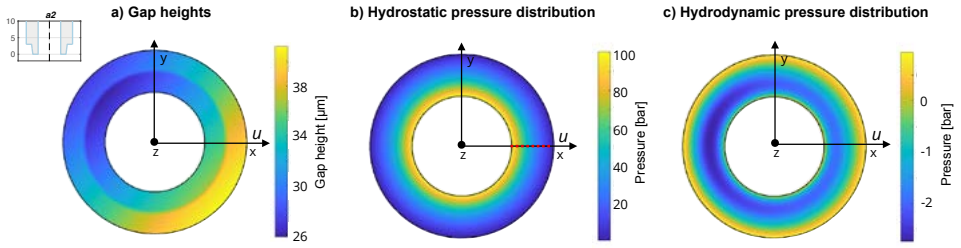

Figure 5.2. Gap height (left), hydrostatic (middle) and hydrodynamic (right) pressure fields for design *a2* at 60°; the red dotted line marks the path analyzed in Figure 5.3.

5.2. Influence on hydrostatic pressure and balance

Figure 5.3 compares the simulated (left) and analytically calculated (right) pressure drop across the leading sealing land for all four designs at $\phi = 60°$. Unlike in chapter 4, the analytical model employs the same pocket diameter of 8.2 mm as the simulation and uses the different mean gap heights at $\phi = 60°$ from Figure 5.1 as inputs. The resulting pressure profiles are qualitatively and apart from minor differences also quantitatively comparable.

Those minor deviations may arise from the pressure component separation methodology [18].

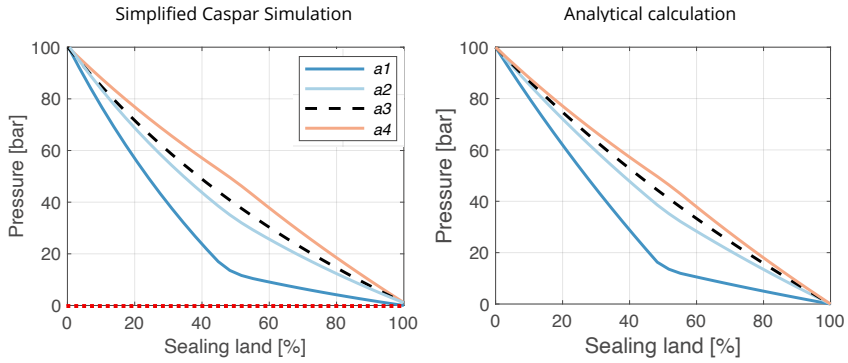

Figure 5.3. Pressure drop over the leading sealing land for all designs *a1-a4* at 60° pump revolution from simulation (left) and analytically calculated (right)

5.3. Influence on hydrodynamic lift and tilting moment

Figure 5.4 displays the respective hydrodynamic pressure fields for designs *a1-a4*, with the resulting tilt axis marked as a dashed line. The opposite tilting moment directions—negative for the outer step (*a4*) versus positive for the inner steps (*a1-a3*)—are clearly visible in the pressure field orientations relative to slipper velocity u. Among designs *a2-a4*, which share similar gap heights, the trend is solely geometry-driven: increasing inner step height leads to a larger positive tilting moment and corresponding tilt axis rotation, aligning with the analytical findings in chapter 4. Design *a1* exhibits a notably stronger hydrodynamic effect due to its much smaller gap height, which amplifies the hydrodynamic lift beyond what the step geometry alone would produce.

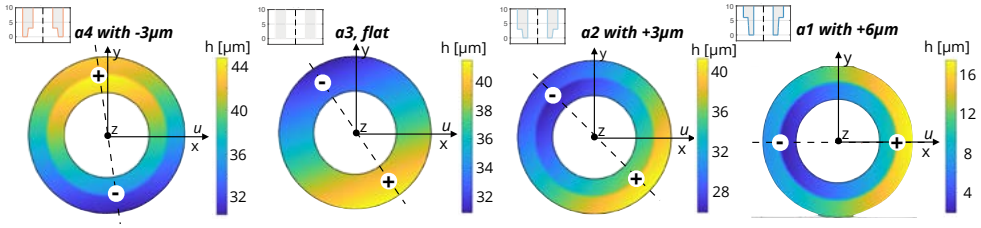

Figure 5.4. Gap height distributions for different step designs *a1-a4* with marked tilt axis at 30° pump revolution during high pressure phase

Figure 5.5 shows the result of this separation for design *a2* at 30° of the pump revolution (high pressure regime), now at an elevated operating pressure of 200 bar (compared to 100 bar in the previous analysis) while maintaining the same speed of 500 rpm. The higher operating pressure was selected because it produces smaller equilibrium gap heights, which in turn amplifies the hydrodynamic pressure generation, making the effect more clearly visible for analysis. The plot on the left displays the isolated hydrodynamic pressure field across the entire slipper land. It clearly shows a region of positive pressure build-up (yellow) and a region of sub-ambient pressure (blue), which is characteristic of the wedge effect. The plot on the right shows the pressure profile along the central x-axis, which is qualitatively

similar to the analytical results for a parallel-step bearing (refer to Figure 2.2), confirming that the step is the primary driver of this hydrodynamic effect.

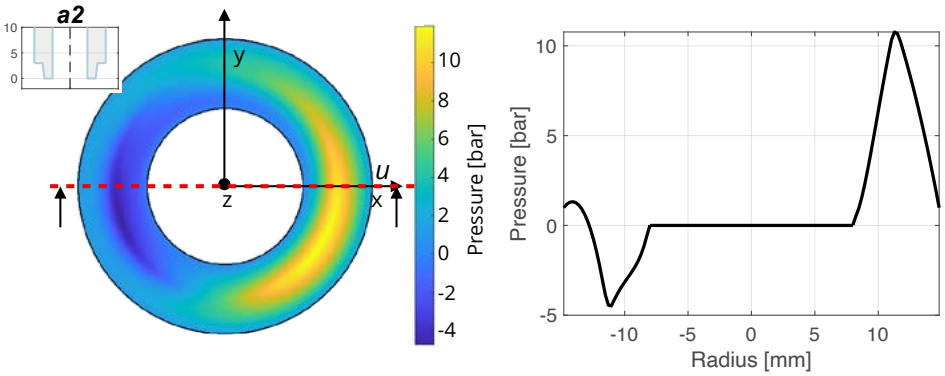

Figure 5.5. Hydrodynamic pressure field at $\phi = 30°$ for design *a2* (left) and hydrodynamic pressure distribution through x-axis (right)

6. DISCUSSION AND OUTLOOK

This study systematically analyzes the influence of meso-structures on the pressure-generating mechanisms in a slipper-swashplate interface, revealing a fundamental trade-off between hydrostatic and hydrodynamic performance. The analytical models and simulation results consistently demonstrate two opposing principles. A reduced gap at the inner side on the sealing land decreases the hydrostatic balance but generates a beneficial positive tilting moment in the direction of motion that promotes hydrodynamic lift. A reduced gap at the outer side of the sealing land by contrast, increases the hydrostatic balance but at the cost of a potentially destabilizing negative tilting moment.

Of particular significance is the observation that the influence of these structures is not constant. The effect on both, hydrostatic balance as well as hydrodynamic lift, becomes more pronounced at smaller gap heights. This non-linear behavior means that the structure's impact is strongest precisely when the slipper operates in critical mixed-friction regimes. This provides a fundamental explanation for the improved reliability of structured surfaces observed in previous experimental work findings provide a clear framework for application-specific design, moving beyond a "one-size-fits-all" approach. For applications dominated by low-speed or start-stop operation where hydrodynamic stability is paramount, a design that guarantees a positive tilting moment is preferable. The associated reduction in hydrostatic balance can be compensated for by adjusting the pocket diameter.

The primary limitation of this analytical study is the neglect of thermo-elastic deformations. As noted in the literature and observed in the FSTI simulations, pressure and temperature-induced deformations can create their own relevant micro-geometry, which may be convex or concave depending on the design and operating point. This deformation can either enhance or counteract the effect of the manufactured structure and has been taken into account for the optimization study in [1].

Beyond the fundamental design trade-offs, the analytical maps presented in this study also provide practical guidance for manufacturing. The contour lines indicate that certain parameters are more tolerant to manufacturing variations than others. For instance, the step position shows relatively flat gradients in the mid-range of the sealing land (approximately 30–60%), meaning that moderate positional deviations have limited impact on the hydrostatic balance. In contrast, the step height exhibits steeper gradients and thus requires tighter manufacturing tolerances to achieve the target performance. This insight is particularly valuable for industrial implementation, as it allows manufacturers to focus precision efforts on the most sensitive parameters while relaxing tolerances where the design is inherently robust.

The findings of this study, particularly the trade-off between hydrostatic balance and hydrodynamic tilting moment, and the non-linear sensitivity of meso-structures at small gap heights, are governed by thin-film lubrication physics and are therefore expected to be transferable to other tribological interfaces in displacement pumps. This includes the valve plate-cylinder block and piston-cylinder bore interfaces in axial piston pumps, as well as the axial thrust bearings in external gear pumps.

ACKNOWLEDGEMENTS

The authors would like to thank Meike Ernst and Andrea Vacca for their foundational methodology on separating hydrostatic and hydrodynamic pressure fields [18], [24]. We are particularly grateful to Meike Ernst for generously providing the original implementation scripts. Access to this sophisticated code greatly facilitated our analysis and saved significant development effort. Special thanks are also extended to Simon Knoll for his diligent work in adapting these scripts for the specific analyses in this study. His development of the 1D analytical model for calculating tilting moments, which formed a significant part of his diploma thesis [23], is also gratefully acknowledged.

Abstract.

Contamination level is a critical indicator in hydraulic systems. The piston/cylinder interface (PCI) serves vital functions in lubrication and load-bearing within axial piston pumps. Under contaminated conditions, PCI performance degrades rapidly, potentially resulting in complete pump failure. A wear model incorporating multiple wear mechanisms at the PCI was developed, along with a predictive method specifically accounting for three-body abrasive wear. An isolated PCI test bench that can accurately control the contamination degree was designed for verification. Both simulation and experimental results demonstrate that contaminated abrasive particles alter wear distribution and significantly accelerate the wear process.

Keywords. Contamination level, piston/cylinder interface, three-body abrasive wear, abrasive particle, wear process prediction.

1. INTRODUCTION

Axial piston machines are widely used as hydraulic power sources in industrial operation systems, offering higher power density in high-pressure applications. The piston/cylinder interface (PCI) is a critical tribological interface in axial piston machines, responsible for lubrication and load support. During operation, this interface undergoes increased wear caused by various mechanisms, including adhesive wear, two-body abrasive wear, and three-body abrasive wear induced by the rolling action of entrained wear particles within the contact interface. These complex wear mechanisms can degrade the oil suction and discharge performance and eventually lead to system failure.

Analyzing the wear process of the piston-cylinder interface (PCI) is crucial for effective predictive maintenance, accurately assessing its service life and reliability, and providing key insights for design optimization aimed at wear resistance and anti-wear properties. During operation, the surface contour of the piston/cylinder pair degenerates over time, accompanied by complex oil film pressure and thickness boundaries. As a result, the wear state of the interface is highly dynamic and coupled with oil film characteristics. Fei Lyu et al. conducted numerical simulations on two-body abrasive and adhesive wear processes of the piston-cylinder interface (PCI) [1,2]. Yu Lin et al. established a dynamic model based on the equivalent load method and proposed a novel wear prediction approach for the PCI by integrating the Archard wear model [3]. Lars Brinkschulte et al. proposed a simulation model, based on the Archard and Fleischer approaches, to predict wear in the piston-cylinder contact [4]. Roman Ivantysyn et al. combined numerical simulation with experimental measurements to analyze the run-in wear behavior of the slipper-swash plate interface in axial piston pumps, demonstrating the stabilization of the lubricating gap and wear profile during early operation [5]. Zunling Du et al. established a mixed lubrication model for the slipper pair within an elasto-hydrodynamic lubrication (EHL) framework, integrating two-body abrasive and Archard adhesive wear theories to formulate an eccentric wear prediction method [6]. Svenja Horn et al. investigated the tribological performance of different slipper designs in axial piston pumps, showing that tailored surface structures can effectively enhance hydrodynamic pressure generation and improve wear condition under mixed lubrication conditions [7]. Xuguang Li et al. proposed a wear prediction model for the cylinder block/valve plate interface, considering the multi-scale evolution of surface topography, including both macroscopic profile wear and microscopic asperity deformation [8].

However, the impact of high oil contamination levels was not considered in these simulations. High contamination levels can cause severe wear on the friction pairs, especially under high-pressure and high-speed PCI conditions, which are more sensitive to contamination levels [9]. Compared with other friction pairs such as the slipper-swash plate interface and the cylinder block/valve plate interface, the PCI shows a stronger dependence of its frictional behavior on clearance design, resulting in increased sensitivity to contaminant particles [10]. The distribution of abrasive particle size and concentration is related to the level of contamination, such as the standard NAS1638 for oil contamination level [11]. Three-body abrasive wear, which is caused by abrasive particles entering the friction pairs, is significantly influenced by the size, hardness, and concentration of the abrasive particles. Therefore, studying three-body abrasive wear of PCI under high contamination levels is crucial for better predicting the wear process.

There is extensive basic research on three-body wear of tribo-pairs. Under high oil pollution conditions, three-body abrasive wear accounts for a large proportion [12], which affects the service life and performance of friction pairs. Different types and sizes of contaminant particles in oil can lead to different wear results of friction pairs [13]. Some studies have explored the effects of materials, textured surfaces, and abrasive particle sizes on the wear process of bearings [14,15]. Nejc Novak et al. studied the effect of oil contaminants on accelerated gear wear [16]. The performance of lubricants and coatings can also affect three-body abrasive wear [17,18]. However, the extreme operating conditions of PCI lead to complex boundary conditions that form wedge-shaped oil films and multiple wear mechanisms acting simultaneously. These studies mainly analyze local specific wear

through wear experiments, and there is no way to directly analyze the distributed lubrication state and multiple complex wear mechanisms in PCI. Therefore, it is necessary to study the coupling of wear and oil film in PCI after considering three-body wear.

This paper proposes a method for predicting wear process in the PCI that incorporates three-body abrasive wear caused by contaminated oil. Section 2 outlines the simulation of lubrication calculation and wear cycle. Section 3 describes the experimental setup for testing a single PCI under different contamination conditions. Section 4 compares simulated and experimental results. Section V concludes the study.

2. WEAR PROCESS SIMULATION

The development of a PCI wear model begins with a dynamic analysis to calculate lubrication boundary conditions such as oil film pressure and thickness. Following this, a distributed wear sub-model performs the wear calculation. The resulting updated contour is then coupled with the oil film, enabling the prediction of the wear process.

2.1. Dynamic Analysis and Lubrication Calculation of PCI

Figure 2.1 shows the general configuration of the axial piston pump, the main external forces applied on the piston are shown in Figure 2.2. The support force of the swash plate F_{SS} and the pressure force F_{P} cause the piston to reciprocate within the cylinder. F_{SSy} is the lateral component of F_{SS}. The friction force of the slipper F_{FS} is generated as the slipper slides on the swash plate. The resultant force of F_{SSy} and F_{FS} is F_{L}. F_{FC} is the friction force between the cylinder and the piston, F_{C} is the centrifugal force of the piston, F_{I} is the inertial force of the piston, and F_G is the gravitational force of the piston. Due to the significant lateral force F_{L}, the piston tilts within the cylinder bore. This radial motion leads to a wedge-shaped oil film being squeezed. When the oil film becomes very thin, solid contact pressure arises. The resulting reaction force that balances the external forces is generated through a combination of the oil film's squeezing effect, dynamic pressure buildup, and solid contact pressure.

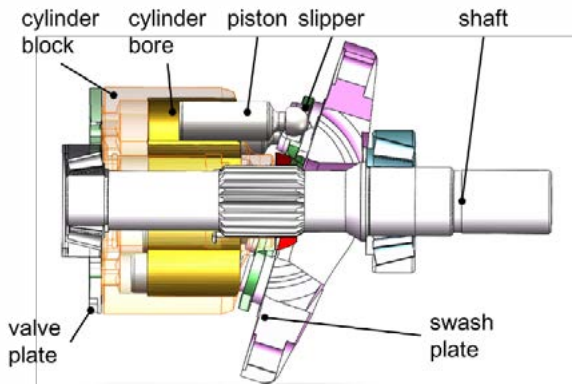

Figure 2.1. Axial piston pump basic structure

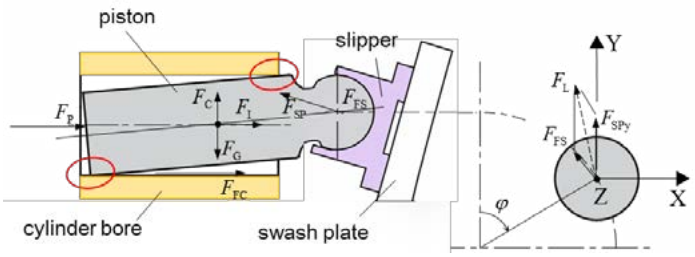

Figure 2.2. PCI dynamic analysis

The oil film thickness between the PCI is related to the posture of the piston in the cylinder bore. When the surface wear occurs, the wear depth $w(l,\theta)$ must be considered to achieve more accurate oil film thickness. Figure 2.3 shows the titling state of the piston in the cylinder bore exaggeratedly. The posture of the piston can be represented by the eccentricities of two sections relative to the cylinder bore. The oil film thickness can be defined as the clearance between the piston and the cylinder bore in the radial direction, and it is given by:

$$h(l,\theta) =$$

$$(D_{\mathrm{C}} - D_{\mathrm{P}})/2 + w(l,\theta) - [e_1 - (e_1 - e_2)l/L_{\mathrm{C}}]cos\theta - [e_3 - (e_3 - e_4)l/L_{\mathrm{C}}]sin\theta \qquad (2.1)$$

where e_1, e_2 and e_3, e_4 are the eccentricities in the X direction and Y direction of the two sections respectively. L_{C} is the length of the cylinder bore, D_{C} and D_{P} are the diameter of the cylinder bore and the piston. The pressure field is divided into $a \times c$ grids and can be expanded to a plane for intuitive as shown in Figure 2.3.

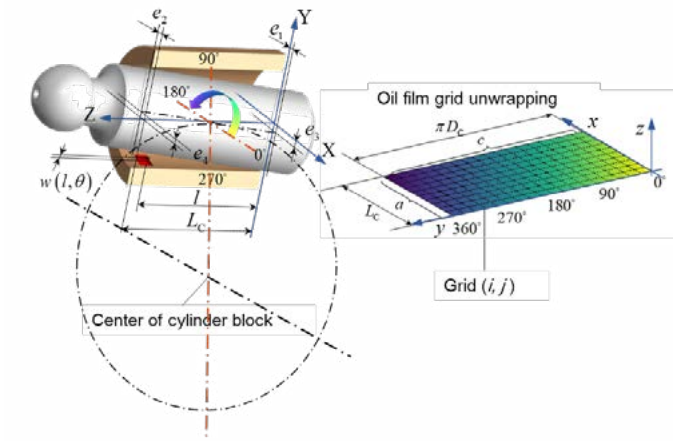

Figure 2.3. Titling state of the piston and expansion of the oil film

The minimum contact oil film thickness hm can be determined by the surface roughness of the friction pair is set to estimate whether the contact occurs. The definition of $h_{\min}$ [19] is shown in Eq. (2.1), where R_{qp} and R_{qc} are the root mean square roughness of the piston and the cylinder bore respectively:

$$h_{\min} = 3\sqrt{{R_{\mathrm{qp}}}^2 + {R_{\mathrm{qc}}}^2} \tag{2.2}$$

The hydrodynamic pressure of the oil film p can be represented by using Reynolds equation:

$$\frac{\partial}{\partial x}\left(\frac{\partial p}{\partial x}\frac{h^3}{\mu}\right) + \frac{\partial}{\partial z}\left(\frac{\partial p}{\partial z}\frac{h^3}{\mu}\right) = 6\left(\omega_{\mathrm{P}}\frac{D_{\mathrm{C}}}{2}\frac{\partial h}{\partial x} + u\frac{\partial h}{\partial z} + 2\frac{\partial h}{\partial t}\right) \tag{2.3}$$

where μ denotes the oil viscosity, and ω_{P} is the spinning speed of piston, u is the sliding velocity of the piston surface. To ensure numerical stability, the oil film thickness h is set to $h_{\min}$ when the calculated result of Eq. (2.2) is less than $h_{\min}$. In Eq. (2.3), the first two terms on the right-hand side represent the dynamic pressure effect generated by the wedge-shaped oil film, while the third term corresponds to the squeezing effect due to micro-scale radial motion of the piston. The Reynolds equation is discretized using the finite volume method, and the Cyclic Tridiagonal Matrix Algorithm is employed to solve the resulting pressure field of the PCI.

The pressure distribution is obtained by solving the discretized Reynolds equation, thereby determining the oil film reaction force acting on the piston. The Newton-Raphson method is then applied to iteratively solve the piston force balance equation.

In Figure 2.4, k is the rotated angle of the cylinder with the resolution of 1°. $\Delta\dot{e}$ is the variation of Δe in each iteration, adjusted automatically via the Newton-Raphson method. P, P_{cs} refers to dynamic oil film pressure and contact pressure between piston and cylinder block. F_{out}, F_{out}, F_{cs} refers to external force, dynamic oil film force and contact force between piston and cylinder block. A convergence threshold $F_{\mathrm{b}} = 0.1$ N is set for the force balance residual. The Newton-Raphson iteration terminates when the condition $\|f(\dot{e}_k)\| \leq F_{\mathrm{b}}$ is satisfied. The simulation is considered converged and lubrication parameters are output when periodic phenomenon is exhibited.

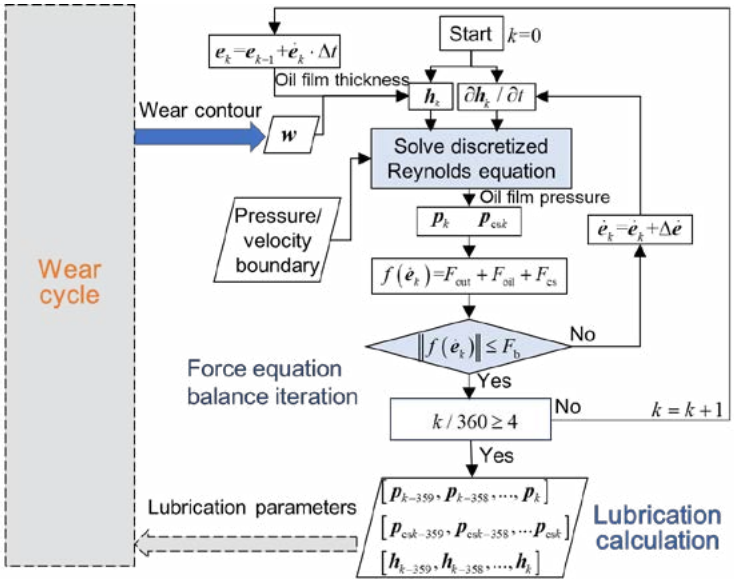

Figure 2.4. Schematic diagram of lubrication calculation

2.2. Wear Cycle

As shown in Fig. 2.5, inputs including the oil film thickness $h(i,j)$, pressure $p(i,j)$, and solid contact pressure $p_{cs}(i,j)$ field for each grid cell from the lubrication calculation model, as well as the contaminant particles size distribution d_a measured in the contaminated oil, are introduced into the wear cycle model. Depending on the local oil film thickness boundaries, each computational grid may undergo different wear mechanisms-including adhesive wear, two-body wear, and three-body abrasive wear-leading to distinct wear depths. And the wear contour is linearly superimposed with the revolutions until the wear depth exceeds a threshold value. Once the threshold is exceeded, the wear curve is fed into the oil film model to update the contours of both the piston and cylinder. The updated wear curve is also output, and the corresponding operating time can be calculated from the pump revolutions and speed. This completes the simulation of the time-varying wear process of PCI.

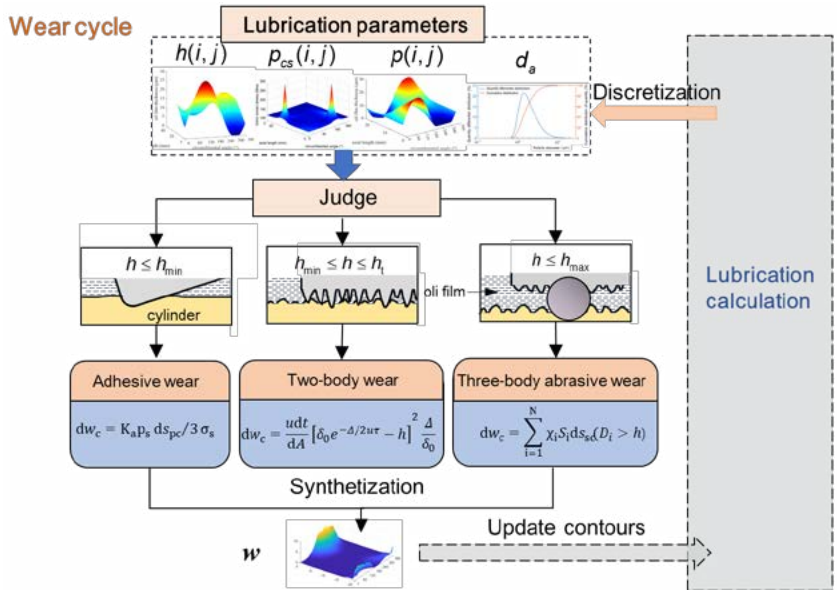

Figure 2.5. Wear cycle model

When the oil film cannot provide sufficient counterforce to balance the external load, the piston and cylinder are squeezed to slide against each other. Under high solid contact pressure, rupture of the oil film occurs, resulting in adhesive wear. The wear depth of the cylinder bore can be calculated using the equation below.

$$\begin{cases} 0 < h < h_{\min} \\ \mathrm{d}w = K_{\mathrm{a}} p_{\mathrm{s}} d_{\mathrm{pc}} / 3\sigma_{\mathrm{S}} \end{cases} \tag{2.4}$$

where d_{pc} is the displacement of the piston relative to the cylinder, σ_{S} is the compressive yield limit, K_{a} is the wear coefficient, p_{s} is the solid contact pressure.

When the oil film thickness is less than h_{t} which characterizes the height of the roughness peak after viscoelastic deformation but remains comparatively larger than the critical thickness $h_{\min}$ for adhesive wear, two-body wear may initiate. Specifically, two-

body wear occurs when the deformed roughness peak exceeds the oil film thickness. The wear depth of the cylinder bore is shown below [27].

$$\begin{cases} h_{\min} < h < h_{\mathrm{t}} = \delta_0 \mathrm{e}^{-\Delta/2u\tau} \\ \mathrm{d}w_{\mathrm{c}} = \frac{u\mathrm{d}t}{\mathrm{d}A}[\delta_0 \mathrm{e}^{-\frac{\Delta}{2u\tau}} - h]\frac{\Delta}{\delta_0} \end{cases} \tag{2.5}$$

where t is the sliding time, and A is the wear area which is equal to the grid area of oil film thickness field, δ_0 is the height of roughness peak, Δ is the wavelength of roughness peak, τ is the delay time of the piston material.

As shown in the Figure 2.6, the real-time oil film contour formed by the reciprocating motion of the piston in the cylinder (as described in Section 2.1) exhibits a wedge-shaped oil film. The contamination level is used to determine the volume concentration within a particle size range. Laser analysis of the contaminated oil sample reveals the proportion of specific particle sizes, yielding the size and concentration distribution of the abrasive particles. When the particle size is smaller than the maximum oil film thickness, there is a certain probability χ_i that the particle will enter the PCI and cause wear [20]. Because the fluid is considered a homogeneous suspension, the probability of a particle entering the interface is assumed to be proportional to the volume of oil in the gap and the volume concentration of particles of different sizes. The influence of abrasive particles on adhesive wear extension is neglected in the simulation [21]. Wear primarily occurs in areas where the particle diameter exceeds the local oil film thickness, resulting in indentation and material removal [22]. In areas where the particle diameter is smaller than the oil film thickness, almost no wear occurs.

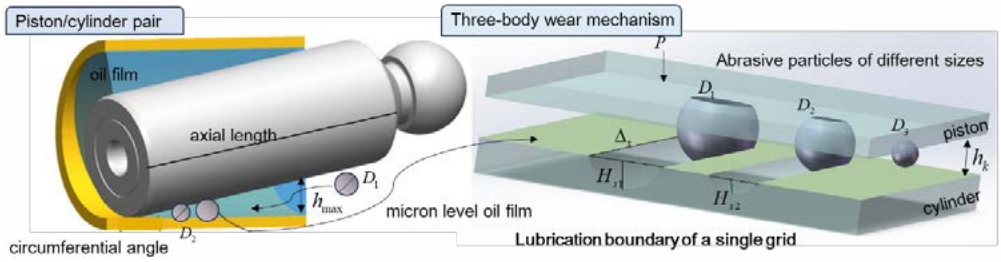

Figure 2.6. PCI three-body wear mechanism

Assuming the abrasive particles are spherical, for each simulation grid cell, particles of different sizes embedded into the cylinder surface will induce wear depths such as H_{S2} [23], which are inversely proportional to the hardness of both the cylinder and piston surfaces. When the particle diameter $D_i > h$, the wear depth on the cylinder can be calculated using Eq. (2.6). Since the size of the computational grid cell is much larger than the abrasive particle diameter, particles of different diameters $(D_1, D_2, \cdots)$ will cause wear in grid cells where the oil film thickness is less than the particle diameter. The cumulative wear volume per unit two-body distance is computed by summing the contributions from particles of various diameters. However, the displacement caused by abrasive particles on the cylinder surface is different from adhesive wear. According to the empirical formula that surface friction is inversely proportional to hardness [24], the sliding distance d_{sc} of the abrasive particles relative to the cylinder surface is calculated by torque balance and rolling kinematics, as shown in Eq. (2.7) and Figure 2.6(b). It is worth noting that different test

conditions can produce two-body grooving or three-body rolling abrasive wear mechanisms [25]. For high-hardness abrasives such as quartz sand, when $D/h > 2$, particles may be embedded in the softer cylinder surface [26]. The sliding distance of the embedded particles relative to the piston surface becomes d_{pc}, which significantly increases wear and causes severe directional grooving on the harder surface. However, in this study, stainless steel powder with a hardness comparable to that of the cylinder material was used. The possibility of these particles adhering to the cylinder surface and causing scratches is very low.

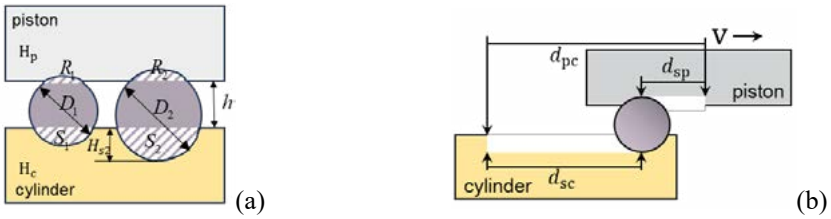

Figure 2.7. Three-body abrasive model

$$H_{S2} = \frac{\mathrm{H_p}}{\mathrm{H_p}+\mathrm{H_c}}(D_i - h) \tag{2.6}$$

$$d_{\mathrm{sc}} = \frac{\mathrm{H_p}}{\mathrm{H_p}+\mathrm{H_c}} d_{\mathrm{pc}} \tag{2.7}$$

Where $\mathrm{H_C}$ and $\mathrm{H_P}$ are the hardness of the cylinder and piston, d_{pc}, d_{sc} and d_{sp} are the sliding distance relatively in Figure 2.7(b).

The wear volume of the cylinder and piston surface meshes is calculated by Eq. (2.8). Given that the calculated three-body wear volume of the piston is approximately 20% of the cylinder's and considering the piston's spinning motion (which promotes uniform axial wear distribution), the experimental analysis does not focus on the piston's wear contour. To optimize wear calculations, the wear contour is linearly superimposed with the revolutions until the wear depth exceeds a threshold value. Once the threshold is exceeded, the wear curve is fed into the oil film model to update the contours of both the piston and cylinder. The updated wear curve is also output, and the corresponding operating time can be calculated from the pump revolutions and speed. This completes the simulation of the time-varying wear process of PCI.

$$\begin{cases} \mathrm{d}w_{\mathrm{c}} = \sum_{i=1}^{\mathrm{N}} \chi_i S_i ds_{\mathrm{sc}}(D_i > h) \\ \mathrm{d}w_{\mathrm{p}} = \sum_{i=1}^{\mathrm{N}} \chi_i R_i ds_{\mathrm{sp}}(D_i > h) \end{cases} \tag{2.8}$$

Where $\mathrm{d}w_{\mathrm{c}}$ and $\mathrm{d}w_{\mathrm{p}}$ are the displacement of the abrasive particles relative to the cylinder and piston. χ_i is the probability of different abrasive particles participating in wear in this grid. S_i and R_i are the areas of the semicircular wear regions in Figure 2.7(a). D_i represents the set of abrasive particle diameters that can cause wear on the grid (i, j) with oil film thickness h.

3. EXPERIMENTAL INVESTIGATION

The isolated PCI test bench that can control the contamination level is designed to carry out the control test under NAS1638 8 and 12. The following is the detailed test method.

3.1. Test Bench Design

To experimentally validate the three-body abrasive wear simulation results of PCI across varying contamination levels, an isolated PCI test bench was built, capable of precisely and directly controlling the contamination levels in the PCI and isolating it from the influence of other friction pairs. In Figure 3.1, add external contamination and detect the contamination level of PCI through an online particle counter (9). Then switch the filter (2,12) through the directional valve (1,13) to control contamination level, when the contamination level gradually increases and exceeds the rated value during operation. The overflow valve (6) maintains the high-pressure input of PCI, and the driving swash plate speed is controlled by the driver (17). Actual picture of the isolated PCI test bench is shown in Figure 3.2.

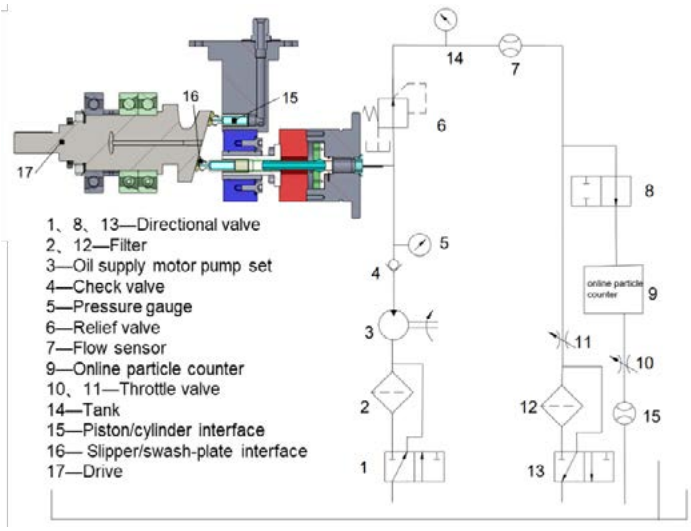

Figure 3.1. Hydraulic schematic diagram of the isolated PCI test bench

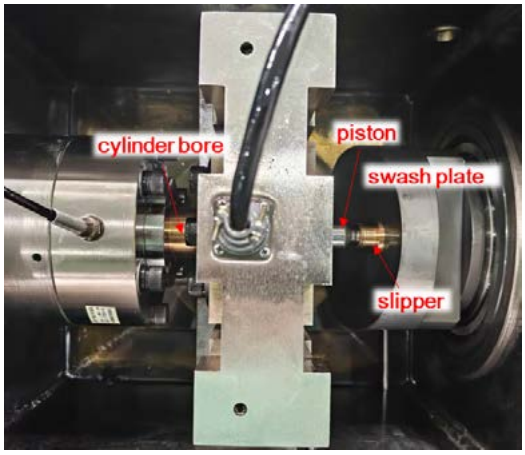

Figure 3.2. Physical photo of the isolated PCI test bench

3.2. Test Samples and Abrasive Particles Preparation

In Figure 3.3, the piston sample (a) and cylinder sample (b) used in this test are made of 38CrMoAl and manganese brass (CuZn37Mn3Al2PbSi) respectively, with a surface roughness of Ra 0.2μm after processing. The red mark is the effective length in contact with the piston.

(a) (b)

Figure 3.3. Test samples

During the test run, 300 mL of oil with additional contaminated abrasive particles was taken, which was the same oil as that used in the PCI operating environment. The abrasive particles added to the oil are mixed with a mass ratio of 30% for <3 μm, 40% for 5 μm, and 30% for 6.5 μm to be closer to the actual contaminated oil abrasive particle distribution. An ultrasonic crusher was employed to ensure optimal dispersion of the particles. Subsequently, the contaminated oil sample underwent wet particle size analysis utilizing a laser particle sizer (Model LS-609, Zhuhai OMEC Instruments Co., Ltd., China). The particle size distribution measurement results are shown in Figure 3.4, and the proportion of each particle size can be obtained. Based on the aforementioned data, the differential percentage by count for specific particle size ranges (e.g., 5-15 μm, corresponding to the first interval of contamination level) can be further derived, as shown in Figure 3.5. Thus, based on the concentration of wear particles within the measured interval range (5-15 μm) detected by the contamination sensor, the proportion of each particle size required to participate in the wear cycle (Figure 2.5) is obtained, and the range is 0-30 μm.

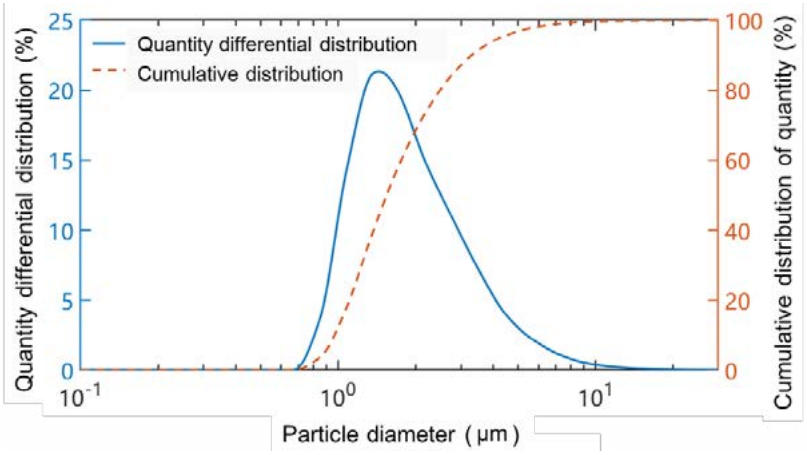

Figure 3.4. Particle size distribution

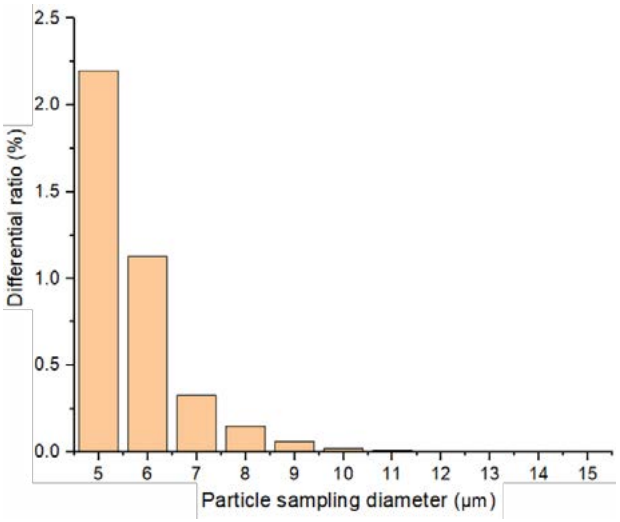

Figure 3.5. Different proportions of sampled abrasive particles

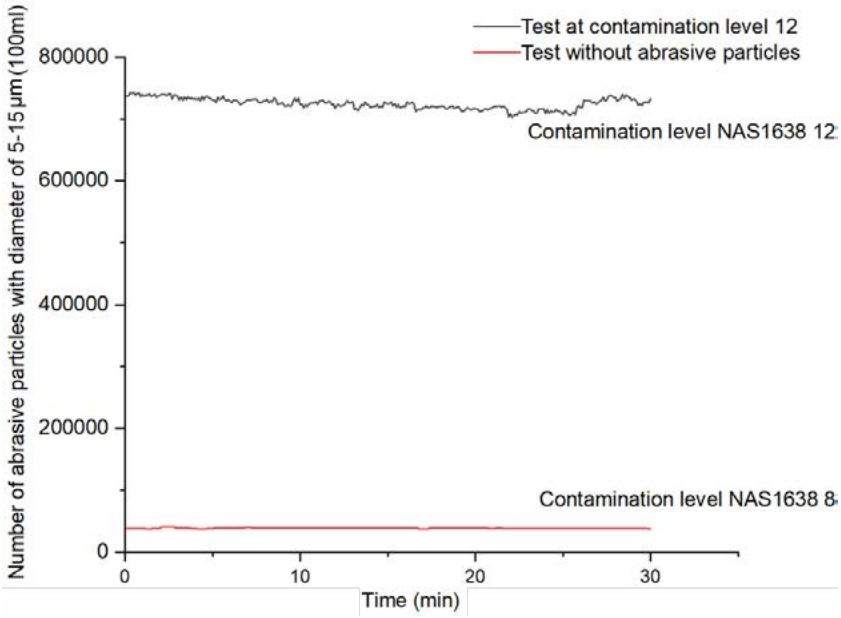
3.3. Experimental Procedures

The operating conditions were maintained at a pressure of 14 MPa and a rotational speed of 1500 rpm. A predetermined concentration of ultrasonically dispersed stainless steel contaminant particles was introduced into the 50 L oil tank. The oil supply motor pump was subsequently activated. After the hydraulic circuit and piston chamber were fully primed with oil, the system pressure was elevated to 14 MPa, corresponding to the preset cracking pressure of the relief valve. A minor volume of excess oil was discharged through a particle counter sensor integrated at the relief valve. Contaminant particles were supplemented in real time based on continuous monitoring until the oil contamination level stabilized. The drive motor was then engaged, and the rotational speed was increased to 1500 rpm to initiate the test. Whenever the contamination level exceeded the predetermined threshold, diversion filtration was activated to prevent particulate accumulation and clogging. Upon completion of the test, a recirculating filtration process was carried out for system flushing and cleaning.

The test was divided into two groups: one with clean oil without added particles, and the other with contaminated oil with a contamination level of 12, containing stainless steel abrasive particles. The two groups were run for 0.5 hours, 1.5 hours, 3 hours, and 5.5 hours, respectively. Stop at the set time, remove the sample and measure the inside of the cylinder using a three-coordinate instrument (Leitz PMM-C). The wear amount is calculated by subtracting the fitted contour before and after wear, thereby obtaining the wear process curve and contour change.

By monitoring the oil contamination level in real time with a particle counter sensor, the curve of the change in the number and volume of abrasive particles (5-15 μm) in the test with abrasive particles is shown in Fig. 14. It can be seen that the contamination level fluctuates within the range of 12. The small fluctuations observed in the experiment indicate the stability and reliability of the contamination control.



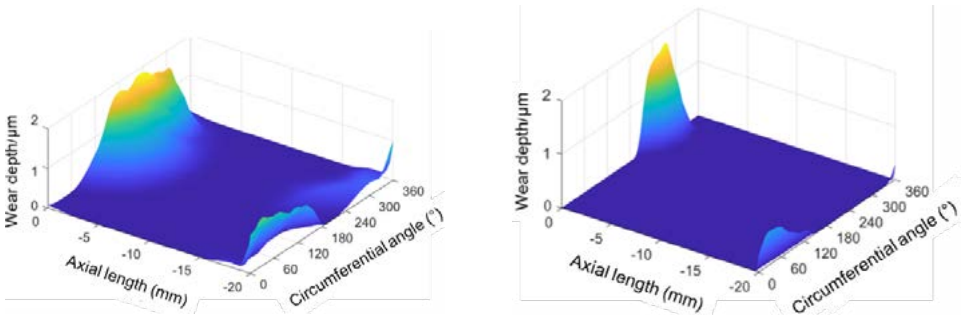


Figure 3.6 Fluctuations in contamination levels during the test

4. RESULTS AND ANALYSIS

Figures 4.2(a) and (b) present the simulated wear contours of the cylinder surface with and without three-body abrasive wear, respectively. The three-body wear model in Figure 4.2(a) reveals a wear distribution extending 90°-360° around the cylinder port, with a depth of 0-7μm. Notably, severe wear is concentrated between 180° and 300° near the port. Additionally, moderate wear extends across the cylinder bottom from 0°-180° and 240°-360°. In contrast, the model without three-body wear in Figure 4.2(b) exhibits a significantly reduced wear zone, confined to 135°-340° at the port with a depth of 0-2.5μm and a distinct wear peak. The area of severe wear is limited, with only minor wear observed at the cylinder bottom.

(a) with three-body abrasive wear (b) without three-body abrasive wear

Figure 4.2. Simulated wear contour of the cylinder surface

Figure 4.4 shows the contour of cylinder after wear test at contamination level 12, while Figure 4.3 shows the contour of cylinder after wear without added abrasive particles. The wear contour is calculated by subtracting the run time after 0.5 hours from the wear time after 5.5 hours.

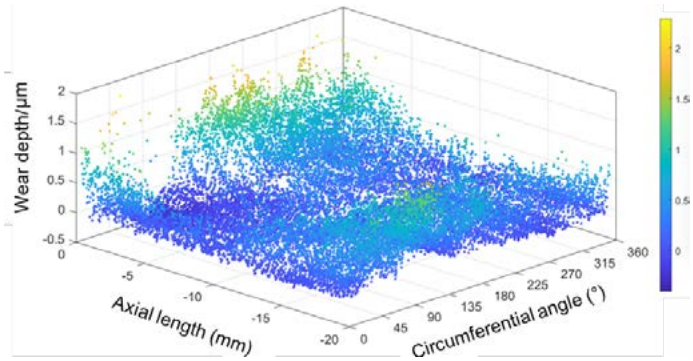

Figure 4.3. Contour of cylinder after wear test at contamination level 12

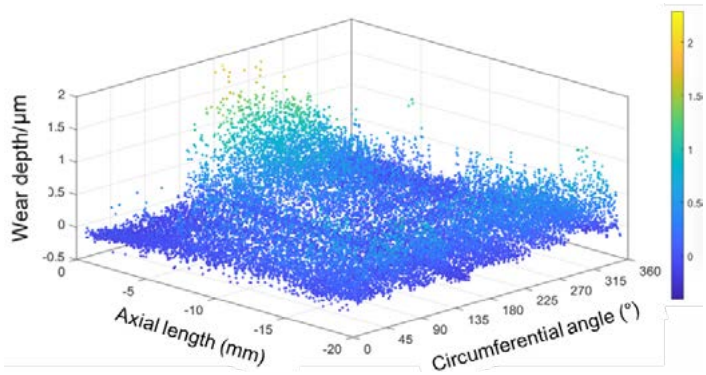

Figure 4.4. Contour of cylinder after wear without abrasive particles

Comparing the simulation results above, Figure 4.3 shows a similar wear range distribution to (a), with wear distribution at 90°-360° and 0-7μm in the cylinder port area, a larger wear distribution at 135°-290°, and a corresponding wear distribution at the bottom of the cylinder, only within a reasonable range of deviation. However, it is somewhat different from Figure 4.2(b), indicating that when the contamination level is high, the model including three-body wear is more accurate for simulation and has a more reasonable wear range.

Figure 4.4 shows the wear contour under the condition of no contamination. The distribution range of the larger wear is smaller, and the wear distribution is similar to the results of the model without the three-body abrasive particle addition, indicating that the wear process can be simulated without the three-body wear model under the condition of no contamination.

5. CONCLUSION

This paper introduces a predictive method for PCI wear that includes three-body abrasive wear due to oil contamination. Comparisons between simulated and experimental surface contours after operation under normal and highly contaminated (NAS1638 12) conditions reveal that, although the maximum wear depth is not significantly affected in the initial hours, the severe wear area and the overall worn area are greatly expanded. This accelerated wear process can deteriorate lubrication, potentially leading to premature failure. The model demonstrates a superior ability to predict both the wear extent and volume under high contamination, highlighting its significance for studying tribo-pairs in contaminated environments.

Authors affiliation, komsan.ng@rmutsb.ac.th

Abstract.

The aim of this research is to study the behavior of and controlling hydraulic oil temperature in bridge circuit with through path bent axis piston motor as load in the test bench. The testing of hydraulic motor efficiency was conducted in accordance with the test circuit for motor unit of ISO 4409. Measurement of inlet flow rate, drainage flow rate, output torque and test fluid temperature were all taken at full rotational speed range of the motor. The load of this circuit used for testing is the hydraulic bent axis motor 160 cc/rev connected with torque sensor 0-10 kNm. The testing of the hydraulic motor started when the load was driven and the piston moved hydraulic oil to flow and pass through the bridge circuit. The valves were checked and circulated into circuit by the proportional pressure control valve. The result showed that a high hydraulic oil flow rate of 160 l/min and high pressure of 150 bar rapidly increased the temperature up to 80 degrees Celsius. The hydraulic oil circulated in this circuit was later separated from the box valve and put into an oil cooler to reduce the temperature. Increasing the oil temperature depends significantly on the variability of the rate of oil flow and pressure. The fan at the cooler driven by a high-speed low torque hydraulic motor was controlled by a proportional relief valve and decentralized controller. The temperature of the hydraulic oil during test should be 33- 60 degrees Celsius while the speed of the hydraulic motor is regulated by input signal from sensor sent to the controller. It was found that the hydraulic bent axis motor can be used to function as load for hydraulic motor testing because the cooling efficiency of the oil greatly regulates the temperature, reduces the degree of the hydraulic bent axis motor wearing and instead increases the lifespan of the oil.

Keywords. Hydraulic oil temperature, bridge circuit, heating generation, charge system, flushing, cooling.

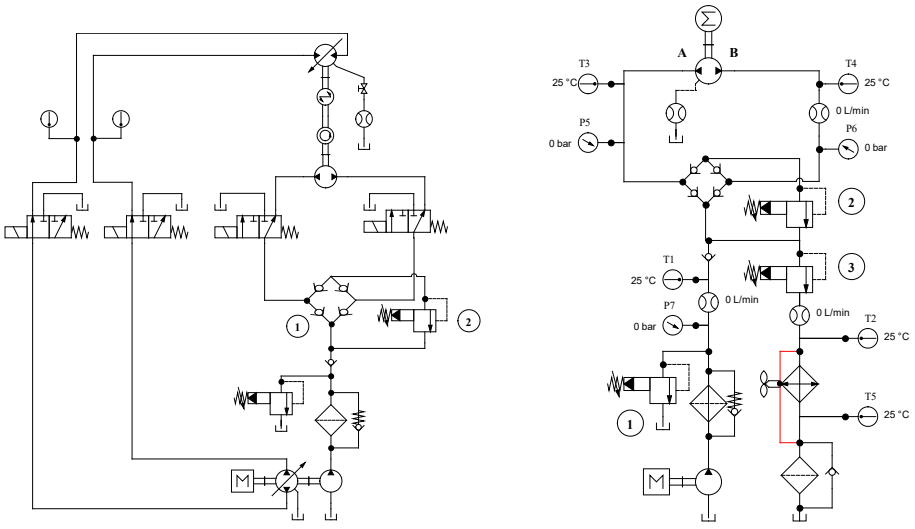
1.INTRODUCTION

Hydraulic motor has been widely used for driving agriculture machinery including rice harvester sugar cane harvester and construction machinery. The transmission of these machinery is purely hydrostatic consisting of an open and close circuit. The repaired hydraulic motor should have high efficiency before being used. The test rig machine built

All Open Access articles are peer-reviewed, distributed under the Creative Commons Attribution-Non Commercial 4.0 International

up from outsource can be operated for efficiency evaluating both hydraulic motor and hydraulic pump using the same driving power and reservoir. With regards to hydraulic pump testing, the system is driven by a close-loop three phase electric motor of 75 kW and an electric displacement control (EDC) close-loop pump of 75 cc/rev. The power drive of this machine can be used in testing hydraulic motor too Figure 1. The size of the reservoir is 400 litres. When testing the hydraulic motor, the hydraulic motor is installed in the test rig machine with its gear shaft connected with another gear shaft of the bent axis motor by chain coupling. When testing the dynamic efficiency, the repaired hydraulic motor has to rotate the load which is the bent axis hydraulic motor A2FM of 160 cc/rev. When it was driven it tend to be a pump as well as a load for testing. At port A and B of the pump, the hydraulic oil circulates through within the hydraulic bridge circuit (Graetz circuit) which consist of four cartridge check valves, proportional pressure relief valve (PRV) and charging system as seen in Figure 2.

At the start of testing the hydraulic motor, hydraulic oil ISO VG68 circulated from pump A2FM to block valve or hydraulic bridge circuit. There are two lines; the high pressure line (HPL) and low pressure line (LPL) with different pressure known as delta pressure (Δp). This circuit is similar to hydrostatic transmission whose major elements are pump (A2FM), motor (hydraulic bridge circuit or graetz circuit) and charge system.



Four check valves together with proportional pressure relief valve are mounted in the block valve, as seen in Figure 2. There are two ports A and B and another port connected to the charge pump and proportional pressure relief valve. This can control the pressure in charge line which corresponds with the flow and circulation of hydraulic oil or speed of load pump. The flow rate of hydraulic oil depends on the speed of rotation of the pump load. When the speed of pump load rotation increases, the flow rate of hydraulic oil also increases, leading to high pressure at proportional pressure relief valve. Also, when the speed of pump load rotation decreases, the flow rate of hydraulic oil decreases, but there will be no corresponding effect on the pressure.

When the loop-line flow rate is high, a pressure drop develops across the pressure control valve, generating a pressure differential and causing hydraulic losses that are converted into heat. The load on the hydraulic motor being tested is increased by increasing the pressure at the proportional pressure control valve. In hydraulic motor efficiency testing, the presence of pressure differentials and high flow rates leads to energy losses that result in elevated heat generation. The hydraulic oil temperature during volumetric efficiency testing of hydraulic pumps and motors should be maintained within the range of 33–60 °C, in accordance with ISO 4409. The hydraulic oil temperature in the low-pressure line during hydraulic motor efficiency testing exceeds 80 °C. This leads to the deterioration of the anti-wear additive performance. As illustrated in the original circuit in Figure 2, the hydraulic oil in the test circuit undergoes no cooling or filtration prior to returning to the reservoir, and only a limited amount returns via the load pump drain line. The reduction of hydraulic oil temperature and the filtration of hydraulic oil are improvements that should be implemented in this test rig. As discussed previously, the load-generating circuit in this efficiency test exhibits characteristics of a closed-loop system and can be improved by incorporating a flushing line to control hydraulic oil temperature and contamination. The improvement analysis of this circuit will be performed by treating it as a closed-loop system, with consideration given to the high-pressure line, low-pressure line, charge pump

pressure and flow, flushing pressure and flow, and the cooling system. In the hydraulic bridge (Graetz) circuit, the flow through the pressure relief valve is unidirectional, and an additional flushing line on the low-pressure side should be connected downstream of the pressure relief valve. The criteria for adjusting the pressure and flow rate of the charge pump, as well as the flushing and cooling flows, are determined based on closed-loop circuit theory. Another proportional pressure relief valve dedicated to flushing is added to the low-pressure line downstream of the load-control proportional pressure relief valve, in order to control the pressure to match the charge pump pressure. Hydraulic oil temperature control within the specified range is achieved using a LabJack T7 Pro, which is employed to monitor key variables such as charge pressure, charge flow, flushing flow, and cooling temperature, and has been found to operate effectively.

Figure 1. Cross-sectional view of the repaired hydraulic motor installed in the test rig and connected as a load motor.

(a) (b)

Figure 2. (a) The original hydraulic circuit used in the hydraulic motor test rig (b) Modified hydraulic circuit incorporating flushing and cooling for the hydraulic motor test rig.

2. The temperature behaviours of the hydraulic oil in the load circuit used for hydraulic motor testing

In the investigation of temperature behaviours in the load-simulation system for a hydraulic motor, the system is treated as an integrated system comprising an A2FM hydraulic motor, a hydraulic bridge circuit, and a charge system. Measurements and data logging are carried out using the HMG 4000 data recorder and HYDAC pressure sensors and temperature sensor. Following testing conducted under ISO 4409 conditions to gain an understanding of temperature behaviours, improvements were then made to the circuit and control system and the hydraulic oil used in the test is ISO VG 68. To study the temperature behaviour caused by heat generation under variable pressure with constant flow rate and variable flow rate with constant pressure, the hydraulic system was operated in the configuration shown in Figure2. (a)and(b). The experimental results indicate that the thermal behaviour is governed by the fundamental energy balance equation

$$mc_p \frac{dT}{dt} = Q_{gen} - Q_{loss} \qquad (2.1)$$

During the experiments shown in Figures 4 and 5, the hydraulic system operated without active cooling, and the oil exchange with the reservoir was limited. Under these conditions, heat dissipation to the surroundings was relatively small, particularly during each constant operating stage. Therefore, the heat loss term Q_{loss} can be considered negligible compared to the generated heat, and the equation can be approximated

$$mc_p \frac{dT}{dt} \approx Q_{gen} \qquad (2.2)$$

The heat generation in a hydraulic system resulting from pressure losses can be expressed as follows

$$Q_{gen} = \Delta pQ \qquad (2.3)$$

The equation is applied to assess heat generation due to pressure losses arising from pump motor losses, throttling valve losses, and flushing relief losses that is employed to calculate the heat generation within the load-simulation loop of the test rig.

2.1 Hydraulic motor testing under no-load conditions.

In this test, a variable-displacement motor is employed as the load driver. Operating at 700 rpm, it produces a circuit flow rate of 130 L/min, with pressures of 27 bar in the high-pressure line and 6.6 bar in the low-pressure line, resulting in a pressure differential of approximately 20 bar. In the no-load test, the temperature rises linearly with a constant slope from 28 °C to 93.2 °C within 10 minutes at the low-pressure line, while the temperature at the high-pressure line reaches 90.7 °C, yielding a temperature difference of 2.5 °C. Although no load pressure is applied, the temperature increases to 93 °C due to the pressure differential between the inlet and outlet of the hydraulic bridge circuit, where the

associated losses are converted into heat. Heat generation results from energy losses caused by flow resistance in drilled orifices, pressure drops across two check valves and the pressure relief valve, as well as valve throttling.

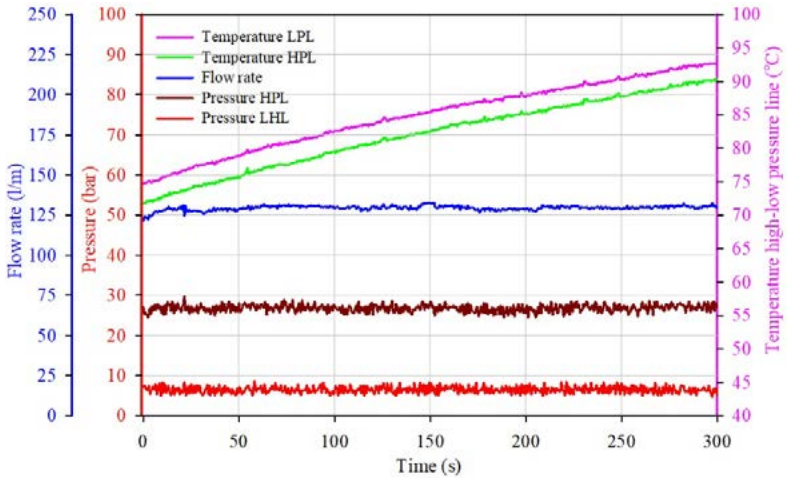


Figure 3. Oil temperature in the high-pressure and low-pressure lines at constant pressure and constant flow rate.

2.2 Hydraulic motor testing under constant pressure with increasing flow rate.

Hydraulic motor testing is performed under multiple operating conditions depending on the motor type and size, since different displacements result in different load capacities. Accordingly, testing is carried out under high-pressure, low-flow-rate and low-pressure, high-flow-rate conditions, and the temperature response due to heat generation under non-cooled conditions is presented in Figure 4. In the initial stage, the load condition was simulated at an operating pressure of 104 bar for 94 s. The pressure differential between the high-pressure and low-pressure lines was 86 bar, and the flow rate was 26 L/min, yielding a heat generation rate of 3.734 kW. In the subsequent stage, under a comparable operating pressure of 109 bar for 64 s, the pressure differential was 89 bar. With the flow rate increased to 42 L/min, the resulting heat generation was 6.242 kW. In the final stage of the graph, under an operating pressure of 101 bar for 10 s, a pressure differential of 81 bar and an increased flow rate of 62 L/min result in a heat generation of 8.386 kW. Despite the short duration, the high heat generation leads to a linear temperature rise with a pronounced slope. Although the pressure differential remains at a comparable level across the three stages, the increase in flow rate leads to a significant rise in heat generation from 3.73 to 8.39 kW, resulting in a linear temperature increase with a steeper slope, even over a short operating duration.

2.3 Hydraulic motor testing under constant flow rate with increasing pressure.

In this test, the initial flow rate was set to 47 L/min, while the hydraulic oil temperature was maintained in the range of 43.5–45.5 °C.

Table 2.1 Heat generation under constant pressure with increasing flow rate.

Stage	Δp HPL–LPL (bar)	Flow (L/min)	Time (s)	Heat generation (kW)
1	86	26	94	3.73
2	89	42	64	6.24
3	81	62	10	8.39

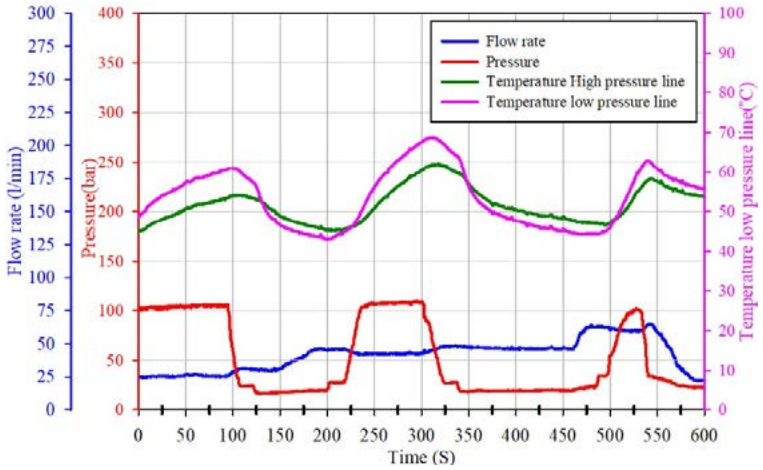

Figure 4. Oil temperature in the high-pressure and low-pressure lines under constant pressure with increasing flow rate.

During the first stage, the simulated load pressure was increased to 53.6 bar for 53 s, producing a pressure differential of 34.86 bar between the high-pressure and low-pressure lines and a corresponding heat generation of 2.74 kW. In the subsequent stage, the simulated load pressure was increased to 79 bar for 87 s. This produced a pressure differential of 61.3 bar between the high-pressure and low-pressure lines, resulting in a heat generation of 4.483 kW. In the final pressure stage, the simulated load pressure was increased to 105.5 bar for 88 s, producing a pressure differential of 88.4 bar between the high-pressure and low-pressure lines and a corresponding heat generation of 6.274 kW. During this period, the hydraulic oil temperature rose continuously to the range of 67.3–74.9 °C, as shown in Figure 5.

Table 2.2 Heat generate constant flow rate with varying pressure.

Stage	Δp HPL–LPL (bar)	Flow (L/min)	Time (s)	Heat generation (kW)
1	34.86	44.4	53	2.58
2	61.3	43.8	87	4.48
3	88.4	42.5	88	6.27

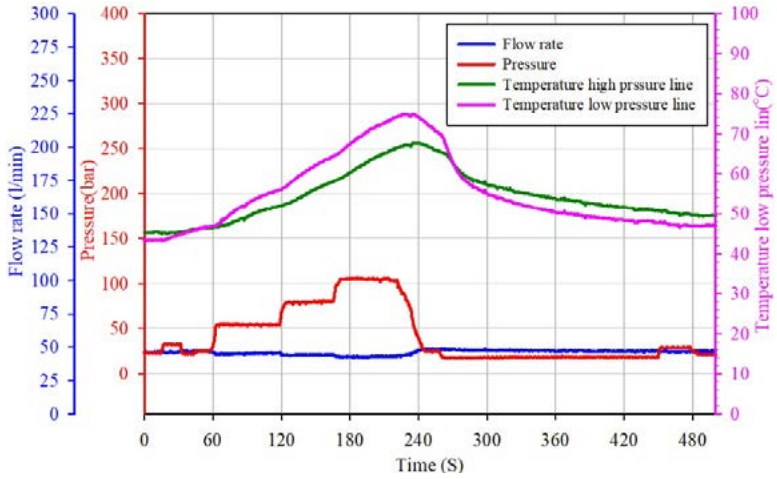

Figure 5. Oil temperature in the high-pressure and low-pressure lines at constant flow rate with varying pressure.

To study the temperature behaviour caused by heat generation under vary pressure with constant flow rate and vary flow rate with constant pressure, the hydraulic system was operated in the configuration shown in Figure 2(a). The experimental results indicate that the thermal behaviour is governed by the fundamental energy balance equation

2.4 Hydraulic motor testing under constant flow rate with increasing pressure.

As described in the preceding paragraph, the operating principle of the load-simulation circuit used for hydraulic motor testing is analogous to that of a hydrostatic closed-loop drive. The main distinction is that the hydraulic motor test circuit lacks a flushing system, whose function is to extract a portion of the high-temperature oil for cooling and filtration prior to its return to the reservoir or reintroduction into the loop. In response to the excessive hydraulic oil temperature in the loop circuit during testing, and based on the heat generation analysis revealing significant thermal generation over short operating durations, the test circuit was modified by incorporating a proportional pressure relief valve, an air cooler, a filtration unit, and a control system, as illustrated in Figure 2(b). The hydraulic oil from this section is returned to the reservoir**.** The modified circuit is installed downstream of the load proportional pressure relief valve on the low-pressure line of the loop.The parameter tuning is carried out in accordance with closed-loop circuit principles. Based on the original circuit configuration, the line equipped with proportional pressure relief valve No. 1 functions as the charge line supplying hydraulic oil to the loop. The charged oil flow rate is governed by the pressure setting of valve No. 1, whereas the drain flow from the load is negligible relative to the main loop flow. As a result, the charge pump is unable to supply sufficient oil to the loop. In accordance with closed-loop circuit theory, the charge flow rate should generally be maintained at approximately 20–30% of the main loop flow. This constitutes an additional cause of the heat generation observed in the previous graph.

To examine the charge flow supplied to the main loop, a test was performed as illustrated in Figure 6. Under a main loop flow rate of 28 L/min and a load pressure of 200 bar applied for 31 s, with the oil temperature rising from 33 °C to 57.3 °C and a charge

pressure of 17 bar, the charge flow into the loop was limited to 0.89 L/min, representing only 4.45% of the main loop flow. Based on the test results, once the operating time exceeds 150 s, and at a charge pressure of 17 bar, the charge pump supplies hydraulic oil to the main loop at a flow rate of 7.25 L/min. This leads to a convergence of the cooling temperatures in the high-pressure and low-pressure lines, which is advantageous because it reduces thermal accumulation within the system.

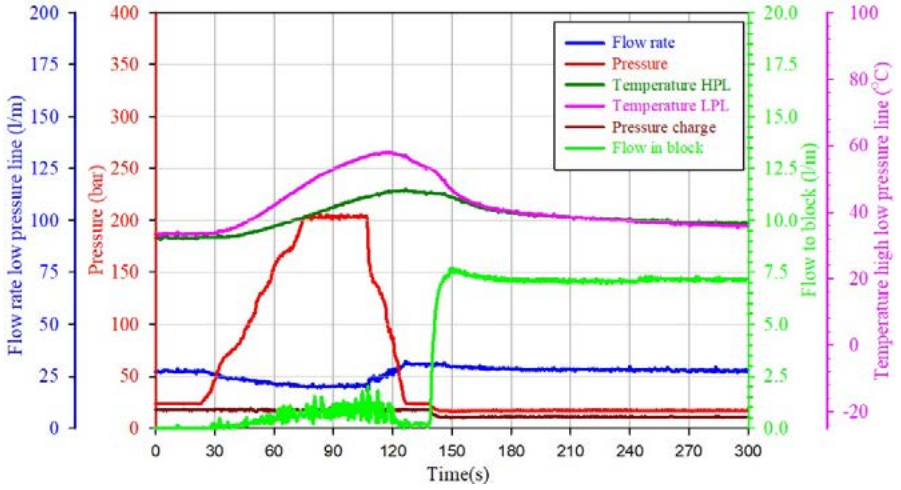

Figure 6. Measured charge flow rate of hydraulic oil supplied to the low-pressure line during testing.

From the study of heat generation in the load-simulation circuit, which is similar to a closed-loop system in mobile machinery, the pressure differential between the inlet and outlet of components leads to energy losses that are converted into heat. The heat generated in this system causes degradation of the hydraulic oil and subsequently leads to failure of hydraulic components. As a corrective measure, the circuit in Figure 2(a) should be modified to allow charge oil supply to the low-pressure line by installing a flushing line downstream of pressure relief valve No. 2, as illustrated in Figure 2(b). In the modified circuit, two proportional pressure relief valves are employed. Valve 1 is used to control the pressure of the hydraulic oil charged into the loop, whereas Valve 2 regulates the flushing line pressure, directing the oil through the cooler and filtration unit before returning it to the tank. In a closed-loop circuit, the charge pump pressure is adjusted to be slightly higher than the flushing line pressure. Both proportional pressure relief valves can be programmed and calculated based on Equation (2.1) to control the hydraulic oil temperature within the range of 33–60 °C under the following conditions.The equation used to control the proportional pressure relief valve.

$$\frac{\mathrm{dT}}{\mathrm{dt}} = \frac{\mathrm{Q_{gen}}}{mc_p} - \frac{hA}{mc_p}(T_{average} - T_{charge}) \qquad (2.4)$$

$$\frac{\mathrm{dT}}{\mathrm{dt}} = 0 \qquad (2.5)$$

$$\frac{\mathrm{dT}}{\mathrm{dt}} > 0 \qquad (2.6)$$

$$\frac{dT}{dt} < 0 \qquad (2.7)$$

According to the conditions specified in Equations (2.5)–(2.7), the program can regulate the oil temperature, as demonstrated by the temperature results presented in Figure 7.

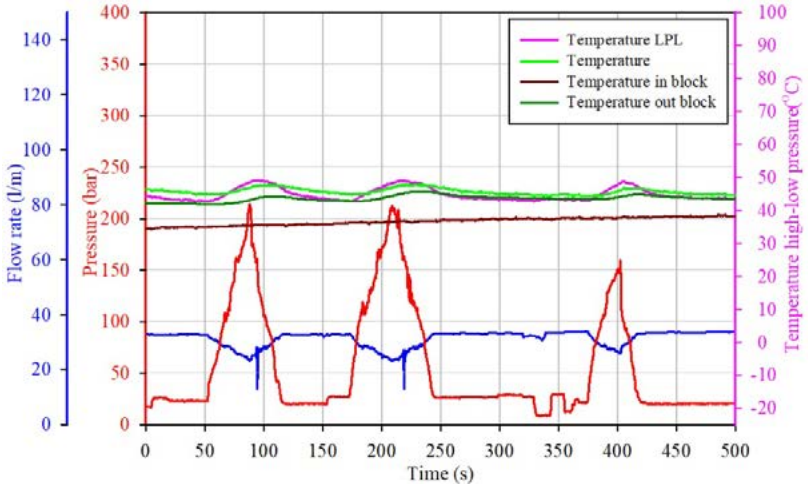

Figure 7. Temperature control achieved through the implementation of a flushing line and regulation of the charge pressure.

3. Conclusion

During no-load motor testing, it was observed that hydraulic oil still flows from the pump through the valve block, resulting in a continuous increase in temperature. This occurs because the high flow rate causes a significant pressure drop across the proportional pressure relief valve, leading to energy losses that are converted into heat.

Operating characteristics under high-pressure load and low-speed(low flow rate) conditions include a high pressure differential in the loop (high Δp) and a low flow rate (low Q). Under these conditions, heat generation is dominated by pressure-induced losses, resulting in a high heat generation per unit flow. Consequently, the loop temperature rises rapidly. High-pressure/low-speed operation therefore represents the worst thermal condition for a hydrostatic drive system.

Operating characteristics under high-speed and low-load conditions include a low pressure level in the loop and a high flow rate. In this regime, the pressure differential (Δp) is low, resulting in relatively small pressure-related losses. Internal leakage per unit time increases slightly, while viscous losses increase with speed. Overall, heat generation remains moderate. The high oil circulation rate enhances heat dissipation, leading to relatively stable loop temperatures with a small temperature difference between the loop and the tank. Flushing has a less pronounced effect compared to heavy-load conditions. In summary, high-speed/low-load operation represents a thermally stable condition.

The addition of flushing and programmed feedback control enables the mitigation of high hydraulic oil temperatures, particularly because hydraulic motor testing involves motors of various sizes and operating functions.

Abstract

Conventional centralized throttling-based hydraulic systems in excavators are robust but inefficient, especially under partial loads and multi-actuator operation. To address the inefficiencies, this work presents a multi-pressure hydraulic system for a 20-ton excavator and the implementation of its control. The system employs four discrete pressure levels, maintained by accumulators and a displacement-controlled pump, and distributed to the Swing, Boom, Arm, and Bucket actuators via 2/2 proportional valves. This enables more efficient use of energy but requires the development of a controller to select the pressure level, meter the flow and maintain machine performance. A force-based control strategy is developed that can manage these tasks while remaining relatively simple for practical implementation. The proposed controller combines discrete pressure levels with continuous modulation yielding near-continuous force resolution. Simulation in MATLAB/Simulink demonstrates 67% reduction in energy consumption against the original machine's load sensing system, and a 32% reduction against a benchmark controller developed previously for the multi-pressure system. Results also showed accurate tracking and preserved actuator dynamics.

1. INTRODUCTION

Hydraulic systems are extensively employed in heavy machinery due to their high-power density and robust performance. However, traditional hydraulic architectures, particularly those relying on throttling-based flow control, often exhibit energy losses. These conventional systems lack regeneration capabilities, differential flow control, and independent metering, resulting in inefficiencies. Recent research has focused on enhancing the energy efficiency of hydraulic work functions through various methods, including hydraulic transformers [1], multi-chamber cylinders [2], displacement control [3], hybrid technologies [4], and electro-hydraulic actuators [5]. Despite demonstrating significant energy savings, none of these approaches has yet seen widespread industrial adoption. While these solutions hold promise for future mobile machinery applications, this study pursues a multi-pressure system (MPS) approach. In an MPS, the actuator is connected to a discrete number of pressure levels achieving several different control modes that can be increased tremendously when coupled with proportional valves which requires the development of an appropriate control algorithm. The controller needs to accomplish different tasks

simultaneously such as selection of pressure levels, modulation of proportional valves and management of mode switching.

Several authors have addressed the challenge of discrete multi-pressure or multi-chamber system control. For instance, Heybroek [6] applied model predictive control to balance force peaks and energy efficiency. Hansen proposed a force switching algorithm for wave energy converters [7]. Huova also presented controllers for a multi-pressure actuator [8] and also tackled a model predictive control for a MPS in [9]. Xu also presents an actuator controller for a Multi-pressure multi-chamber cylinder system, which handles the pressure trajectories during transients using a MPC [10]. Building upon the insights presented in these research, the force-based controller developed in this work integrates concepts from Linjama's [2] work on secondary control along Hansen's [11] effort in reducing pressure oscillations to yield a practical and implementable control solution for the MPS.

This paper presents the development and evaluation of a force-based control strategy aimed at maximizing the energy-saving potential of the MPS. The proposed controller uses velocity feedback to generate a reference force needed to accelerate the piston and dynamically selects the chamber pressure levels maintaining controllability and reducing losses. The algorithm generates valve commands for both inflow and outflow actuator valves to satisfy operator inputs. This control approach also effectively mitigates force peaks caused by the different pressure dynamics during a mode switch in individual actuator chambers, as detailed in the control algorithm section. The proposed controller is benchmarked against a previously developed concept and the original machine's system using simulations.

2. SYSTEM ARCHITECTURE

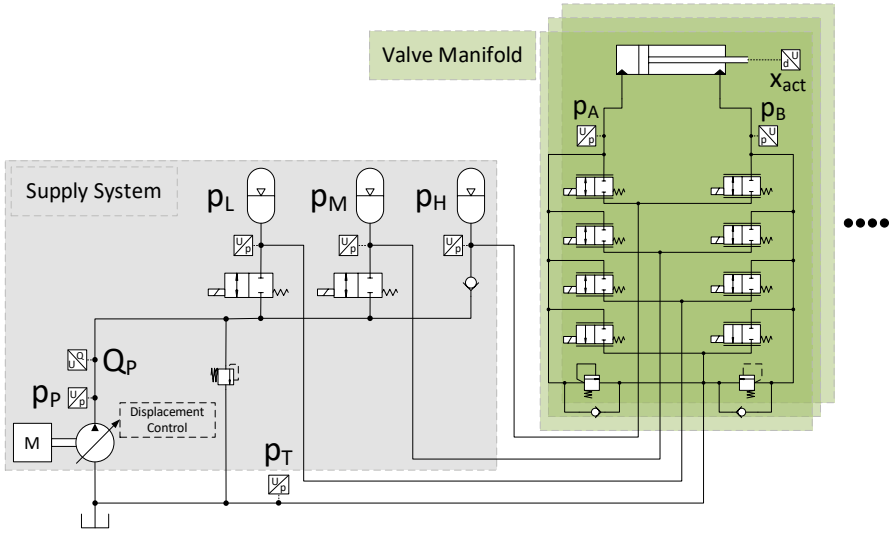

Figure 2.1: Simplified hydraulic circuit diagram of the Multi-Pressure System detailing the supply system and valve manifolds

The MPS illustrated in Figure 2.1. consists of three hydraulic accumulators operating at different pressure levels $[p_L, p_M, p_H]$ and a tank line p_T which establishes the system's multi-pressure supply lines. These lines are connected to the excavator's hydraulic work functions

[Swing, Boom, Arm, Bucket] via valve manifolds equipped with sets of 2/2 proportional bidirectional valves. Each valve modulates flow into and out of the actuator chambers by connecting to the appropriate pressure line and controlling flow metering in both piston and rod chambers. Pressure sensors on both actuator ports and a piston position sensor deliver feedback signals essential to the valve controller functionality. This feedback enables the control of valve commands to achieve desired actuator force outputs. The accumulator pressure levels are maintained between set thresholds by the excavator's hydraulic supply system, comprising of a diesel engine coupled to a variable-displacement piston pump. The pump output is regulated to charge the accumulators through dedicated charge valves.

3. CONTROL ALGORITHM

In the proposed MPS each actuator manifold contains four proportional bi-directional valves at the piston side and four at the rod side each connected to a pressure level. The role of the control algorithm is to choose the appropriate pressure level and actuate its corresponding valve according to the system requirements and load conditions. This is accomplished by using signals from the chamber $[p_A, p_B]$ and supply line pressures $[p_T, p_L, p_M, p_H]$, the cylinder position x as well as the joystick signal from the operator v_{ref} and the piston velocity v which can be estimated from the position sensor. The next section presents how the controller is formulated and how each decision is made, and the overall flow of the algorithm is shown in Figure 3.1.

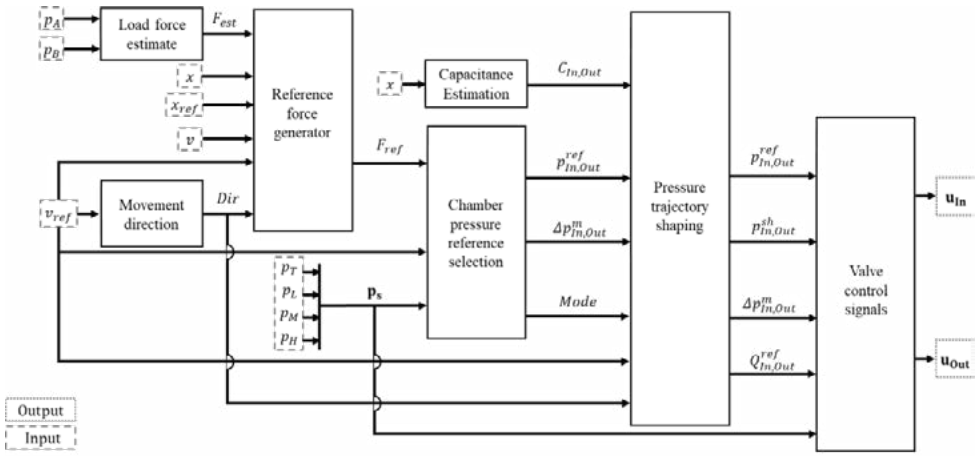

Figure 3.1: Force control algorithm - overall flow

The main idea is to generate a reference force F_{ref} based on the velocity error between the velocity reference v_{ref} (which could be e.g. a joystick command) and the measured velocity estimated from the piston position x (in case of a cylinder actuator). Following the force reference requires high resolution of achievable forces which can be accomplished by on/off-type control of the valves, for example, as demonstrated in Linjama [2]. However, when using two-chamber cylinders and four discrete pressure levels, the resolution obtained in this way is not sufficient for practical operation. To overcome this limitation, the proportional control valves employed are used to introduce a pressure differential in each of

the chambers, thereby enabling finer adjustment of the actuator forces and significantly improving the achievable force resolution.

The pressure selection chooses chamber pressure references for the inflow and outflow sides $p_{In,Out}^{ref}$ that match the generated reference force. The chamber reference selection is done through a cost function that minimizes force error, unnecessary variation of chamber pressures and power losses.

In the next step, the valve commands are selected such that the chamber pressure references are achieved. The references are generated in two different ways depending on the operating condition. During regular motion, when no pressure transient is needed i.e., during a pressure shift, it is kept as the selected pressure reference, whereas during a pressure shift where the selected lines are changed, it follows a predefined pressure trajectory $p_{In,Out}^{Sh}$. In both cases, the valve commands are determined based on the required flow rate and the calculated pressure differential, which accounts for both the supply pressure and the chamber pressure reference. The required flow rate is obtained from the piston velocity, the derivative of the chamber pressure reference, and the estimated hydraulic capacitance. This is done in order to avoid force peaks originating from different pressure dynamics in the piston and rod side chambers during a mode switch. The details of each step are illustrated in the next sections.

3.1. Movement direction

The first step is determining the movement direction of the actuator's piston. This is done using the velocity reference generated by the operator. This step is necessary to assign the variables of the controller to the inflow and outflow sides. Where the variable Dir is calculated using:

$$Dir = \begin{cases} 1 & If \begin{cases} v_{ref} \geq v_{start}\ OR \\ v_{ref} > v_{stop}\ AND\ Dir^{-1} = 1 \end{cases} \\ -1 & If \begin{cases} v_{ref} \leq -v_{start}\ OR \\ v_{ref} < -v_{stop}\ AND\ Dir^{-1} = 1 \end{cases} \\ 0 & else \end{cases} \tag{1}$$

The logic includes hysteresis to avoid repetitive initiation of motion, where v_{start} and v_{stop} are velocity thresholds to start and stop the movement and Dir^{-1} is the direction variable in the previous timestep. The parameters, inputs and outputs of the control algorithm are assigned based on the value of the direction variable to the inflow and outflow sides. The logic is used throughout the controller, and an example is shown for the effective areas of the chambers for the inflow A_{In} and the outflow A_{Out} where:

$$A_{In} = \begin{cases} A_A & Dir \geq 0 \\ A_B & Dir < 0 \end{cases}; A_{Out} = \begin{cases} A_B & Dir \geq 0 \\ A_A & Dir < 0 \end{cases} \tag{2}$$

where A_A and A_B are the chambers effective areas on the piston and rod sides.

3.2. Reference force generator

The reference force is generated using a PI – controller based on the velocity error. An outer position loop is added to the existing velocity controller to correct for position error where the corrected reference velocity v_{ref_x} is calculated using:

$$v_{ref_x} = \big(x_{ref}(t) - x(t)\big)K_{px} + v_{ref} \tag{3}$$

where x_{ref} is the position reference, K_{px} is the gain for position loop. The reference force F_{ref} is generated using:

$$F_{ref} = \big(v_{ref_x} - v\big)K_P + K_I \int \big(v_{ref_x} - v\big)dt \tag{4}$$

K_p and K_i are the proportional and integral gains respectively and v is the measured piston velocity. An important note, in operating intervals where no velocity command is provided by the operator, i.e. *Dir* equals zero, the reference force is gradually driven toward an estimated hydraulic force F_{est}, computed from the measured chamber pressures as:

$$F_{est} = p_A A_A - p_B A_B \tag{5}$$

The motivation for this is to prevent delays or wrong movement directions when valve actuation starts. By aligning the reference force with the estimated force during inactive periods, the system ensures a smooth transition between inactive and active phases of operation, thereby improving responsiveness and allowing for smoother operation.

3.3. Chamber pressures selection

The principle of pressure selection is to match the reference force by choosing appropriate chamber pressures from a set of virtual levels. Since there is a limited number of accumulators and they cannot provide arbitrary pressure values, intermediate pressure levels are virtually generated by linearly interpolating between the current accumulator pressures. These "virtual" levels represent pressures that can be realized in practice through throttling across the metering valves for the inflow and outflow sides. The available accumulator pressures $\mathbf{p_s}$, is defined as:

$$\mathbf{p_s} = [p_T, p_L, p_M, p_H] \tag{6}$$

These serve as the boundary values for constructing virtual multi-level buses along with the minimum and maximum system pressures. This produces a denser grid of chamber pressures for the inflow and outflow sides using the constructed vector $\mathbf{p_{virt}}$. The vector expands the resolution of the achievable force levels beyond the discrete accumulator values while preserving physical feasibility. A combination matrix $\mathbf{M}$ is formed based on the number of virtual levels n created where:

$$\mathbf{M} = \begin{bmatrix} 1 & 1 & \dots & 1 & 2 & 2 & \cdots & n \\ 1 & 2 & \dots & n & 1 & 2 & \cdots & n \end{bmatrix} \tag{7}$$

where the matrix $\mathbf{M}$ has the size $2x n^2$. Pressure references are created using the vectors $\mathbf{p_{In}^{ref}}$, $\mathbf{p_{Out}^{ref}}$ and $\mathbf{p_{virt}}$:

$$\begin{aligned} \mathbf{p_{In}^{ref}} &= \mathbf{p_{virt}}\big(\mathbf{M}(1,:)\big) \\ \mathbf{p_{Out}^{ref}} &= \mathbf{p_{virt}}\big(\mathbf{M}(2,:)\big) \end{aligned} \tag{8}$$

For each candidate pair of inflow and outflow side pressures an achievable actuator force **F** is calculated where:

$$\mathbf{F} = \mathbf{p_{In}^{ref}} \mathrm{A_{in}} - \mathbf{p_{Out}^{ref}} \mathrm{A_{Out}} \tag{9}$$

where A_{in} and A_{Out} are the effective areas of the inflow and outflow sides dictated by the Dir variable.

To calculate the static power losses for the cost function each candidate is paired with an accumulator that can meter the flow in or out of the chamber depending on the direction of motion. For the inflow side an accumulator with higher or equal pressure to the virtual chamber pressure reference is chosen and for the outflow side an accumulator with lower or equal pressure is chosen. This creates the bus matrices $\mathbf{p_{In}^{Bus}}, \mathbf{p_{Out}^{Bus}}$. The two vectors can be used to calculate the throttle free force and consequently the static power loss $\mathbf{P_{loss}}$ where:

$$\mathbf{P_{loss}} = \left(\left(\mathbf{p_{In}^{Bus}} A_{In} - \mathbf{p_{Out}^{Bus}} A_{Out}\right) - \mathbf{F}\right) * |v_{ref}| \tag{10}$$

On the other hand, not all chamber pressures are hydraulically realizable. Therefore, a feasibility check is performed to eliminate the unfeasible pairs where:

$$\begin{aligned} \mathbf{feas} = \ & \mathbf{p_{In}^{Bus}} - \mathbf{p_{In}^{ref}} \geq \Delta p_{In}^{m} \text{ AND} \\ & \mathbf{p_{In}^{Bus}} > 0 \text{ AND} \\ & \mathbf{p_{Out}^{ref}} - \mathbf{p_{Out}^{Bus}} \geq \Delta p_{Out}^{m} \end{aligned} \tag{11}$$

Where Δp_{In}^{m} and Δp_{Out}^{m} are the minimum differential pressure across the valve to allow for metering and is calculated using the valve orifice equation:

$$\Delta p_{In,Out}^{m} = \left(\frac{A_{In,Out} v_{ref}}{K_{In,Out}^{V}}\right)^2 \tag{12}$$

where $K_{In,Out}^{V}$ is the valves flow coefficient calculated using the nominal flow rate and pressure difference.

A cost function **J** is formulated to choose the reference chamber pressures for the inflow and outflow where:

$$\begin{aligned} \mathbf{J} = \left|\mathbf{F} - F_{ref}\right| + W_{prs}\left(\left|p_{In}^{ref^{-}} - \mathbf{p_{In}^{ref}}\right| A_{In} - \left|p_{Out}^{ref^{-}} - \mathbf{p_{Out}^{ref}}\right| A_{Out}\right) \\ + W_{loss}\mathbf{P_{loss}} + W_{dp}\mathbf{\Delta p_{eq}} \end{aligned} \tag{13}$$

where W_{prs}, W_{loss} and W_{dp} are weighing terms for the static losses, the magnitude of the chamber pressure change and for equalizing the pressure differential at the inflow and outflow sides, $p_{In}^{ref^{-}}$ and $p_{Out}^{ref^{-}}$ are the selected chamber pressure references at the previous time step.

The final term in the cost function attempts to ***equally*** distribute the needed overall pressure differential to both the inflow and outflow sides, this helps in reducing the valve activity and also avoids having high pressure difference in the inflow side and low-pressure difference on the outflow side. The term $\mathbf{\Delta p_{eq}}$ is calculated using:

$$\mathbf{\Delta p_{eq}} = \left|\left(\mathbf{p_{In}^{Bus}} - \mathbf{p_{In}^{ref}}\right) - \left(\mathbf{p_{Out}^{ref}} - \mathbf{p_{Out}^{Bus}}\right)\right| \tag{14}$$

The infeasible combinations are set to infinity and the chosen chamber pressure references for the inflow p_{In}^{ref} and outflow p_{In}^{Out} sides are chosen as:

$$p_{In,Out}^{ref} = \mathbf{p}_{\mathbf{In,Out}}^{\mathbf{ref}}[k] \tag{15}$$

where k is the index of minimizing the cost function. Each selected chamber pressure has a corresponding chosen accumulator that is combined to the $Mode$ variable where:

$$Mode = \left[\mathbf{p}_{\mathbf{In}}^{\mathbf{Bus}}(k)\ \mathbf{p}_{\mathbf{Out}}^{\mathbf{Bus}}(k)\right] \tag{16}$$

The chosen chamber pressure references $\left[p_{In}^{ref}, p_{Out}^{ref}\right]$, and M$ode$ are input to the trajectory shaping algorithm which is explained in the next section.

3.4. Pressure trajectory shaping

Chamber pressure references can change in two ways, which determines how valve commands are generated. For small changes within the chamber that do not require switching accumulators; flow is displacement induced, and valve commands are computed using the calculated pressure differential (supply and chamber reference) and the valve orifice equation. Larger changes, which require one or both chambers to switch accumulators, actuate multiple valves simultaneously can produce a "force peak". Uneven pressure build-up owed to different hydraulic capacitance results in sudden acceleration or deceleration of the piston due to the force peak. To prevent this, valve commands are shaped to make the chamber pressures follow a predefined pressure trajectory. The implemented algorithm is derived from the work in [11].

The idea is to generate a flow rate reference Q_{ref} and consequently a valve opening u_v that corresponds to the pre-defined pressure trajectory. The trajectory used in this work is a third order polynomial which is calculated from:

$$p_{In,Out}^{sh} = -\frac{2\Delta p_{In,Out}}{\tau_{Sw}^3}t^3 + \frac{3\Delta \mathrm{p}_{In,Out}}{\tau_{Sw}^2}t^2 + p_{In,Out}^0 \tag{17}$$

where $\Delta p_{In,Out}$ can be defined as:

$$\Delta p_{In,Out} = p_{In,Out}^{ref} - p_{In,Out}^0 \tag{18}$$

and p_0 is the chamber pressure at the beginning of the shift, t is the current time step and τ is the time dedicated for the pressure switch to be completed.

To calculate the flow rate reference needed to complete the pressure switch for both sides, the pressure build-up equation can be used after re-arranging for Q_{In}^{ref} where:

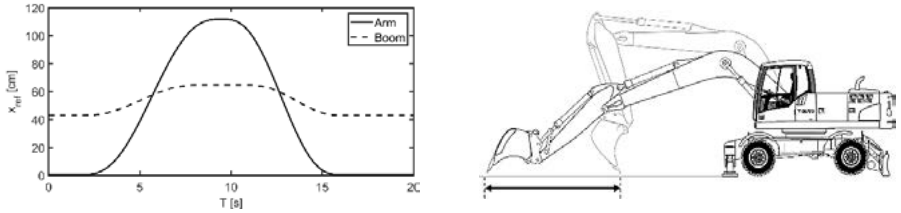
$$\begin{aligned} Q_{In}^{ref} &= A_{In}v_{ref} + C_{In}\left(-\frac{6\Delta p_{In}}{\tau_{Sw}^3}t^2 + \frac{6\Delta p_{In}}{\tau_{Sw}^3}t\right) \\ Q_{Out}^{ref} &= -A_{Out}v_{ref} + C_{Out}\left(-\frac{6\Delta p_{Out}}{\tau_{Sw}^3}t^2 + \frac{6\Delta p_{Out}}{\tau_{Sw}^3}t\right) \end{aligned} \tag{19}$$

where C_{In} and C_{Out} are the hydraulic capacitances estimated from the piston position [12].

It is important to note that the pressure shaping algorithm is only active at times where there is a mode switch occurring dictated by the variable $Mode$ changing values. When no mode switching is occurring the valve commands are calculated using the displacement flow reference which is the first part of equation (19) and $p_{In,Out}^{sh}$ are set as $p_{In,Out}^{ref}$.

3.5. Valve actuation logic

The valve reference generation for the inflow and outflow sides is formulated such that the reference flow rates $Q_{In}^{ref}, Q_{Out}^{ref}$ are distributed to the accumulators that are hydraulically feasible. For the inflow side, the accumulator is considered feasible If the pressure differential to p_{In}^{sh} is higher than or equal to Δp_{In}^{m}. The feasible accumulators are sorted by their proximity to p_{In}^{ref} at each time step. The maximum achievable flow from one accumulator is calculated from:



$$Q_{In,Out}^{max} = \begin{cases} K_{In}^{V}\sqrt{\mathbf{p_s}(j) - p_{In}^{sh}} & \mathbf{p_s}(j) - p_{In}^{sh} \geq \Delta p_{In}^{m} \\ -K_{Out}^{V}\sqrt{p_{Out}^{sh} - \mathbf{p_s}(j)} & p_{Out}^{sh} - \mathbf{p_s}(j) \geq \Delta p_{Out}^{m} \end{cases}$$

where j is the index of the feasible accumulator after sorting. The valve command is then calculated using:

$$u_{In,Out}(j) = \frac{Q_{In,Out}^{ref}}{Q_{In,Out}^{max}} \tag{20}$$

and the non-feasible indices are set to zero. If the valve is not fully opened this means that the flow reference is satisfied. However, if the opening is more than one this means that another valve needs to be opened to meet the requirement. This is done by setting the current valve to fully open and the new flow reference to the difference between current valve's maximum flow and the original flow required and calculating the opening using the new reference. The outflow side is calculated in a similar fashion with the main difference being that the p_{Out}^{sh} must be higher than accumulator pressure by Δp_{Out}^{m}. Finally, the inflow and outflow valve commands $\mathbf{u_{In}}$, $\mathbf{u_{Out}}$ are routed to the piston and rods sides using the Dir variable.

4. SIMULATION AND RESULTS

(a) (b)

Figure 4.1: (a) Reference trajectories for the boom and arm actuators (b) Motion of the machine's components relative to the commands

The simulation uses a 20s air grading cycle from the JCMAS standard which is shown in Figure 4.1, where the boom and arm cylinders are extended and retracted simultaneously representing a leveling operation. The cycle was adopted for this simulation study as it is well established in literature and provides a suitable basis for evaluating system performance under multi-actuator operation and high flow demands [13]. It is also based on measurements performed with the original base-line machine performing the same trajectories. The detailed simulation model, cycle description and the previously developed

controller, used here as a benchmark, are presented in [14]. In this work, the focus is on assessing the proposed force-based controller relative to that benchmark as well as the original machine's system which is also detailed in the cited publication. The main parameters used in the simulation model are listed in Table 4.1 while the controller parameters are illustrated in Table 4.2.

Table 4.1: Main parameters for the simulation

Machine mass	21160	kg
Accumulator pressure	[0, 106, 213, 320]	bar
Valve coefficient K_V	$1.088\text{x}10^{-5}$	$\text{m}^3/(\text{s}.\text{Pa}^{1/2})$

4.1. Performance

Figure 4.2 and Figure 4.3 show the simulation results for the boom and arm cylinders during the simulated cycle. The first two plots show the position and velocity tracking. The second diagram shows the multi-pressure lines, chamber pressure references, shaped chamber pressures and finally the simulated chamber pressures. Next diagram illustrates the forces including the reference force F_{ref}, selected force (representing the selected pressure references $p^{ref}_{In,Out}$), shaped force (representing the shaped pressure references $p^{sh}_{In,Out}$) and finally the boom force calculated from the chamber areas and pressures. Finally, the valve commands for the piston (A) and rod (B) sides are shown where the colors match those of the pressure lines in the third plot.

Figure 4.2 illustrates the dynamic behavior of the boom actuator, highlighting the performance of the control strategy and MPS. The piston velocity and position closely follow their reference trajectories, indicating that the controller tracks the commanded inputs well. Minor deviations in velocity tracking are observed during both extension and retraction phases attributable to arm motion conditions. However, these do not significantly affect the position tracking of the boom, which remains accurate throughout.

The tracking performance is enabled by the regulation of chamber pressure references to follow the reference force, as shown in the pressure subplot. At the start of motion, when the piston velocity is low, the controller connects piston side chamber to the medium-pressure line and the rod side chamber to the low-pressure line. This configuration allows

the tracking of the desired reference force through throttling on both sides. As the piston velocity increases along with associated power losses the controller transitions piston side chamber to the low-pressure line and the rod side chamber to the tank-line. This mode is maintained throughout the extension phase as it balances between force tracking and static losses. As the piston approaches its target position and decelerates, the controller reduces the output force as needed by increasing the pressure in the rod side chamber while simultaneously decreasing the pressure in piston side chamber. This allows close tracking of the reference force that is decreasing.

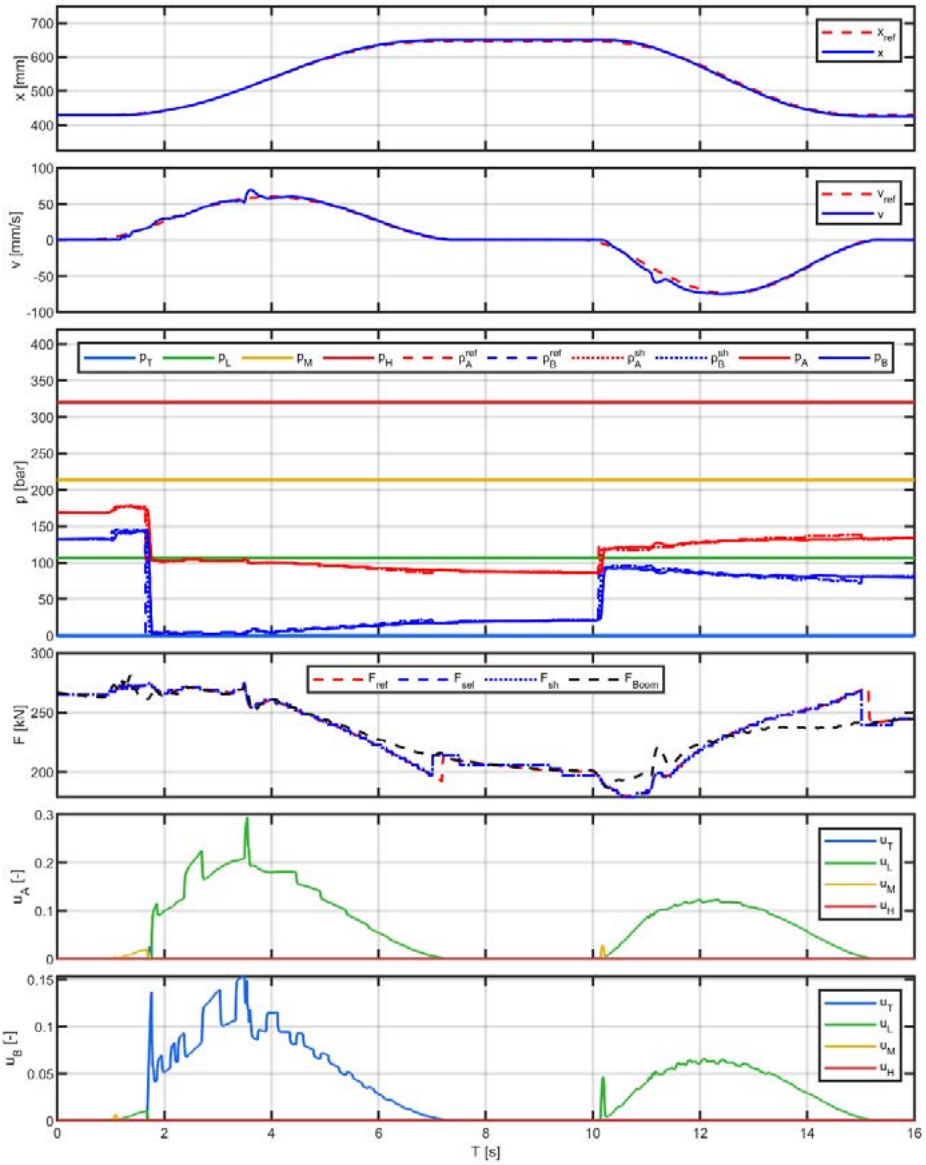

Figure 4.2: Simulation results for the control algorithm of the boom actuator

During retraction, both chambers are connected to the low-pressure line, implementing a differential flow strategy. When the reference force increases, the controller responds by raising the pressure in the piston side chamber and reducing the pressure in the rod side chamber, thereby maintaining effective velocity tracking while reducing the losses. There is an instance where the controller operates at near minimum pressure differential for both chambers at the start of retraction motion contributing to fewer losses and is a core strength of the proposed logic. Additionally, it can be seen that the chamber pressure references change in a stepwise manner at mode switches, but the actual pressures follow the trajectory shaping pressure reference which is detailed more in the upcoming sections.

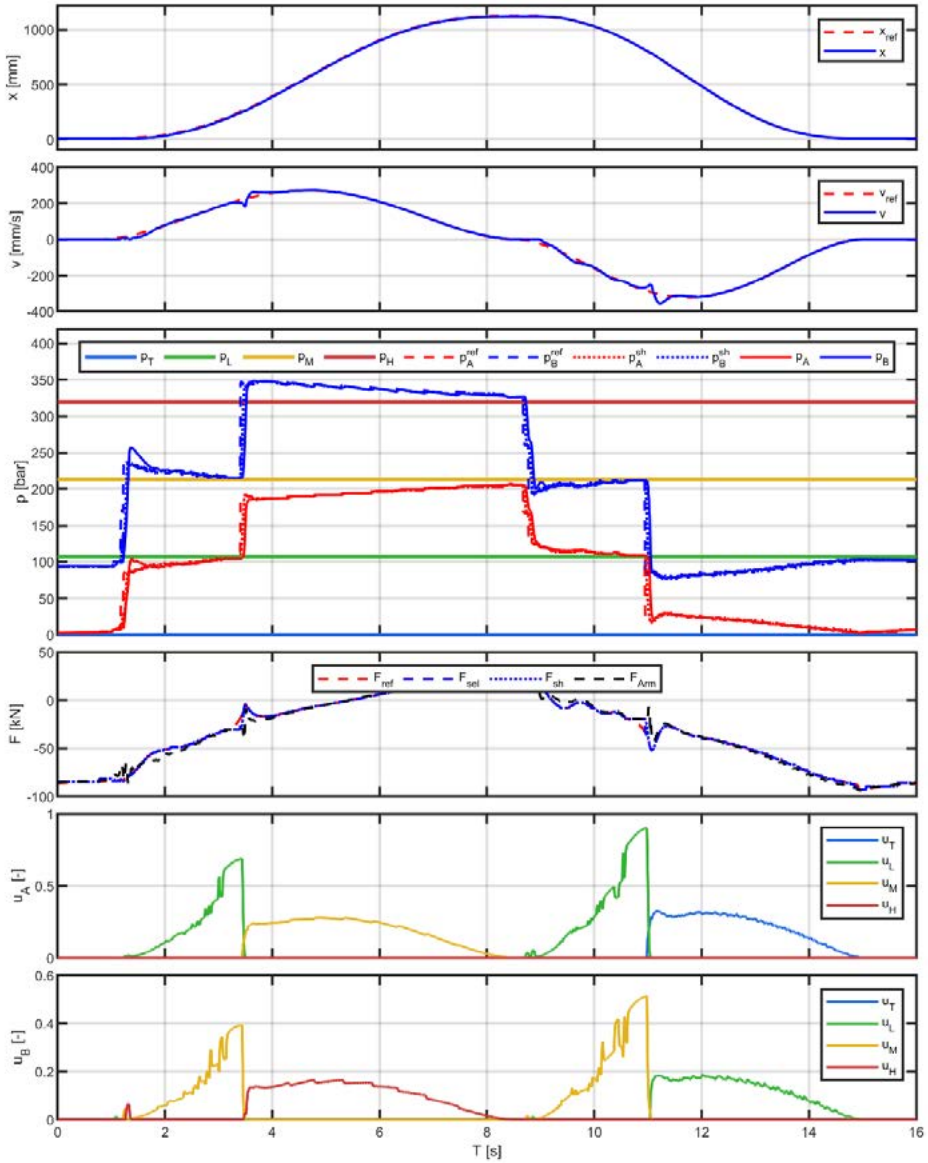

Figure 4.3: Simulation results for the control algorithm of the arm actuator

The arm actuator shows similar results in terms of precise velocity and position tracking with the similar observation of smaller deviations in velocity that are not noticed in position response during motion. The arm actuator chamber pressure references show more activity than the boom actuator mainly due to the force distribution resulting from the available pressure levels and effective areas.

At the beginning, the piston side chamber is connected to low-pressure line while the rod side chamber is connected to medium-pressure line achieving the required negative reference force. Similarly to the boom actuator, the reference force is matched by increasing the pressure in the piston side chamber and reducing pressure in the rod side chamber. The deviation in velocity seen at around 3.5 seconds is due to the algorithm selecting a mode with negative force error that enables reduction of power losses, which is another key strength of the proposed controller in terms of energy savings. As the force error increases the algorithm shifts to reduce the error and introduces throttling as a consequence where it now chooses medium-line for piston side and high-line for rod side. This mode is kept for the rest of the duration of extension. The reference force is again matched by manipulating the chamber pressure references for both edges.

During retraction, the controller initially selects low-line for the piston side chamber and high-line for the rod side chamber. As the losses increase quickly the chambers are switched to a lower pressure reference using the same line for the piston side chamber and switching to medium-line for the rod side chamber, which yields lower losses. The mode remains feasible and highly efficient as it has near minimum pressure differential. The force reference is again matched by regulating both chamber pressures until just before 11 seconds, where it becomes infeasible. At this instance, some force error is allowed by the controller to reduce losses before switching to a different mode which can be seen in the velocity tracking (piston slowing down then speeding back up). To reduce the force error, the control switches to a different mode that can match the reference at the cost of power losses. The chosen mode is tank for the piston side chamber and low for the rod side chamber. Similarly to the end of the extension stroke the mode is preserved and the force reference is matched by increasing the pressure in the rod side chamber and reducing the pressure in the piston side chamber.

The stepwise nature of some of the valve command signals on both sides of both actuators is attributed to the discrete pressure reference selection algorithm. While this approach simplifies implementation, it introduces a higher utilization of the valves. A finer and more consistent valve command profile could be achieved by increasing the number of virtual pressure levels available n. This would enhance control resolution, but at the cost of increased computational load. An optimization study for the number of virtual levels along with other parameters are left for future studies.

4.2. Pressure trajectory shaping

The pressure shaping algorithm is illustrated in Figure 4.4 where the top figures show the pressures in both chambers and how they evolve during the switching period $[t_0 \rightarrow \tau_{sw}]$ and their corresponding flow rate references in the bottom plots.

The figure highlights the pressure shift occurring in the boom actuator just before 2 seconds during extension. For piston side chamber the pressure reference shifts from medium to low.

It can be seen that the pressure reference p_A^{ref} changes instantly while the chamber pressure steadily follows the generated shaped pressure reference shown in dotted. This is accomplished by modifying the flow rate reference using the third order polynomial defining the needed flow to complete the shift. Initially, the flow rate reference is due to the displacement flow needed by the piston motion, at the instant where the chamber reference shifts the flow reference is modified to shape the chamber pressure. The reference is followed by sequential valve control starting with closing the medium-line valve to reduce the flow rate and pressure as needed, then opening the tank valve to supply the required negative flow (flow out of the chamber) which reduces the pressure further. At the end of the shift the low line valve is opened to complete the shift and continue supplying the displacement flow.

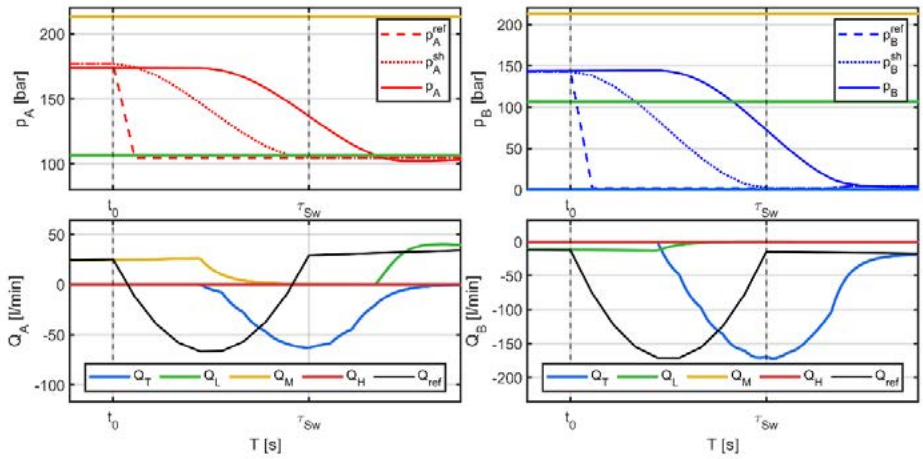

Figure 4.4: An excerpt from the results highlighting the pressure shaping algorithm

On the other hand, at the rod side chamber (figure to the right) similar behavior is observed with the exception that the flow reference doesn't change signs during the shift. The shaping can be accomplished by closing the low-pressure line valve and then opening the tank-line valve. More details on the reasoning behind flow direction changes can be found in Hansen's work [11]. The delay between the flow rate reference and the achieved one is attributable to the valve dynamics. Finally, it is important to note that the switching time τ_{sw} is set to 90 ms and the sampling rate is 10 ms which explains the steps in the flow rate signal.

4.3. Energy savings

A key strength point of the proposed algorithm is that it enables metering of the flow with minimum required differential pressure accomplished by manipulating the chamber pressure references. This is reflected in the power consumption of both actuators where there are several instances of the controller operating at minimal losses. Figure 4.5 shows the input and out powers of the proposed controller against the cited benchmark control [14]. The difference between proposed and benchmark can be seen in the boom actuator input power. The proposed controller initially matches the benchmark at the start of motion but as the piston speed increases it switches to a minimum differential pressure mode which critically minimizes the power consumption. The power losses slightly increase at the end of the extension stroke as some throttling is introduced to match the reference force. However, the

proposed controller outperforms even when throttling. During retraction both controllers exhibit similar performance as they both use an efficient differential mode.

Similar behavior is seen in the arm actuator, soon after the motion starts the proposed controller switches to a near minimum differential pressure mode reducing the power losses significantly. This can be observed during the acceleration phase of the extension stroke. Due to the reference force increasing the mode becomes infeasible and a compromise in power losses must be made, both controllers exhibit similar losses. As the piston retracts the proposed controller again chooses a highly efficient mode with minimal losses while the benchmark performance is poorer. Finally, both controllers show similar behavior during the rest of the retraction phase.

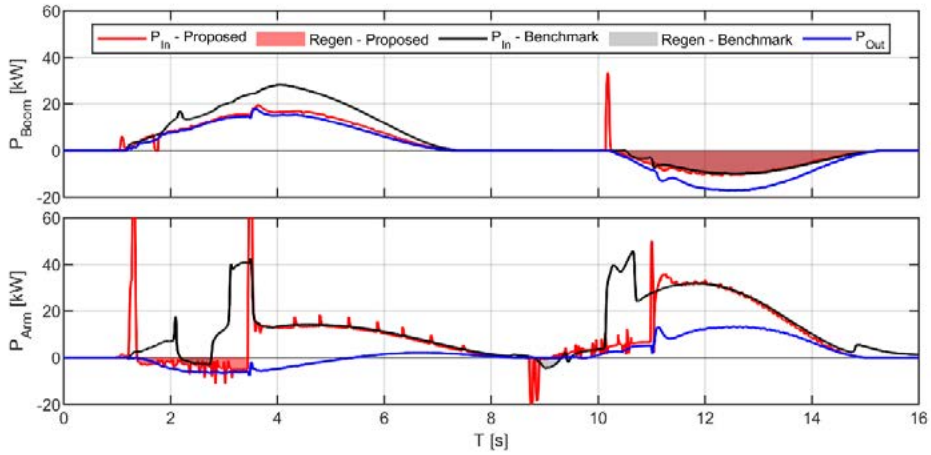

Figure 4.5: Power consumption of the proposed control algorithm against benchmark control

One key difference can be seen during the durations of pressure switching where the proposed controller concentrates the switch in a short time τ_{sw} while the benchmark one takes longer contributing to higher losses. Another advantage of the proposed controller is that it can allow for slight negative force error which allows for more utilization of efficient modes. Although this reflects in the piston velocity where it decelerates and accelerates, the deviation is small and unnoticeable.

Figure 4.6 shows the input energy of the proposed control against the original machine's load sensing system and the benchmark control. The results demonstrate the effectiveness of the proposed MPS system and control algorithms in reducing power losses compared to the conventional load sensing (LS) system. The LS baseline exhibited total power consumption of 518 kJ. By introducing the MPS system with the benchmark controller, the losses were reduced to 250 kJ, corresponding to a 52% reduction. Further improvement was achieved with the proposed controller, where the energy consumption decreased to 176 kJ, representing a 67% reduction relative to the original LS system and an additional 32% reduction compared to the benchmark controller. These results highlight the significant efficiency gains enabled by the MPS architecture and the proposed control strategy.

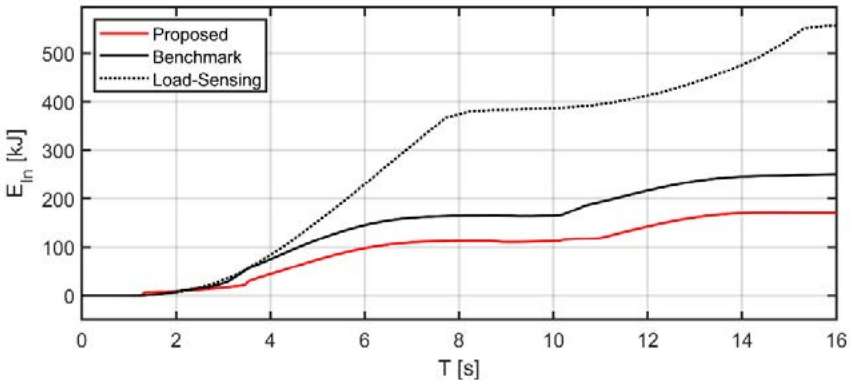

Figure 4.6: Input energy of proposed control algorithm against benchmark control

While these findings demonstrate the potential of the proposed control, it is important to note the limitations of the air grading cycle used for evaluation. The cycle does not fully represent real operating conditions. In particular, it may exaggerate the energy savings when compared to an LS system, which inherently shows higher compensation losses in no-load situations. Furthermore, the inclusion of energy recovery can distort the efficiency profile, suggesting greater savings than might actually occur under practical working conditions. Therefore, the results should be interpreted as an indication of relative system improvements rather than a direct prediction of real-world energy savings. The MPS along with the proposed controller are planned for future experimental work to provide more concrete energy saving estimates under real-world operating conditions.

5. Conclusion and Future Work

This paper presented a novel control strategy for a Multi-Pressure System (MPS) for an excavator's work functions. Simulation results for boom and arm actuators demonstrated accurate tracking of position, velocity, and force references, while significantly reducing energy consumption. The proposed controller dynamically selects chamber pressures to minimize throttling losses and optimize efficiency. The proposed controller ability to operate at near-minimum pressure differential and tolerate slight force error allows for higher energy savings. The proposed method achieved up to 67% reduction in energy consumption compared to conventional Load Sensing (LS) systems and 32% compared to an MPS benchmark controller, highlighting its potential for improving the machine's overall efficiency.

Abstract.

Hydraulic systems dominate heavy-duty robotic arm applications due to their high power density and inherent impact resistance. However, conventional architectures suffer from severe throttling losses at valve ports and considerable dissipation of gravitational potential energy, resulting in overall system efficiencies of less than 30 % - a key contributor to the high energy consumption of heavy-duty equipment. To overcome these limitations, this paper proposes a novel hydraulic system integrating a three-chamber hydraulic cylinder with hydraulic-pneumatic energy storage, incorporating pump-valve coordination and independent metering control for heavy-duty robotic arms. In the proposed system, the energy-storage chamber of the three-chamber hydraulic cylinder is directly connected to a hydraulic accumulator. A multi-stage pressure-adjustable valve is designed to adaptively regulate energy storage under varying working conditions, enabling efficient recovery and reuse of gravitational energy. Pre-charging the hydraulic accumulator to counterbalance the arm's self-weight improves dynamic response and significantly reduces flow demand. The two driving chambers of the three-chamber hydraulic cylinder adopt independent metering control, combined with a pump-valve coordinated control strategy dominated by velocity feedforward and regulated by position feedback. This approach minimizes throttling losses and mitigates the reverse nonlinear charging characteristics of hydraulic accumulators. This strategy also overcomes traditional constraints on actuator chamber area imposed by conventional valve configurations. To fully exploit the synergy between independent metering and hydraulic-pneumatic energy storage, a newly designed independent metering valve manifold is introduced, offering low pressure loss, rapid response, and high precision and reliability. A 38-ton hydraulic excavator boom system was selected as a representative case study. Firstly, energy flow analysis was conducted. Subsequently, a multidisciplinary

All Open Access articles are peer-reviewed, distributed under the Creative Commons Attribution-Non Commercial 4.0 International

co-simulation model was developed. Then, system parameters and control strategies were optimized based on the machine's operational characteristics. Finally, a prototype was built to evaluate performance and energy efficiency. Results demonstrate that, compared with existing solutions under identical conditions, the proposed system reduces flow demand by approximately 38 %, peak power by around 48 %, and achieves a gravitational energy recovery efficiency of nearly 70 %, leading to overall energy savings of up to 40 %. Additionally, the system exhibits excellent tracking accuracy, rapid dynamic response, and stable operation with minimal pressure and velocity fluctuations.

Keywords. Heavy-duty robotic arm, pump-valve coordinated control, independent metering control, hydraulic-pneumatic energy storage, velocity-position compound control.

1. INTRODUCTION

Heavy-duty robotic arms are typically powered by centralized hydraulic systems with valve-controlled power distribution, which provide advantages such as high power density and strong impact resistance. However, relevant studies have shown that the overall energy efficiency of such systems is often below 30 % [1], becoming a critical bottleneck for the sustainable and energy-efficient development of heavy equipment. The main reasons are twofold: on the one hand, traditional four-edge valve spools exhibit mechanical coupling between the inlet and outlet ports, leading to simultaneous throttling and severe energy losses. Moreover, only one control variable can be regulated at a given time, resulting in low degrees of freedom and poor controllability. On the other hand, during the lowering process of heavy-duty robotic arms, large amounts of gravitational potential energy are dissipated as heat through throttling orifices, not only wasting energy but also requiring additional cooling devices, which increase system complexity and failure risk.

Independent metering control offers an effective means to decouple actuator chamber regulation, thereby improving both energy efficiency and control performance. Backé pioneered the concept by developing a hydraulic cylinder system controlled by four cartridge valves [2]. Subsequently, Jansson and Palmberg addressed the problem of energy dissipation in valve-controlled systems by employing four Valvistor valves with pressure compensation and flow regeneration to reduce losses [3]. Hu and Zhang further introduced a proportional valve in parallel at the pump outlet based on a four-spool configuration, enabling multiple neutral control functions [4]. Lyu, Chen and Yao proposed a pump-valve coordinated scheme, where the pump supplied the main flow and the valve ensured accuracy, reducing energy consumption by about 50 % [5]. Zhong et al. employed high-speed switching valves as the pilot stage of a dual-spool electro-hydraulic proportional valve, improving dynamic response by 21 % and control accuracy by 16 % [6].

In terms of control strategies, Meyer, Weiler and Murrenhoff developed a discrete logic control method for independent metering control systems, dynamically adjusting piston-rod side pressure to enhance stiffness and efficiency [7]. Lu and Yao proposed a multi-level adaptive robust control strategy utilizing five cartridge valves and an accumulator, resulting in 30–40 % energy savings [8]. Xu et al. combined pump-valve control strategies to optimize both flow and pressure regulation, significantly reducing energy consumption while improving performance [9]. Shi et al. introduced a mode-switching velocity–position compound control strategy based on pump-valve coordination and independent metering control, achieving smooth operation and high positioning accuracy under low energy

consumption [10]. Li et al. integrated adaptive robust control with online parameter estimation to dynamically compensate for fluid compressibility and valve flow deviations, thereby improving control accuracy and stability [11].

Energy recovery from heavy-duty robotic arms primarily involves hydraulic, electrical, and mechanical approaches, which are also crucial for enhancing system efficiency. In hydraulic methods, Tong et al. proposed coupling high- and low-pressure accumulators with pump-motor torque, reducing energy consumption by 28–35 % [12]. Yang et al. developed a system using a three-chamber accumulator, increasing energy storage density by 43 % [13]. Tan et al. combined auxiliary and intensifying cylinders for energy recovery, achieving an efficiency of 58 % [14]. Beyond academic research, several manufacturers, including Liebherr (Germany), Sennebogen (Germany), Mantsinen (Sweden), Changlin Group (China), and Sunward Intelligent Equipment Group (China), have implemented mass compensation solutions based on energy-storage cylinders combined with accumulators. Reported applications indicate that such solutions can reduce the overall energy consumption of the machine by more than 30 % [15]. In electrical methods, Li, Wu and Cao controlled boom energy recovery based on excavator operation and battery state, improving recovery efficiency [16]. Lin et al. used proportional valves to control hydraulic motors, obtaining 35 % recovery efficiency with enhanced dynamic performance [17]. Do and Ahn employed hydraulic motors with planetary gearboxes, achieving 73 % regeneration efficiency and extending battery life by 16 % [18]. In mechanical methods, Latas and Stojek integrated a variable-inertia flywheel with a variable-displacement pump/motor in a novel hydromechanical accumulator, enabling multi-mode storage and improving energy density [19]. Li and Zhao combined flywheels, pump/motors, and regenerative valves, achieving 62 % recovery efficiency [20]. Cronk, Van and Strohmaier hybridized hydraulic accumulators with flywheels, reaching a conversion efficiency of 78 % and realizing dual-domain storage of hydraulic and kinetic energy [21].

Despite these significant advances, several challenges remain. independent metering control systems improve efficiency and control performance but involve complex multi-variable coordination, which limits their widespread adoption. Meanwhile, energy recovery techniques often involve multiple conversion stages, high system complexity, and trade-offs between efficiency and cost-effectiveness. Independent metering control and hydraulic-pneumatic energy storage offer complementary advantages in enhancing energy efficiency and control performance, yet their deep integration remains a challenge.

To address this gap, this study proposes a novel pump-valve coordinated and independent metering control system for a three-chamber hydraulic cylinder with hydraulic-pneumatic energy storage in heavy-duty robotic arms. In this system, the energy-storage chamber is directly connected to a hydraulic accumulator, together with a multi-level pressure-adjustable control valve. Through hydraulic-pneumatic balance, the system efficiently stores and utilizes gravitational potential energy under varying operating conditions. The two driving chambers of the cylinder adopt independent metering control principles, combined with a pump-valve coordinated strategy integrating velocity feedforward and position feedback, enabling smooth switching between operating modes to achieve high power density, high performance, and high energy efficiency. Based on theoretical analysis, a multidisciplinary co-simulation and experimental system was developed to investigate the

operating characteristics and energy efficiency of the proposed heavy-duty robotic arm system.

2. SYSTEM PRINCIPLE

The principle of the proposed pump-valve coordinated and independent metering control system with hydraulic-pneumatic energy storage for heavy-duty robotic arms is illustrated in **Figure 2.1**. The system consists of an electrohydraulic power source, an independent metering valve manifold, a three-chamber hydraulic cylinder, a heavy-duty robotic arm, a hydraulic accumulator, and a multi-stage pressure-adjustable valve. The three-chamber hydraulic cylinder includes one energy-storage chamber and two driving chambers, with the two driving chambers designed to have equal effective areas.

The energy-storage chamber of the three-chamber cylinder is directly connected to the hydraulic accumulator via the multi-stage pressure-adjustable valve. Through hydraulic-pneumatic balancing, the self-weight of the robotic arm is compensated, allowing for the efficient storage and utilization of gravitational potential energy [14]. Depending on operating conditions, the energy-storage chamber can also be connected to the electrohydraulic power source or the tank via the adjustable valve to satisfy oil replenishment or pressure release requirements. The two driving chambers are connected to the independent metering valve manifold, enabling fully decoupled control [3]. Furthermore, the manifold is optimized to integrate flow regeneration, allowing direct interconnection between the two driving chambers of the cylinder.

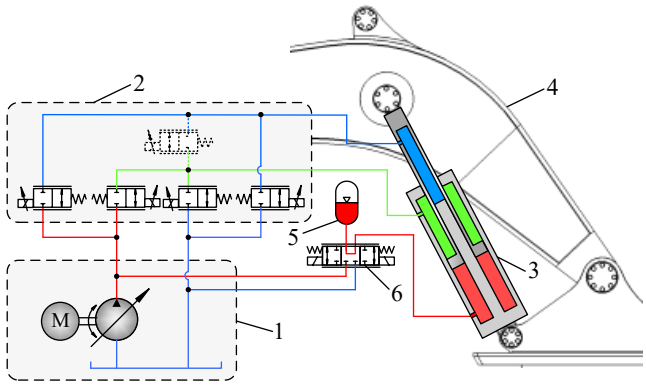

Figure 2.1. Principle of the pump-valve coordinated and independent metering control system with hydraulic-pneumatic energy storage for heavy-duty robotic arms.
1-Electrohydraulic power source,2-Independent metering valve manifold,3-Three-chamber hydraulic cylinder,4-Heavy-duty robotic arm,5-Hydraulic accumulator,6-Multi-stage pressure-adjustable valve.

According to load and operating conditions, the system can switch among different modes by adjusting motor speed, pump displacement, and valve openings [5]. This enables pump-valve coordinated control, independent metering control, energy recovery, and flow regeneration.

2.1. Resistive Extension Mode

As shown in **Figure 2.2**, the resistive extension mode operates in the first quadrant. In this mode, the inlet valve, outlet valve, and pressure-adjustable valve are fully open. The two driving chambers of the three-chamber cylinder are connected to the hydraulic pump and the tank, respectively, while the energy-storage chamber is connected to the accumulator. The cylinder is therefore driven jointly by the hydraulic pump and the accumulator to extend against the external load. The cylinder velocity is controlled through motor speed and pump displacement, with the system operating in pump control mode. This significantly reduces throttling losses while lowering overall flow demand.

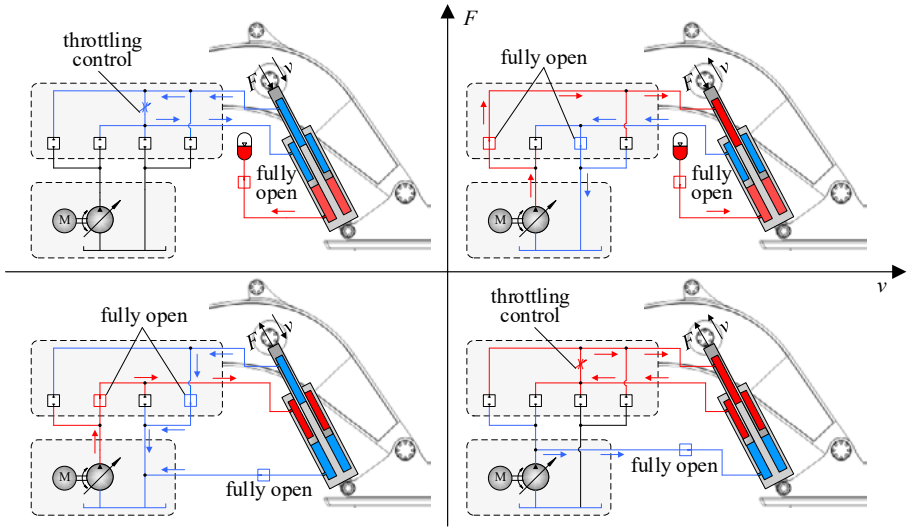

Figure 2.2. Operating modes of the pump-valve coordinated and independent metering control system with hydraulic-pneumatic energy storage for heavy-duty robotic arms.

2.2. Overrunning Retraction Mode

As shown in **Figure 2.2**, the overrunning retraction mode operates in the second quadrant. In this mode, the pressure-adjustable valve is fully open, and the two driving chambers of the cylinder are interconnected through the flow regeneration valve, while the energy-storage chamber is connected to the accumulator. In this condition, the gravitational potential energy of the robotic arm is directly recovered as hydraulic energy and stored in the accumulator. The cylinder velocity is regulated by throttling through the flow regeneration valve, which also mitigates the nonlinear back-pressure characteristic of the accumulator during charging. The system therefore operates in valve control mode with both energy recovery and flow regeneration.

2.3. Resistive Retraction Mode

As shown in **Figure 2.2**, the resistive retraction mode operates in the third quadrant. Similar to the resistive extension mode, the inlet valve, outlet valve, and pressure-adjustable valve are fully open. The two driving chambers are connected to the hydraulic pump and tank, respectively, while the energy-storage chamber is connected to the tank. In this case, the hydraulic pump drives the cylinder to retract against the load. The cylinder velocity is

controlled by adjusting motor speed and pump displacement, and the system operates in pump control mode.

2.4. Overrunning Extension Mode

As shown in **Figure 2.2**, the overrunning extension mode operates in the fourth quadrant. Similar to the overrunning retraction mode, the pressure-adjustable valve is fully open. The two driving chambers are interconnected through the flow regeneration valve, while the energy-storage chamber is connected to the pump. In this case, the hydraulic pump replenishes oil into the energy-storage chamber to prevent cavitation and oscillations. The cylinder velocity is regulated through throttling by the flow regeneration valve, and the system operates in valve control mode.

3. SYSTEM ANALYSIS

A theoretical framework was developed for the proposed system, combining energy-flow analysis with mathematical modeling to support control strategy design.

3.1. Energy Flow Analysis

The energy flow of the pump-valve coordinated and valve-orifice independent control system with hydraulic-pneumatic energy storage for heavy-duty robotic arms is illustrated in **Figure 3.1**. Pump-valve coordinated control reduces throttling losses by switching between pump-control and valve-control modes. In addition, by coordinating motor speed with pump displacement, the pump supply matches actuator demand, minimizing overflow losses. Independent metering control enables independent regulation of pressure and flow in each chamber. This decouples the oil supply and return paths, eliminates simultaneous throttling, and enhances system controllability while reducing losses. Furthermore, return oil is either recovered by the hydraulic accumulator or directly regenerated to another actuator chamber, thereby realizing energy recovery and circulation [8]. Unlike conventional systems, where potential energy is dissipated as heat, the proposed system converts these losses into reusable energy, improving overall efficiency.

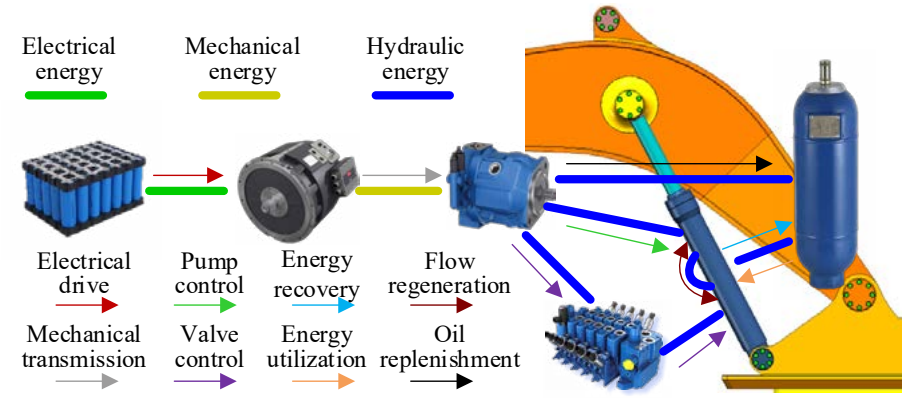

Figure 3.1. Energy flow of the pump-valve coordinated and independent metering control system with hydraulic-pneumatic energy storage for heavy-duty robotic arms.

3.2. System Modeling

Mathematical models are created for the main components and links. These models provide the basis for simulating system performance and evaluating energy efficiency.

The discharge power of the battery is:

$$\mathrm{P_b} = \frac{\mathrm{T_e}\omega_\mathrm{e}}{\eta_\mathrm{e}} \tag{3.1}$$

where P_b is the battery discharge power, T_e is the electromotor torque, ω_e is the electromotor speed, and η_e is the electromotor efficiency.

The torque balance of the electromotor and hydraulic pump is:

$$J_{ep}\dot{\omega}_e + B_{ep}\omega_e = T_e - T_p \tag{3.2}$$

where J_{ep} is the total rotational inertia of the electromotor and pump, B_{ep} is the total viscous damping coefficient, and T_p is the pump torque.

The pump torque is:

$$T_p = \frac{D_p p_p}{\eta_p} \tag{3.3}$$

where D_p is the pump displacement, p_p is the pump pressure, and η_p is the pump efficiency.

The pump flow rate is:

$$Q_p = D_p\omega_e - C_{lp}(p_p - p_t) \tag{3.4}$$

where Q_p is the pump flow, C_{lp} is the pump leakage coefficient, and p_t is the tank pressure.

The valve flow equation is:

$$Q_{v,j} = C_d w_{v,j} x_{v,j}\sqrt{\frac{2\Delta p_{v,j}}{\rho}} \cdot \mathrm{sgn}(\Delta p_{v,j}) \tag{3.5}$$

where $Q_{v,j}$ is the flow through the valve orifice, C_d is the flow coefficient, $w_{v,j}$ is the orifice area gradient, $x_{v,j}$ is the valve spool displacement, $\Delta p_{v,j}$ is the pressure drop across the valve, and ρ is the oil density.

The continuity equation of the three-chamber hydraulic cylinder is:

$$\dot{p}_j = \frac{\beta_e}{V_j}(Q_{v,j} - A_j\dot{x}_c - C_{lc}\Delta p_c) \tag{3.6}$$

where p_j is the chamber pressure, β_e is the effective bulk modulus, V_j is the chamber volume, A_j is the piston area, x_c is the piston displacement, C_{lc} is the cylinder leakage coefficient, and Δp_c is the chamber pressure differential.

The force balance of the three-chamber hydraulic cylinder is:

$$m_{eq}\ddot{x}_c + B_c\dot{x}_c + K_c x_c = A_1 p_1 - A_2 p_2 + A_3 p_3 - F_L \tag{3.7}$$

where m_{eq} is the equivalent mass of piston rod and load, B_c is the viscous damping, K_c is the stiffness, A_1, A_2 are the driving chamber areas with pressures p_1, p_2, A_3 is the energy-storage chamber area with pressure p_3, and F_L is the external load.

The accumulator pressure dynamics are:

$$\dot{p}_3 = \frac{\beta_a}{V_a} Q_a \tag{3.8}$$

where β_a is the effective bulk modulus of the accumulator, V_a is the effective volume, and Q_a is the accumulator flow.

The energy stored in the accumulator is:

$$E_a = \frac{p_y V_y - p_x V_x}{\gamma - 1} \tag{3.9}$$

where E_a is the energy stored in the hydraulic accumulator, p_x, p_y are the pressures of the accumulator, V_x, V_y are the volumes of the accumulator, and γ is the adiabatic index.

4. CONTROL STRATEGY

To further improve system performance and efficiency, a pump-valve coordinated control strategy with velocity feedforward and position feedback regulation is adopted [9]. Velocity feedforward serves as the primary control loop, generating real-time commands for motor speed, pump displacement, and valve opening based on the desired velocity profile. This enables rapid response to target motions. Position feedback is introduced as a compensatory loop: the deviation between desired and actual position is used to correct the feedforward commands, thereby suppressing tracking errors caused by nonlinear factors such as leakage, friction, and fluid compressibility [11].

The motor speed feedforward signal u_{ef} is:

$$u_{ef} = \frac{v_e \cdot A}{D_p \omega_{emax}} \tag{4.1}$$

where A is the piston area of the driving chamber, and ω_{emax} is the maximum motor speed.

The pump displacement feedforward signal u_{pf} is:

$$u_{pf} = \frac{v_e \cdot A}{D_{pmax} \omega_e} \tag{4.2}$$

where D_{pmax} is the maximum pump displacement.

The valve opening feedforward signal u_{vf} is:

$$u_{vf} = \frac{v_e \cdot A}{Q_n} \sqrt{\frac{\Delta p_n}{\Delta p_{v,j}}} \tag{4.3}$$

where Q_n is the rated valve flow at pressure drop Δp_n.

The position feedback signal u_b is:

$$u_b = K_p \left(\int_{t_0}^{t_1} v_e \mathrm{d}t - x_c \right) + K_i \int_{t_0}^{t_1} \left(\int_{t_0}^{t_1} v_e \mathrm{d}t - x_c \right) \mathrm{d}t + K_d \frac{\mathrm{d}\left(\int_{t_0}^{t_1} v_e \mathrm{d}t - x_c \right)}{\mathrm{d}t} \tag{4.4}$$

where K_p, K_i, and K_d are proportional, integral, and derivative gains, respectively.

The overall control input is:

$$U = \left[u_{ef} + u_b, u_{pf} + u_b, u_{vf} + u_b \right] \tag{4.5}$$

This strategy leverages velocity feedforward for rapid response and position feedback for nonlinear compensation. Combined with pump-valve coordinated and energy recovery mechanisms, it enables high-precision control and energy-efficient operation of the heavy-duty robotic arm hydraulic system [21].

5. Simulation Study and Preliminary Experimental Validation

The boom system of a 38-ton hydraulic excavator was selected as a representative case for investigation. A multidisciplinary co-simulation model was developed in SimulationX, incorporating the mechanical, electrical, hydraulic, and control subsystems [10]. To further validate the operating characteristics and energy-saving performance, an experimental platform was constructed on a 38-ton excavator, as shown in **Figure 5.1**.

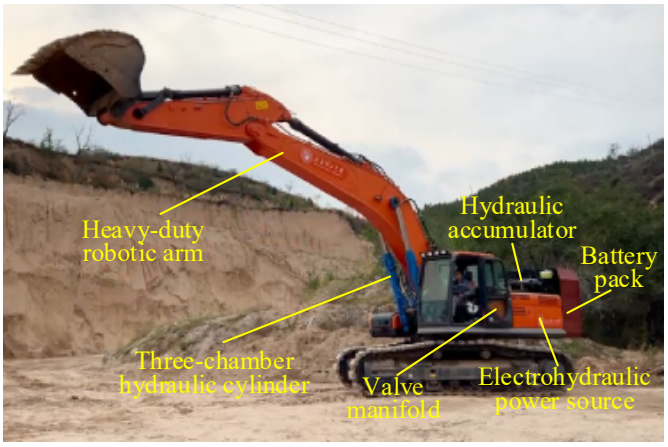

Figure 5.1. Experimental platform of the 38-ton hydraulic excavator.

The displacement and velocity curves of the boom cylinder are illustrated in **Figure 5.2**, where the maximum extension velocity was set to 200 mm/s and the maximum retraction velocity to 400 mm/s. The boom lifted from 2 to 7.5 s, remained stationary from 7.5 to 9 s, and descended from 9 to 12.5 s. As shown in **Figure 5.2**, both the original valve-controlled two-chamber cylinder system and the proposed pump–valve coordinated and independent metering controlled three-chamber cylinder system were able to track the desired displacement with overall smooth velocity profiles. During the initial lifting phase, the energy-storage chamber of the new system was directly connected to the hydraulic accumulator, thereby counterbalancing the boom's gravitational load and overcoming the inertial resistance. With the assistance of the accumulator, the proposed system exhibited faster dynamic response compared to the conventional system. However, the nonlinear charging/discharging characteristics of the accumulator introduced minor velocity fluctuations.

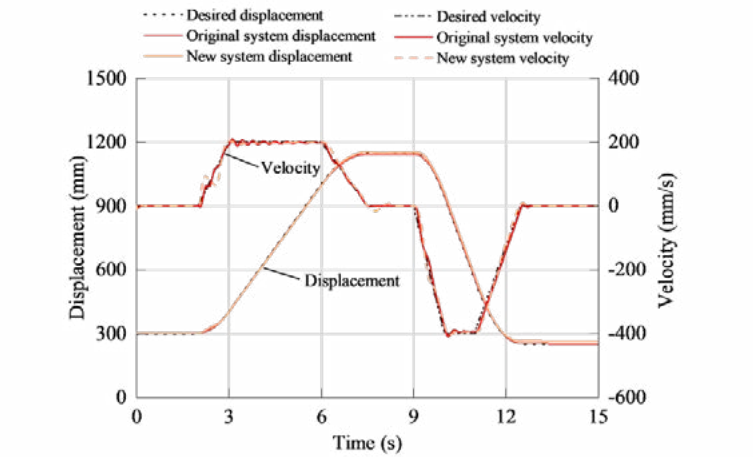

Figure 5.2. Displacement and velocity curves of the boom cylinder.

Figure 5.3 presents the pump output flow and accumulator pressure curves of both systems. For the conventional system, the required pump flow reached 424 L/min during boom lifting and 432 L/min during lowering. In contrast, the proposed system required only 173 L/min during lifting and 357 L/min during lowering. In the lifting phase, the accumulator discharged into the energy-storage chamber of the three-chamber cylinder, with its pressure gradually decreasing as stored energy was directly utilized. During lowering, the energy-storage chamber charged the accumulator, causing its pressure to increase as gravitational potential energy was converted into hydraulic energy and stored for subsequent reuse. Compared with the conventional two-chamber system, the smaller effective areas of the two driving chambers in the proposed three-chamber cylinder allowed a significant portion of the required flow to be supplied by the accumulator, thereby reducing the pump output flow by approximately 38 %.

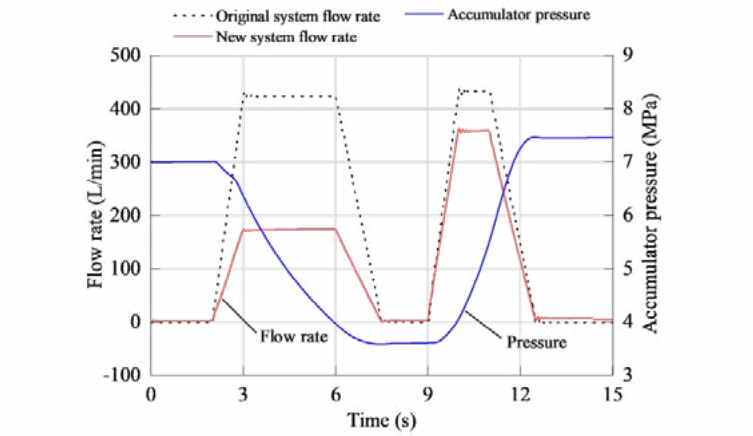

Figure 5.3. Pump output flow and accumulator pressure curves.

Figure 5.4 shows the system power and energy profiles. In the conventional system, the peak power reached 104 kW during lifting and 224 kW during lowering, with a total energy

consumption of 821 kJ. In the proposed system, the corresponding peak powers were reduced to 54 kW and 175 kW, with a total energy consumption of 479 kJ. By integrating chamber-independent valve control and the three-chamber cylinder, the proposed system effectively reduced throttling losses and directly recovered gravitational potential energy. As a result, the peak power demand was reduced by approximately 48 %, the gravitational energy recovery rate reached about 70 %, and the overall energy savings were around 40 %.

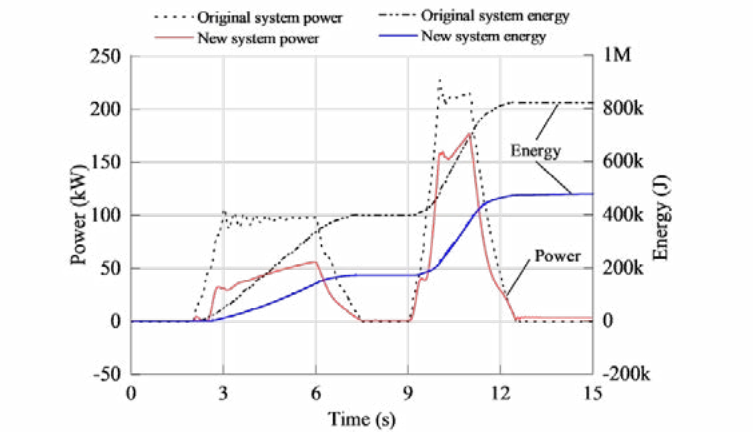

Figure 5.4. System power and energy curves.

6. CONCLUSIONS

A pump–valve coordinated and independent metering control three-chamber hydraulic cylinder system with hydraulic–pneumatic energy storage, together with a velocity feedforward–position feedback regulated pump–valve coordination strategy, has been proposed for heavy-duty robotic arms. Taking the boom system of a 38-ton hydraulic excavator as a representative case, the main conclusions are summarized as follows:

(1) The operating principle of the proposed system was analyzed. The system integrates pump–valve coordination and independent metering control with energy recovery and flow regeneration. It is capable of switching among different operating modes according to working conditions, thereby achieving high power density, superior performance, and improved energy efficiency.

(2) The energy flow of the system was examined, and a comprehensive mathematical model was established. A velocity feedforward–position feedback pump–valve coordination strategy was developed, enabling fast dynamic response through velocity feedforward and nonlinear error compensation through position feedback. Coupled with energy recovery, this strategy further enhances both control performance and system efficiency.

(3) Simulation and experimental validation demonstrated that, under identical working conditions compared to conventional systems, the proposed system reduced pump flow demand by approximately 38 %, peak power by 48 %, and achieved a gravitational energy recovery rate of about 70 %, resulting in overall energy savings of approximately 40 %. Moreover, the system exhibited excellent tracking accuracy and rapid dynamic response without significant pressure or velocity fluctuations.

This study provides a high-performance, high power density, and energy-efficient drive and transmission solution for heavy-duty equipment, offering significant potential for practical implementation and scalability in energy-saving, cost-reduction, and carbon-reduction applications.

Abstract.

This paper investigates how human operators influence the performance of a wheeled excavator. A 16t wheeled excavator with a load-sensing hydraulic system was instrumented with sensors enabling kinematic and hydraulic measurements. Two professional and five non-professional operators executed a standardized 90° dig-and-dump-operation under controlled operating conditions. From the recorded data, three indicators were derived: mean cycle time, simultaneity level of actuator operation and mean hydraulic pump power. The correlation between these indicators was analysed across multiple repetitions performed by each operator. The results highlight the influence of operator behaviour on machine performance.

Keywords. Excavator, mobile machines, mobile hydraulics, operator, duty cycle

1. INTRODUCTION

Improving the energy efficiency of off-highway mobile machinery is a key lever for reducing fuel consumption, operating costs, and emissions in construction and mining. Hydraulic excavators are among the most energy-intensive machine types. While extensive research is conducted on improving component and system efficiency (optimized hydraulic architectures, energy recovery, advanced control strategies etc.), the influence of the human operator on the energetic performance of the machine has received comparatively less attention. Modern excavators offer increasing degrees of automation and assistance, making it important to understand which aspects of operator behaviour most strongly affect performance, and how they interact with the hydraulic system.

This gap is addressed by experimentally studying the influence of different operators on the performance of a wheeled excavator during a standardized load cycle. However, the scope of this work is limited to a 90° dig-and-dump-operation.

2. STATE OF THE ART

While many authors agree that the operator is one of the largest influences on machine performance, rigorous quantitative studies are still relatively scarce, especially for excavators. This section briefly summarizes a selection of existing research on this topic.

All Open Access articles are peer-reviewed, distributed under the Creative Commons Attribution-Non Commercial 4.0 International

Kunze et al. [1] analysed 153 measurements of 7 different operators, ranging from novice to expert level, performing trenching operations with a 20t wheeled excavator. From the gathered data and video analysis they computed the mean cycle time and simultaneity level ("[…] the number of hydraulic cylinders being manipulated through the joystick axes at the same time, averaged over a closed working cycle." [1]). The exact signal-processing steps are not described in detail. They found that cycle time correlates negatively with simultaneity level and used k-means clustering to separate operators into groups (Figure 2.1), that correspond well to their skill level.

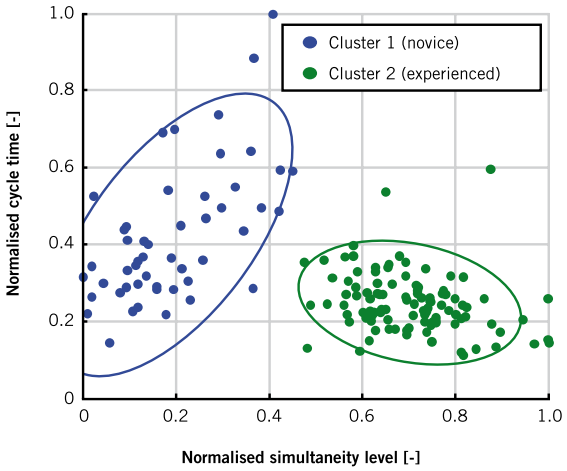

Figure 2.1. Clustering excavator operators by skill level [1]

Mieth et al. [2] extended this approach to 285 trenching cycles and included mean cycle power as an additional feature. Their results indicate that more skilled operators not only achieve higher simultaneity and shorter cycle times, but also higher hydraulic power usage.

Extensive research by *Filla et al.* [3–7] and *Frank et al.* [8, 9] addressed operator interaction with wheel loaders, ranging from development of operator models [3–5], to studies on machine operability (i.e. the ease with which the operator can perform the task) by using psychophysiological measurements (heart rate, finger temperature etc.) [5–7] and operator influence on machine performance [8, 9]. *Frank et al.* [8, 9] performed different loading cycles with 73 operators and measured productivity (moved material per time , t/h), and efficiency (moved material per fuel consumption, t/l). Their results show that for predefined duty cycles, productivity can increase by up to eight times, and fuel efficiency by up to three times for highly skilled operators. One interesting finding from machine operability research is that design changes in components or control logic can unintentionally increase operator workload, worsen bucket handling and reduce fuel efficiency if they conflict with established operator strategies [5].

Sturm [10] used measurements from three excavator operators to validate a developed operator model, but did not systematically analyse the operator influence itself.

Inderelst et al. [11] studied various influences on a 21t crawler excavator, including hydraulic system principle (LS vs. NFC), engine speed, operator (four different operators), and ground conditions. They found that the spread in fuel consumption and digging

performance caused by different operators is comparable in magnitude to changes achieved by hardware or parameter modifications.

Fecke [12] used fleet management telemetry data from nearly 12000 machines (excavators and wheel loaders). His work focusses on deriving standardized duty cycles and reducing operator variability in efficiency measurements.

3. METHODOLOGY

The objective of this study is to quantify the influence of the human operator on the performance of a wheeled excavator. The used methodology is similar to *Kunze et all* [1] and *Mieth et al.* [2].

To this end, a Volvo EW160D wheeled excavator was instrumented with an extensive sensor array and operated by drivers with different experience levels under controlled test conditions.

In detail, the methodology comprises four main elements:

- Test machine and instrumentation: description of the excavator and the additional measurement equipment installed on the hydraulic and mechanical subsystems.
- Test operation and operators: definition of the task and the participating operators.
- Derivation of performance indicators: computation of used hydraulic pump power, simultaneity level of actuator operation, and mean cycle time from the recorded data.
- Assessment of limitations: discussion of constraints and uncertainties of the experimental design and data evaluation.

The following sections describe each element in detail.

3.1. Test Machine

The experiments were conducted using a Volvo EW160D, a 16t wheeled excavator equipped with a load-sensing hydraulic system. The machine remained in its original configuration; no major modifications were made to the drivetrain or the control system. Only measurement equipment was added to enable data acquisition.

3.2. Data Gathering

The excavator was equipped with a range of sensors to capture the relevant hydraulic and kinematic quantities during operation. There is additional measurement equipment installed (for example, optical sensors), these were used for research outside the scope of this work and therefore aren't described here.

3.2.1. Kinematic Measurements

Figure 3.1 schematically depicts the placement of the wire-based linear position sensors on the boom, stick, bucket, and auxiliary boom cylinders. These sensors (S1–S4) measure the extension and retraction of the respective cylinders, enabling the calculation of the linear actuator velocities via numerical differentiation.

In addition, Inertial Measurement Units (IMUs) were mounted on the upper carriage and on the individual components of the excavator arm. These IMUs provide the rotational motion

of the upper carriage and the arm links as well as the inclination, allowing reconstruction of the excavator arm kinematics.

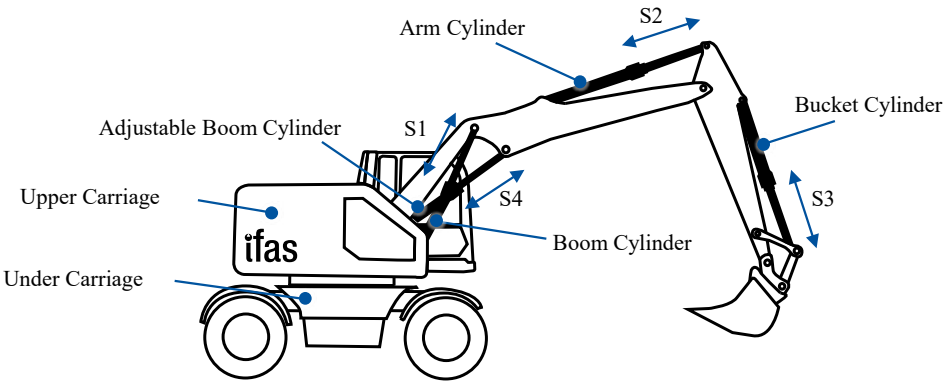

Figure 3.1. Measuring technology mounted on the test machine to record movement

3.2.2. Hydraulic Measurements

Figure 3.2 presents a simplified hydraulic circuit schematic, showing the locations of the sensors integrated into the hydraulic system. Numerous pressure sensors were installed at different points in the hydraulic circuit to measure:

- Actuator chamber pressures (excluding dozer shield and outrigger cylinders)
- Pressures at the main control valve (for the linear actuators)
- Load-sensing pressure p_{LS}
- Supply: Pressure of the main (p_{pump}) and secondary pumps (supply pilot pressure, braking and steering)
- Tank pressure
- Actuator pilot pressures

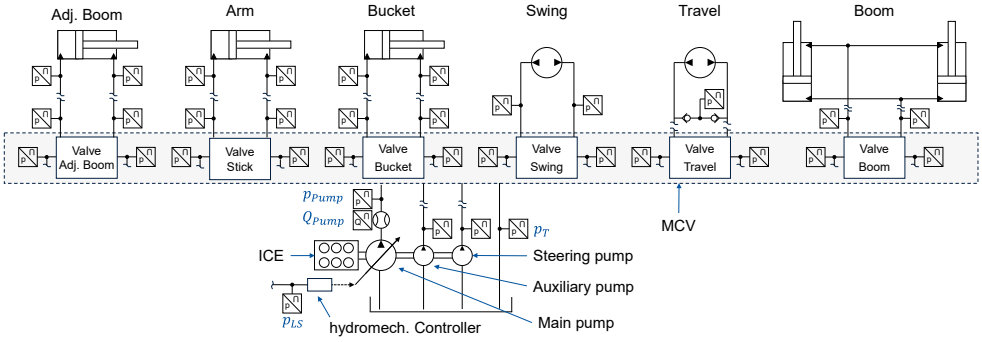

Figure 3.2. Measuring technology mounted to the hydraulic drivetrain

A turbine-type volume flow sensor was installed in the main pump outlet line to measure the pump flow. Note, that this introduces an additional pressure loss in the supply line, that is not present in series machines.

3.3. Performed Operation

Wheeled excavators are versatile machines typically used for digging, trenching, and grading operations [13]. Several defined operations were performed with the test machine during the measurement campaign; however, this paper focuses exclusively on an elevated 90° dig-and-dump-operation.

Figure 3.3 depicts the executed 90° dig-and-dump-operation. Each cycle consists, in simplified form, of:

1. Positioning the bucket at the excavation area
2. Filling the bucket with material
3. Swinging the upper carriage by approximately 90°
4. Dumping the material at the designated dump location
5. Returning to the initial position to start the next cycle

For this operation, the machine was positioned on top of a hill, approximately three meters above ground level. The material was loaded at ground level and dumped at excavator level. All operators performed repeated cycles under comparable conditions.

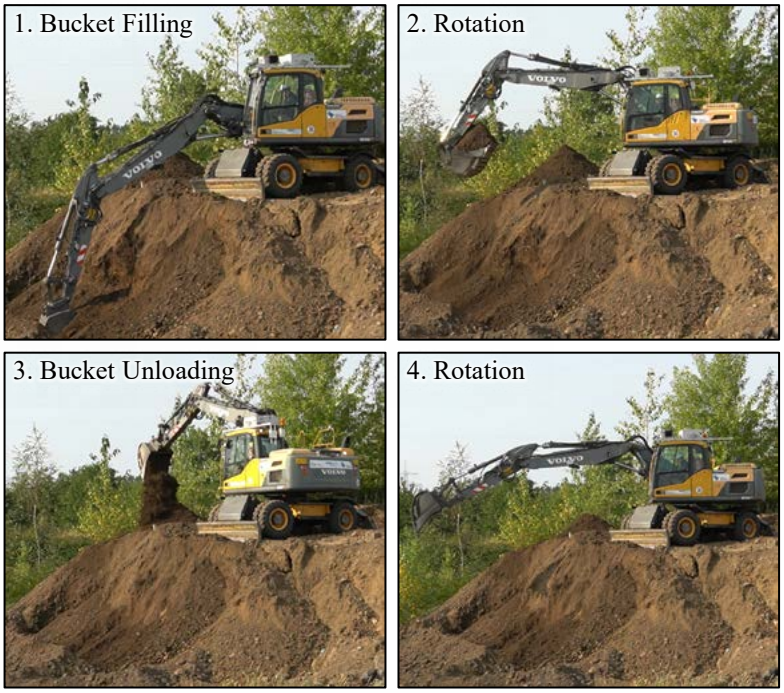

Figure 3.3. Example of performed 90° dig-and-dump-operation

The test series included two operator groups:

- Two professional operators (P1, P2), with substantial prior experience in operating excavators in daily construction work

- Five non-professional operators (NP1–NP5), with varying amounts of experience, ranging from intermediate to novice level

All operators executed the same predefined dig-and-dump-operation using the same machine and test setup (for example positioning), so that differences in performance can be attributed primarily to operator behaviour.

3.4. Calculated System Variables

From the recorded sensor data, several indicators were derived to quantify operator performance:

- Mean Pump power (compare *Mieth et al.* [2])
- Simultaneity level of actuator operation (compare *Kunze et al.* [1])
- Mean cycle time of the 90° dig-and-dump-operation (compare *Kunze et al.* [1])

The following subsections describe each indicator in detail.

3.4.1. Pump Power

Figure 3.5 shows the load-sensing pressure, pump pressure, flow and power for an excerpt of one of the measurements.

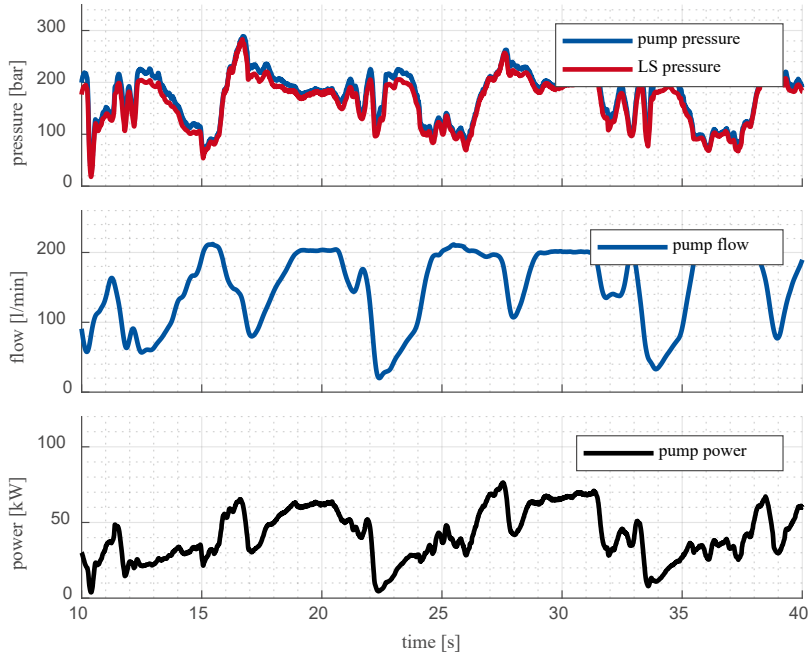

Figure 3.5. LS pressure, pump pressure, flow and power

The pump flow Q_{Pump} can be calculated from recorded impulses of the turbine-type volume flow sensor using a corresponding calibration curve. The instantaneous hydraulic power of

the Pump P_{Pump} is calculated from the pump flow Q_{Pump} and pressure p_{pump} (equation 3.1).

$$P_{Pump} = Q_{Pump} \cdot p_{pump} \qquad (3.1)$$

During the measurement campaign, the pump pressure sensor proved to be unreliable, meaning that for some of the performed measurement the pump pressure value was not available. Instead, the pump pressure is calculated according to equation (3.2),

$$p_{Pump} = p_{LS} + \Delta p_{ls} \qquad (3.2)$$

where p_{LS} is the load-sensing pressure (maximum supply pressure of all active actuators) and Δp_{ls} is the load-sensing pressure difference. In equation (3.2) it is assumed, that Δp_{ls} is a constant offset, however in reality this is not true, as figure 3.6 shows (measurement with intact pump pressure sensor)

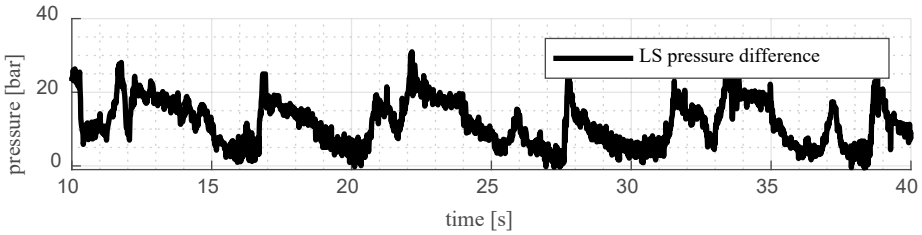

Figure 3.6. LS pressure difference

For the pump pressure calculation, a constant value derived from averaging was used. This introduces a small error in the pump power calculation. A more sophisticated approach would be evaluating the dependency of Δp_{ls} on pump pressure and flow, fit a function to the data und use this as the pump pressure estimation for the affected measurements, but this is outside the scope of this work.

With this approach focussing on pump power, potential operator influences on the total machine energy consumption or fuel consumption that arise from different engine operating points cannot be identified. The analysis is limited to the hydraulic subsystem. Specifically, the operator influence on the hydraulic power demand is captured, while effects related to engine and drivetrain efficiency lie outside the scope of this work.

The mean pump power $P_{Pump,mean}$ can be calculated by averaging P_{Pump} across operation duration.

3.4.2. Simultaneity Level

The simultaneity level, described by *Kunze et al.* [1] quantifies the mean number of actuators that are active in parallel during operation. Since operating several actuators simultaneously requires more coordination, a higher simultaneity level is typically associated with higher operator skill [1]. Within this work, the simultaneity is calculated as follows:

First a binary logic signal (filter) is generated for each actuator i, indicating whether this actuator is actively commanded at time t_n.

Figure 3.7. shows the measured stroke and pilot pressures for the bucket cylinder and the calculated cylinder velocity and activity filter signal for an excerpt of one of the measurements.

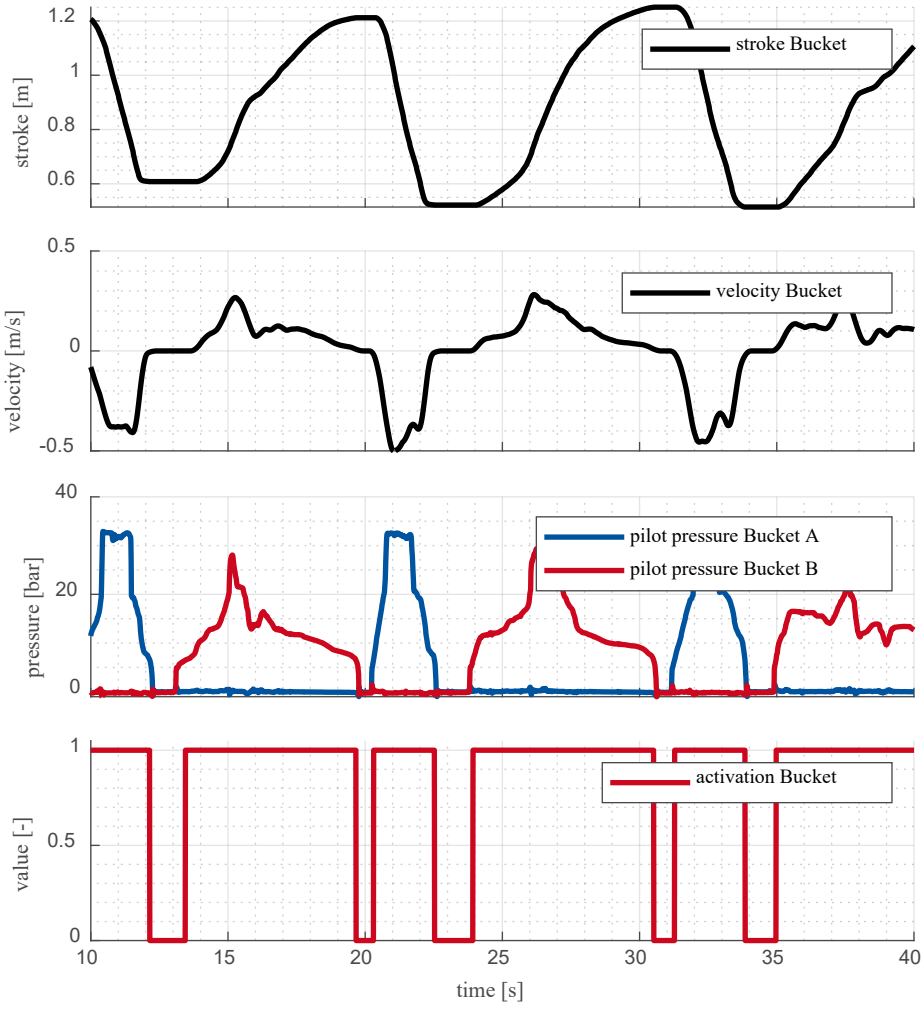

Figure 3.7. Bucket stroke, velocity, pilot pressure and activity filter signal

A straightforward approach would be to decide based on non-zero actuator (angular) velocity. However, numerical differentiation of the measured cylinder strokes introduces noise into the velocity signals. Filtering these velocities can in turn introduce phase delays, which complicates accurate detection of the onset and end of actuator movement.

To avoid this issue, the method used here relies on the pilot pressures of the hydraulic joysticks. The machine is equipped with hydraulic joysticks which pilot pressures actuate the spools of the main control valves. Thus, the pilot pressures $p_{\mathrm{pilotA},i}$ and $p_{\mathrm{pilotB},i}$ for each actuator i can be used as an indicator of operator command.

For each actuator i, the logic filter filter$_i[t_n]$is defined by equation 3.3 as

$$filter_i[t_n] = \begin{cases} 1\,, if\ p_{pilotA,i}[t_n] \geq p_{tresh}\ or\ p_{pilotB,i}[t_n] \geq p_{tresh} \\ 0\,, otherwise \end{cases} \quad (3.3)$$

where $p_{\text{thresh}}$is a pressure threshold determined experimentally. Note that only the main actuators were considered: Boom, Adjustable Boom, Arm, Bucket, Swing, Travel (not used during the evaluated operation). Auxiliary functions like the dozer blade and outriggers were not considered.

The simultaneity level is then obtained from the individual filters of all considered actuators by addition at each time step and then averaging over the entire observation period:

$$\text{simultaneity level} = \text{mean}(\textstyle\sum_i filter_i) \quad (3.4)$$

This yields the average number of actuators that are commanded simultaneously during the task.

3.4.3. Cycle Time

Cycle time is used in this study as a proxy for operator productivity. A more precise metric would be measuring the productivity directly in t/h, obtained by weighing the moved material and relating it to the working time. However, such measurements are beyond the scope and resources of this work.

All test operations were recorded on video. The number of completed buckets (i.e., cycles) was determined manually by reviewing the footage. For each operator and test run, the mean cycle time $t_{cycle,mean}$ was calculated with equation (3.5) as

$$t_{cycle,mean} = \frac{t_{eff}}{N_{buckets}} \quad (3.5)$$

where t_{eff} is the total effective working time and N_{buckets} is the number of counted buckets. Only successful cycles with a clearly full bucket were counted. This choice intentionally penalizes poor bucket filling, as cycles with low bucket fill would reduce the achievable t/h productivity and are therefore not treated as equivalent to full cycles. Non-productive pauses within were excluded from the total effective working time by cutting these intervals during the timing evaluation. In this way, the resulting mean cycle time reflects the net time required by each operator to perform one productive dig-and-dump-operation under the given test conditions.

3.5. Limitations

The methodology employed in this study is subject to several limitations and potential sources of uncertainty that must be considered when interpreting the results. First, the influence of operator fatigue and the sequencing of the different tests was not systematically controlled or analysed. Possible learning effects, warm-up effects, or performance degradation over time may therefore affect the measured performance, but investigating these effects in detail would require a substantially more extensive experimental design and is beyond the scope of this work.

Second, the characteristics of the excavated material were not captured. Neither the mass of the excavated material nor other properties like its moisture content was measured. The material was not uniform; it consisted mostly of soil with varying amounts of rubble.

Variations in density, cohesion, and moisture may influence digging resistance and thus the required hydraulic power and achievable productivity. Consequently, some portion of the variability in the results may be attributable to changing material conditions rather than purely to operator behaviour.

Third, the number of repetitions per operator and the total number of participating operators is relatively low. This limited sample size restricts the statistical robustness of the findings and makes it difficult to fully average out day-to-day performance fluctuations of individual operators. The results should therefore be interpreted as indicative trends rather than as statistically rigorous population estimates.

In addition, the determination of cycle times and bucket counting was carried out manually by reviewing video recordings. This process is inherently prone to human error. Although care was taken to ensure a consistent procedure, small inaccuracies cannot be ruled out.

Moreover, the chosen performance indicators simultaneity level and cycle time primarily describe the operator's handling of the machine during the active working phases. As previous work by the authors has shown [14]–[16], the machines spent a substantial proportion of the shift on typical road construction sites in idle, and the time share of different operations may fluctuate heavily from day to day. Consequently, depending on the type of construction site, the derived indicators may have limited explanatory power with respect to the operator's overall daily productivity. The results are likely more representative for quarry-like sites or other applications with relatively constant, repetitive operations than for urban road construction sites with highly variable tasks.

The dig-and-dump-operation used in the tests represents a simplified, standardized duty cycle that does not fully reflect the variability and irregularity of real-world operation. Instead, the focus and strength of the present methodology lies in comparing relative differences between operators under controlled, reproducible conditions, with particular emphasis on the hydraulic subsystem.

4. RESULTS

This chapter presents the results for the 90° dig-and-dump-operation. For each operator, the three calculated indicators mean cycle time, simultaneity level and mean pump power were evaluated. Pairwise relationships between these indicators are analysed using scatter plots (Figures 4.1–4.3) and the Pearson correlation coefficient r, which measures the linear association between two variables [17].

Figure 4.1 shows the mean cycle time and simultaneity level. A strong, negative correlation is observed ($r = -0.86$), measurements performed by operators with higher simultaneity levels achieve shorter cycle times. The two professional operators (P1, P2) lie close together, combining the lowest cycle times with the highest simultaneity levels. The non-professional operators (NP1–NP5) are more widely scattered, with generally lower simultaneity and longer cycles. NP1, who has the most experience among the non-professionals, approaches the region occupied by P1 and P2. This supports the interpretation of simultaneity level as an indicator of operator skill. It also confirms, that this effect found during trenching operation in [1, 2] appear to apply to 90° dig-and-dump-operation as well.

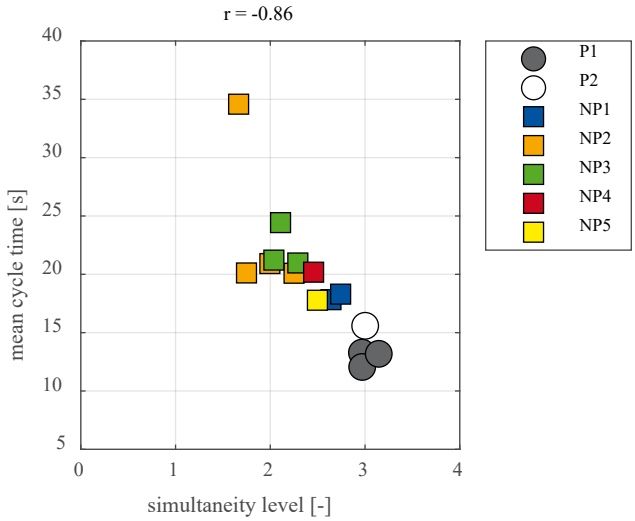

Figure 4.1. mean Cycle time and simultaneity level

Figure 4.2 plots mean cycle time against mean pump power. Here, a moderate negative correlation is found ($r = -0.49$). Overall, faster operation comes with a higher mean pump power, but the relationship is not strong. Further analysis can be conducted. This result aligns with results found during from trenching operations reported in [2]. An approach could be to analyse the net used power and system efficiency to find how effective the machines power is used by differently skilled operators.

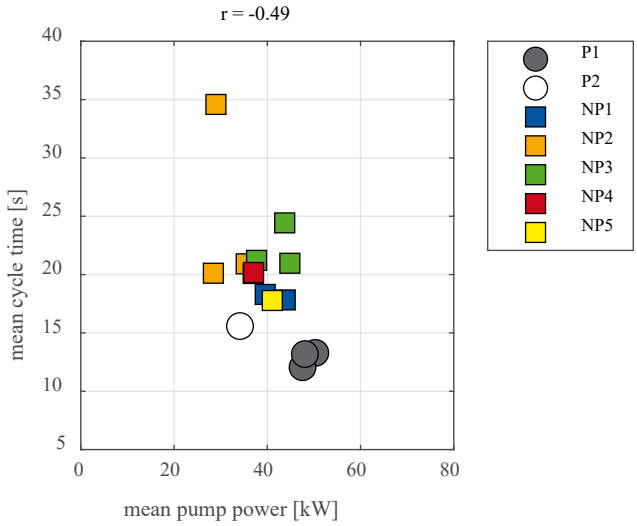

Figure 4.2. mean Cycle time and mean Pump Power

Figure 4.3 shows simultaneity level as a function of mean pump power. In this case, a moderate positive correlation is obtained ($r = 0.7$). Operators with higher simultaneity

levels tend to exhibit higher mean pump power, which is consistent with the expectation that more frequent parallel actuator operation increases hydraulic power demand. This result corresponds to a similar trend found during trenching operation in [2].

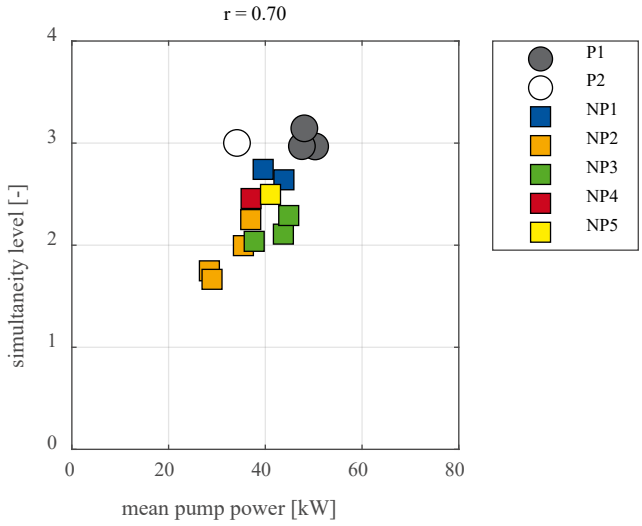

Figure 4.3. Simultaneity level and mean pump power

In summary, simultaneity level correlates strongly with cycle time and with mean pump power, whereas mean pump power and cycle time are only moderately related in this task.

5. Conclusion and Outlook

This work showed that operator behaviour has a clear and measurable influence on the performance of a wheeled excavator during a standardized 90° dig-and-dump-operation. Using an instrumented Volvo EW160D and a mixed group of professional and non-professional operators, it was possible to relate objective indicators such as cycle time, pump power and a pilot-pressure-based simultaneity level to differences in how the machine is handled. In particular, the simultaneity level proved to be a useful proxy for operator skill, capturing how effectively actuators are coordinated.

Building on these findings, future work should move from power-based to energy-based evaluation by relating input energy at the pump to useful work at the actuators, enabling a more direct assessment of hydraulic efficiency under different operators and load cycles. It is also promising to extend the analysis to the additional recorded operations to understand how robust the identified relationships are across varying tasks. In the longer term, the indicators could be used in operator training or assistance systems and help improve both productivity and energy efficiency of mobile hydraulic machines in real-world applications.

Biographies

Bernhard Sender received the bachelor's degree in mechanical engineering and the master's degree in product development from RWTH Aachen University. Since 2023, he is working as a research associate at the Institute for Fluid Power Drives and Systems (ifas) at RWTH Aachen University. His research focusses on hydraulic systems in mobile machines.

Johannes Sprink studied mechanical engineering at RWTH Aachen University. Since 2021, he has been a research associate at the Institute for Fluid Power Drives and Systems (ifas) at RWTH Aachen University. Johannes is the group leader of the Mobile Machines research group, which focuses on fluid-mechatronic and information technology innovations at the machine level. He investigates greenhouse gas emissions in the fluid power industry; his research also includes analysing operating cycles of hydraulic excavators.

Prof. Katharina Schmitz studied mechanical and chemical engineering at RWTH Aachen University and Carnegie Mellon University, Pittsburgh (USA) and graduated 2015 as Dr.-Ing. at RWTH Aachen University. Since 2018, she is full professor at RWTH Aachen University and director of the Institute for Fluid Power Drives and Systems (ifas). In addition, she is Vice Dean of the Faculty for Mechanical Engineering at RWTH Aachen, a position she holds since 2020. Prof. Schmitz's awards and honors include several best paper awards and 2023 IMechE Joseph Bramah Medal award.

Optimal preliminary design of electro-mechanical actuators over drive-cycle for mobile machinery

Róger Mateus Sehnem, Samuel Kärnell and Liselott Ericson

Linköping University, roger.mateus.sehnem@liu.se

Abstract.

Electromechanical actuators (EMAs) are increasingly being considered as replacements for hydraulic systems in mobile machinery due to electrification trends and efficiency requirements. Conventional EMA design approaches select representative steady-state operating points from the drive cycle, potentially yielding suboptimal designs when systems must operate over wide dynamic ranges. This paper explores the benefits of incorporating full drive-cycle dynamics into the preliminary design process using a bilevel optimization framework. A simplified hypothetical crane drive cycle demonstrates the approach by comparing dynamic optimization against the more conventional static multi-design-point optimization. Despite a higher computational cost per optimization round, the dynamic approach consistently outperformed the static approach, achieving not only copper losses that are four times lower than using the static optimization approach, but also smaller diameter, and superior trajectory tracking while respecting voltage and current limits. It is shown that the performance advantages persist when evaluated on drive cycles outside the optimized one. While the simplified models (neglecting iron losses, thermal limits, and saturation effects) limit direct applicability to real designs, the results demonstrate significant potential benefits of drive-cycle-aware optimization for preliminary EMA design in mobile machinery applications.

Keywords. Optimization, EMA, PMSM, Mobile machines, Optimal control.

1. Introduction

With the current global trend towards electrification and stricter regulations on emissions, mobile machinery is being pushed towards being electrically driven. Since current battery technology has lower power density than traditional fuel-driven solutions, the efficiency of the actuators is now becoming a much more relevant design goal. This is one of the reasons why electromechanical actuators (EMAs) are now being considered as, to some extent, replacements for hydraulics in mobile machinery.

Designing an EMA can be framed as a complex optimization problem that needs to consider several physical domains. Optimality in this context can often be framed as maximizing the power density of the actuator and its efficiency while ensuring that the relevant constraints are met or not exceeded, e.g., maximum current and desired power. Most systems in engineering can be precisely described by nonlinear differential equations. Dealing with differential equations in preliminary design is, however, difficult, and it is a common practice to simplify the design process by considering only static or steady-state behavior. To this end, the designer needs to

All Open Access articles are peer-reviewed, distributed under the Creative Commons Attribution-Non Commercial 4.0 International

choose a design point that is representative of the system's operation range. In cases where the system operates in a wide range of conditions, as in EMAs for mobile machinery, this choice is by no means trivial, and this approach can lead to suboptimal designs.

In reality, the designer is either attempting to optimize the performance of the system over the entire drive cycle on which the EMA will operate or a significant reference drive cycle exemplified for a lorry crane application in [1]. In any case, for drive cycles that require significant transient behavior of the system, it is reasonable to expect that considering the full dynamics of the system can lead to better designs than using steady state approaches. The main goal of this paper is to show that this is indeed the case.

1.1. *Previous Work*

Considering more of the drive cycle in design has been proposed by several authors in different ways. For instance, [2] proposed a convex model fitted on high-fidelity simulation data to allow efficient convex optimization and global optimum results. The approach considers a simplified dynamical model, thus attempting to be more representative of the system behavior. Another approach is to somehow aggregate several different steady state operating points into some that are then used to design the electrical machine, this is the approach of [3], where the energy center of gravity (ECG) of the torque-speed plot is used to create 8 clusters, which are then weighted according to their energy usage in the drive cycle and then have their centers used as steady state design points. Another example of this approach is [4], which uses a multi-objective optimization approach to optimize the design of a PMSM considering multiple operating points and uses simple formulas to estimate the transient losses in the optimization problem. However, all those methods have strong simplifying assumptions about the true dynamics of the system.

The main challenge in the attempt to consider the full dynamics of the system in the design process is that the output of the system depends on the control input, and if one chooses a suboptimal control strategy, the performance of the system will be underestimated. The problem of finding an optimal control strategy for a given system is known as an optimal control problem (OCP), which is known to be numerically difficult to solve in the nonlinear case [5, 6]. Considering the optimization of the system parameters together with the control inputs is thus expected to be an even more sensitive and hard problem.

However, when one considers linear systems with quadratic cost functionals in the state deviations and control inputs, known as the Linear Quadratic Regulator (LQR) problem [5, 6], the problem has an analytical solution. Although the LQR problem is designed for linear systems, it can be used to design controllers for nonlinear systems with the usage of some form of linearization technique, giving a controller that in practice works well for a wide range of operating conditions in many applications.

1.2. *Contribution*

To address the conjoint optimization of an EMA and the solution of the OCP in a sensible way, in this work, a two-step optimization process is used. The lower problem is a standard OCP, which, for a given system, finds the optimal control inputs that minimize a relevant cost functional. The upper problem then chooses the system parameters to minimize a cost function that penalizes energy loss, tracking error and the size of the EMA, which is evaluated by solving the lower OCP. Dividing the optimization as described is known as bilevel optimization and has been used in several applications [7]. In this way, it is possible to directly consider the full dynamics of the system in the design process. To simplify the OCP problem, a standard field-oriented control with feedback linearization and P controllers for the currents and velocity and a PI controller for the position are used. The controller gains are chosen using the LQR method on an error system, allowing the efficient solution of the internal OCP for a given set of system parameters.

As a proof of concept, this paper explores the potential benefits of considering the full dynamics of the system in the preliminary design of an EMA for a simplified hypothetical loader crane drive cycle. A standard PMSM model from [8] with parameters calculated from physical dimensions is considered, together with very simple models for the gears and ball screw. The approach is then compared to using only some relevant design points considering only the steady-state dynamics of the system, analogous to the approach of [4]. The PMSM model used in this work neglects several effects that are present in real machines, such as saturation, thermal limits, eddy currents, hysteresis losses and non-sinusoidal magnetic field distributions. The same can be said about the mechanical components, their models are overly simplified to be useful in the design of a real EMA. However, the models are considered to be sufficient for the purpose of this work, which is to explore the potential benefits of considering the full dynamics of the system in the design of an EMA for a hypothetical drive cycle.

The results show that the EMA optimized considering the full system dynamics dissipates four times less energy to follow the design trajectory, all while being able to respect the electrical constraints and having the desired geometry.

2. Electro-mechanical Actuator Model

The EMA model consists of a PMSM, a gearbox and a ball screw and is shown schematically in Figure 2.1. In the following subsections, the model of each component is described in detail.

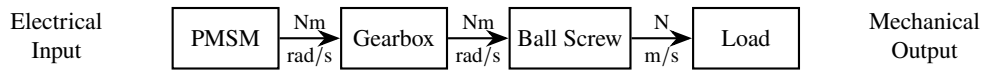

Figure 2.1 Schematic representation of the EMA system considered. The PMSM drives a ball screw through a gearbox, which then moves a load linearly. The electrical subsystem is represented on the left, while the mechanical subsystem is represented on the right. The arrows indicate the power flows in the system.

2.1. *Permanent Magnet Synchronous Machine*

The PMSM model is traditionally composed of electro-mechanical constants that are usually obtained from experimental data or finite element analysis. In this work, however, the PMSM parameters are estimated from simplified physical considerations of the motor geometry and magnetic field distribution. This not only allows a more direct connection between the physical dimensions of the motor and its performance but also has very low computational complexity. The model follows the developments in [8] closely, with the additional parametrization for the torque constant K_m and stator resistance R_S from physical dimensions, which are not directly given in the reference. The PMSM model assumes a sinusoidal magnetic field distribution, no saturation, eddy current or hysteresis losses and is given by the following set of differential equations in the stator reference frame [8]:

$$\begin{aligned} \frac{d\theta_r}{dt} &= \omega, \\ J\frac{d\omega}{dt} &= K_m\left(-i_{Sa}\sin(n_p\theta_r) + i_{Sb}\cos(n_p\theta_r)\right) - f(\omega) - \tau_L, \\ L_S\frac{di_{Sa}}{dt} &= -R_S i_{Sa} + K_m\sin(n_p\theta_r)\omega + u_{Sa}, \\ L_S\frac{di_{Sb}}{dt} &= -R_S i_{Sb} - K_m\cos(n_p\theta_r)\omega + u_{Sb}. \end{aligned} \tag{2.1}$$

where θ_r is the rotor position, ω is the rotor angular velocity, i_{Sa} and i_{Sb} are the stator currents in phases a and b, u_{Sa} and u_{Sb} are the stator voltages in phases a and b, J is the rotor inertia,

K_m is the motor torque constant, n_p is the number of pole pairs. L_S is the stator inductance, R_S is the stator resistance, $f(\omega)$ is a friction model and τ_L is the load torque.

The derivation of L_S closely follows the developments in [8]. Both L_S and K_m assume a full-pinched winding, but the model can be adapted to short-pinched or long-pinched windings by adding the winding factor κ_w to the equations for L_S and K_m.

2.1.1. *Stator Inductance from Physical Dimensions*

For the parameters calculation, assume that the magnetic field distribution in the air gap is approximated by a sinusoidal distribution for each phase. Following [8], the total magnetic field in the air gap due to the stator currents is then given by

$$\boldsymbol{B}_s(i_{Sa}, i_{Sb}, r, \theta) = \boldsymbol{B}_{Sa} + \boldsymbol{B}_{Sb} = \frac{\mu_0 N_s r_r}{2g} \frac{1}{r} \left(i_{Sa} cos(\theta) + i_{Sb} \sin(\theta)\right) \boldsymbol{e}_r, \tag{2.2}$$

where μ_0 is the permeability of free space, N_s is the number of turns per phase, r_r is the rotor radius, g is the air gap length, r is the radial position in the air gap, θ is the angular position in the air gap, and $\boldsymbol{e}_r$ is the radial unit vector. The magnets in the rotor of the PMSM are distributed such that the magnetic field in the air gap generated by the rotor is also sinusoidal, thus

$$\boldsymbol{B}_R = B_m \frac{r_r}{r} \cos(\theta - \theta_r) \boldsymbol{e}_r, \tag{2.3}$$

where B_m is the peak magnetic field in the air gap generated by the rotor.

The total flux linkage of the stator describes how much magnetic flux flows through the stator windings and is a useful quantity to calculate K_m and L_S. It is defined as

$$\lambda_{Sa}(\boldsymbol{i}_s, \theta_R) = {}_s\lambda_{Sa}(\boldsymbol{i}_s, \theta_r) + {}_r\lambda_{Sa}(\theta_r) = \int_{\mathbb{L}_{Sa}} \boldsymbol{B}_s d\boldsymbol{S} + \int_{\mathbb{L}_{Sa}} \boldsymbol{B}_R d\boldsymbol{S}, \tag{2.4}$$

where $\boldsymbol{i}_s = \begin{bmatrix} i_{Sa} & i_{Sb} \end{bmatrix}^T$ and $\mathbb{L}_{Sa}$ is a set of surfaces that envelops all stator windings of phase a. To calculate ${}_s\lambda_{Sa}$, one calculates the flux in a single loop of the stator and then integrates over all loops. If the given loop is at an angle θ from the a phase of the stator, then its other side is, considering full-pinched windings, at $\theta - \pi$. Thus, the flux in the cylindrical surface is given, for the a phase of the stator, by

$${}_s\phi_{Sa}(\boldsymbol{i}_s, \theta) = \int_{\theta-\pi}^{\theta} \int_0^{l_1} \boldsymbol{B}_S(\boldsymbol{i}_s, \theta)|_{r_s} \boldsymbol{e_r} \cdot (r_s d\theta dz \boldsymbol{e_r}) = \frac{\mu_0 r_r l_1 N_s}{g} \left(i_{Sa} \sin(\theta) - i_{Sb} \cos(\theta)\right). \tag{2.5}$$

The flux linkage ${}_s\lambda_S$ between θ and $\theta + d\theta$ is then given by multiplying by turns density distribution, as

$$d\,{}_s\lambda_{Sa} = {}_s\phi_{Sa}(\boldsymbol{i}_s, r, \theta) \frac{N_s}{2} \sin(\theta) d\theta = \frac{\mu_0 r_r l_1 N_s}{g} \left(i_{Sa} \sin(\theta) - i_{Sb} \cos(\theta)\right) \frac{N_s}{2} \sin(\theta) d\theta, \tag{2.6}$$

where the $\frac{N_s}{2} \sin(\theta)$ term comes from the winding distribution in the stator. Integrating Equation (2.6) from 0 to π gives the total flux linkage in phase a of the stator due to the stator magnetic field, which is given by

$${}_s\lambda_{Sa}(\boldsymbol{i}_s) = \frac{\mu_0 r_r l_1 \pi N_s^2}{4g} i_{Sa} = \frac{\mu_0 l_1 l_2 \pi N_s^2}{8g} i_{Sa} \coloneqq L_S i_{Sa}, \tag{2.7}$$

where $l_2 = 2r_r$ is the stator diameter. Equation (2.7) defines the stator inductance L_S. The flux linkage in phase b of the stator can be calculated in a similar way, giving the same result for L_S.

2.1.2. *Torque Constant from Physical Dimensions*

To get the rotor flux linkage, it is important to account for the leakage κ in the magnetic field. Following [8], the rotor flux linkage at the stator side is given by modifying Equation (2.3) to

$$\boldsymbol{B}_R|_{r_s} = \kappa B_m \frac{r_r}{r_s} \cos(\theta - \theta_r)\boldsymbol{e}_r, \tag{2.8}$$

where r_s is the stator radius.

To calculate ${}_r\lambda_{Sa}$, the same approach as in the stator flux linkage is used. The flux in a single loop of the stator at angle θ is given by

$${}_r\phi_{Ra} = \int_{\theta-\pi}^{\theta}\int_0^{l_1} \kappa B_m \frac{r_r}{r_s}\cos(\theta - \theta_r) r_s dr dz = 2\kappa B_m l_1 r_r \sin(\theta - \theta_r). \tag{2.9}$$

With that is possible to write the rotor flux linkage differential, using the sinusoidal winding for the stator phase a, as

$$d\,{}_r\lambda_{Sa} = \phi_{Ra}\frac{N_S}{2} sin(\theta) d\theta = \kappa B_m l_1 r_r N_S \sin(\theta - \theta_r) sin(\theta) d\theta. \tag{2.10}$$

Integrating Equation (2.10) from 0 to π gives

$${}_r\lambda_{Sa} = \int_0^{\pi} \kappa B_m l_1 r_r N_S \sin(\theta - \theta_r) sin(\theta) d\theta = \kappa B_m l_1 r_r N_S \frac{\pi}{2}\cos(\theta_r) \coloneqq K_m \cos(\theta_r), \tag{2.11}$$

which defines the torque constant K_m.

2.1.3. *Stator Resistance from Physical Dimensions*

The stator resistance is greatly defined by the length of the wire used in the winding, which greatly depends on how it is wound. Figure 2.2 shows how one loop is wound in the stator.

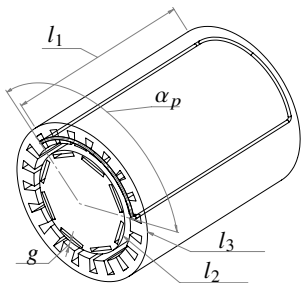

Figure 2.2 3D view of the PMSM with the stator and rotor, showing the stator length l_1, stator outer diameter l_3, stator inner diameter l_2, air gap g and winding with pitch angle α_p.

Figure 2.2 shows a single loop of winding. This winding is made with a wire of diameter ϕ_w, and it is of a distributed winding type with pitch angle α_p. Assuming no skin and proximity effects, the resistance R_S of the stator winding can be estimated from the total length l_s of wire used in the stator, its cross section S_s and the electrical resistivity of the wire $\rho_{e,w}$ using

$$R_S = \frac{\rho_{e,w} l_s}{S_s}. \tag{2.12}$$

In a distributed winding stator, the total length of wire l_s is given by the arc made by the angle α_p, which is assumed to be at the stator's inner diameter l_3, together with the length of wire needed to traverse the stator's length l_1. Thus, the total length of wire is given by

$$l_s = (l_3\alpha_p + 2l_1) N_S n_p n_f, \tag{2.13}$$

where n_f is the number of phases, l_3 is given by

$$l_3 = l_2 + 2g. \tag{2.14}$$

Thus, the resistance of the stator winding is fully defined by the physical dimensions of the motor as

$$R_S = \frac{(l_3\alpha_p + 2l_1)N_S n_p n_f \rho_{e,w}}{S_s}. \tag{2.15}$$

2.2. *Gearbox and Ball Screw*

The gearbox and ball screw mechanisms are modeled in a very simplified way, assuming a constant efficiency η_g and η_{bs} for the gearbox and ball screw, respectively. Each of the mechanisms is modeled as a simple torque and speed transformation, given by

$$\begin{aligned} \tau_{out} &= \eta_g G \tau_{in}, \\ \omega_{out} &= \frac{\omega_{in}}{G}, \end{aligned} \tag{2.16}$$

for the gearbox, where G is the gear ratio, τ_{in} and ω_{in} are the input torque and speed, respectively, and τ_{out} and ω_{out} are the output torque and speed, respectively. The ball screw is modeled in a similar way, given by

$$\begin{aligned} F_{out} &= \eta_{bs} \frac{2\pi}{p} \tau_{in}, \\ v_{out} &= \frac{p}{2\pi} \omega_{in}, \end{aligned} \tag{2.17}$$

where p is the pitch of the ball screw, τ_{in} and ω_{in} are the input torque and speed, respectively, and F_{out} and v_{out} are the output force and speed, respectively.

3. CONTROLLER

To be able to evaluate the performance of the EMA over the drive cycle, a control strategy that allows the EMA to follow the desired trajectory needs to be defined. This can be achieved by following [8] and using a standard field-oriented control with feedback linearization, P controllers for the currents and velocity and a PI controller for the position. The controller gains are in turn chosen using the LQR method, allowing the efficient computation of the optimal controller gains for a given set of system parameters.

3.1. *Field-oriented Control*

The field-oriented control (FOC) is a widely used control strategy for PMSMs, which allows decoupling of the torque and flux control. The FOC is based on the transformation of the stator currents and voltages from the stationary reference frame to the rotating reference frame, which is aligned with the rotor magnetic field, known as the d-q reference frame.

To transform Equation (2.1) to the d-q reference frame, one simply rotates the stator currents and voltages by the electrical angle $n_p\theta$ using the counter-clockwise rotation matrix [8]. Applying the transformation to the PMSM model given by Equation (2.1), resulting in the

following equations in the d-q reference frame

$$\begin{aligned} L_S \frac{di_d}{dt} &= -R_S i_d + n_p L_S \omega i_q + u_d, \\ L_S \frac{di_q}{dt} &= -R_S i_q - n_p L_S \omega i_d - K_m \omega + u_q, \\ J \frac{d\omega}{dt} &= K_m i_q - f(\omega) - \tau_L, \\ \frac{d\theta}{dt} &= \omega, \end{aligned} \tag{3.1}$$

where i_d and i_q are the d-axis and q-axis stator currents, respectively, and u_d and u_q are the d-axis and q-axis stator voltages, respectively.

For a given reference trajectory $r(t) = \begin{bmatrix} \theta_{\text{ref}}(t) & \omega_{\text{ref}}(t) & \alpha_{\text{ref}}(t) \end{bmatrix}^T$, it is possible to calculate the reference state and control inputs trajectories needed to follow the reference trajectory. By considering its steady-state condition, it is possible to obtain the $i_{d,\text{ref}}$ that maximizes the torque, which in turn allows the obtention of $i_{q,\text{ref}}$ from ω_{ref} and α_{ref}. With those, the reference voltages needed to follow the $r(t)$ directly follow.

With the reference system dynamics and control inputs, it is possible to create error dynamics by subtracting the reference dynamics from the system dynamics in Equation (3.1). This results in a nonlinear system that can be linearized using the following feedback linearization [8]

$$\begin{aligned} u_d &= -n_p L_S \omega i_q + u_{d,\text{ref}} + n_p L_S \omega_{\text{ref}} i_{q,\text{ref}} - L_S v_d, \\ u_q &= n_p L_S \omega i_d + u_{q,\text{ref}} - n_p L_S \omega_{\text{ref}} i_{d,\text{ref}} - L_S v_q, \end{aligned} \tag{3.2}$$

where v_d and v_q are the new control inputs for the error dynamics and the variables with subscript *ref* are the reference values. Using Equations (3.2) in the error dynamics results in a linear system that is amenable to standard linear control techniques.

To eliminate the steady-state error, an integrator state for the position error is introduced, $e_z = \int e_\theta dt$, which gives the augmented error state vector $\boldsymbol{e} = \begin{bmatrix} e_{i_d} & e_{i_q} & e_\omega & e_\theta & e_z \end{bmatrix}^T$. The augmented error dynamics is then given by

$$\frac{d\boldsymbol{e}}{dt} = \begin{bmatrix} -\frac{R_S}{L_S} & 0 & 0 & 0 & 0 \\ 0 & -\frac{R_S}{L_S} & -\frac{K_m}{L_S} & 0 & 0 \\ 0 & \frac{K_m}{J} & -\frac{f'(\omega)}{J} & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 \end{bmatrix} \boldsymbol{e} + \begin{bmatrix} \frac{1}{L_S} & 0 \\ 0 & \frac{1}{L_S} \\ 0 & 0 \\ 0 & 0 \\ 0 & 0 \end{bmatrix} \boldsymbol{v}, \tag{3.3}$$

where $\boldsymbol{v} = \begin{bmatrix} v_d & v_q \end{bmatrix}^T$, for which a state feedback controller can be designed using the LQR method.

3.2. *Linear Quadratic Regulator Controller Design*

The setup of the LQR problem consists of finding the control input $\boldsymbol{u}(t)$ that minimizes the quadratic cost functional

$$J = \int_0^\infty \left(\boldsymbol{e}(t)^T Q \boldsymbol{e}(t) + \boldsymbol{u}(t)^T R \boldsymbol{u}(t) \right) dt, \tag{3.4}$$

where Q is a positive semi-definite matrix and R is a positive definite matrix. For a system given by

$$\frac{d\boldsymbol{x}}{dt} = A\boldsymbol{x}(t) + B\boldsymbol{u}(t), \tag{3.5}$$

the LQR problem consists of finding the control input $\boldsymbol{u}(t)$ that minimizes the cost functional of Equation (3.4), subject to the system dynamics of Equation (3.5).
